In order to place troops standing in columns in order of battle towards any side, the following rule must be observed: When troops are placed in column without intervals, the forming front forwards is executed by deploying to the right; when all the divisions, except the last, face to the right, and march in double quick time to the flank of their next division to the left, the command is given: Halt front, march, dress! the last division only marches straight forward. (Fig. 20.) In deploying to the left forwards, the first division remains on the spot, and the others perform the above movements reversed. In deploying from the middle, the divisions in front of the middle one face to the right, and those in the rear of it to the left. The division which remained in its place marches forwards into the alignement of the most advanced; the others form front, advance into the alignement, and dress. (Fig. 21.) When the troops march off to the left, and the last division forms the head, all the above movements are then reversed. (Plate CCCLXXXII. Fig. 22.) In forming front to the rear, all that is necessary previous to deploying is, that each division counter-march in itself. (Fig. 23.) To form front to the flank, or in an oblique direction, when the columns are placed without intervals, is a manœuvre not easily performed without creating disorder. The head division would be obliged to wheel into the proposed alignement, and the others then face to the right or left, place themselves behind it, and then deploy in the usual manner. (Fig. 24, 25.) When the battalion has been formed into columns by wheeling, it may be placed in order of battle to the front, by marching up; (Fig. 26.) but this must always be a tedious movement, because, in order to preserve the distances, it must always be performed in ordinary time; and it must be still more tedious, when the troops have marched off to the right, and up to the left. (Fig. 27. It is usual, however, to form divisions, and then to advance and deploy. (Fig. 28.) If it be intended to form front to the rear of the march, and that by marching up, if the troops had marched off to the right, all the sections might be made to face to the right about, and then march up to the left, so that the battalion would then stand precisely so, as if it had faced to the right about. Or each section may be made to counter-march in itself, and then march up to the right, (Fig. 29.) or deploy, (Fig. 30.) so that the battalion stands exactly in its usual order. If the troops have marched off to the left, it is easiest to form upon the right flank, and *vice versa;* and herein consists the advantage of this kind of march. (Fig. 31.) It is equally easy to form left to left, and right to right, if it be not objected that the battalion stands with reversed front. (Fig. 32.) If it be only intended to bring the first rank forward, it is only necessary to make the sections wheel inwards, towards that side. (Fig. 33.) But if the usual order of the battalion is to be completely preserved, with the first platoon upon the right flank, the whole must counter-march, while the first section wheels to the right about, and all the rest after it, as they arrive at the spot. Now, when the first platoon arrives at the place of the last, and the last upon that of the first, they wheel inwards. (Fig. 34.) But if it be intended, when the battalion stands thus in column, to take an oblique position, it is only necessary that the sections should advance or retire, by the right or left, round the point about which the column is to turn, taking care always to preserve their proper distance, and then to wheel inwards as soon as they arrive with their flanks in the new alignement. (Fig. 35, 36) In the flank-march, a battalion can instantly form the proper or reversed front to the flank of the march. It is a more tedious operation to form front to the front or rear of the march; but this may be very easily performed, either by coming round, if the battalion is to be placed towards that side where the third line stands; or, if it is to be placed towards the other side, by a double marching up,—the one in the diagonal line, if the ground be clear behind; the other, by making each soldier go along the two small sides of the right-angled triangle formed by his position in march and that which he takes up in the order of battle. This last is very useful in marching up close to a defile; and it is also the basis of what is called the bridge-manœuvre. (Fig. 37.)

As it is necessary, however, that a battalion, as soon as it arrives in the neighbourhood of the enemy, should be placed in order of battle, and so advance, frequently through difficult ground, it must not be permitted to break its order at every obstacle, but when any such presents itself, the part of the battalion which comes before it should face to the right or left, and hang on the rear of the march, and afterwards immediately march up into the line, when the obstacle is passed. (Fig. 38.)

Before we quit this branch of the subject, we must briefly notice a very celebrated mode of placing troops, which has been frequently adopted, but of which the utility in actual service has been much doubted, viz. the *battalion quarrée*, or square. There are various methods of forming the square; one or other of which may be preferable upon particular occasions, according to the facility of its execution, the nature of the ground, the attack to be sustained, &c. In Miller's *Elements of the Science of War*, the reader will find eight different methods described. (Vol. II. pp. 54, &c.) In the neighbourhood of the enemy, the sides proceed by the flank-march; but when unmolested they may prosecute their march broken into quarter sections.

It is scarcely necessary to observe that the movements we have described above are not executed, upon a long march, with the same precision as upon parade. The principles, however, are the same; and the officers must not only march in their proper places, but must not suffer the different sections to get into confusion, or extend too far in length; so that on the first signal, all may take up their respective positions, and proceed in proper order. We now proceed to the more general arrangements which are necessary for an army on a march.

If an army were to form a single column, and to march to the right or left, to the front or rear, it would occupy, especially with baggage and artillery, far too long a line, and would require too much time to form in order of battle. Hence it must form more than one column. The number must depend upon the nature of the ground, and its relative situation with respect to the enemy. The following rules, however, are to be observed. 1. In marching forwards towards the enemy, or rear-wards from him, it is of advantage to form as many columns as the ground will admit of, because the troops can be placed more speedily in order of battle, according as the columns are more numerous, and consequently shorter. The ground will admit of as many columns as there are good roads. But the desire of having many columns must not induce us to assign to any one too difficult a road, because whatever detains one column is a hindrance to the whole army. 2. When only a few columns can be formed, all our precautions must be doubled, in order to prevent an attack from the enemy, or, at least, to have sufficient time to receive it in good order. 3. When on a march our flank is exposed to the enemy, it is necessary to march by lines, in order that each line may be able to form immediately by wheeling. This measure, however, must depend very much upon the degree of probability of a sudden attack from the enemy. For if it be known that he cannot make a sudden attack, it is more convenient for the army to march in several columns.

As to the arrangement of the columns, it must depend, in a great measure, upon the nature of the ground. The general rule is: To encamp as we would fight, and to march as we would encamp. But to this rule there are exceptions. In marching through woods and hilly ground, the cavalry must not form the outward columns, but should march under cover of the infantry. The artillery and baggage should always have the most secure road. In marching forwards or backwards, the columns are always composed of portions of both lines. In marching forwards, the regiments of the first line generally form the head; and in marching to the rear, they follow those of the second.

For the security of the march, the following precautions are taken. 1. In marching forwards, a strong advanced guard precedes the army, which, according to the nature of the ground, consists either of many cavalry and few infantry, or *vice versa*, and of light troops. The latter explore the country through which the army is to march, on all sides, and to as great a distance as possible, in order to give timely notice of the approach of the enemy, &c. The other troops not only support the light troops, but also cover the army in its march, against the enemy's detachments, drive back such of the enemy as come in their way, and keep him in check by their manœuvres, when he advances with his whole force, until the army has time to place itself in order; for which reason they frequently carry cannon along with them. In marching backwards, or retiring, a rear-guard is appointed, in the same manner, and for a like reason. Its nature, strength, and distance from the main body of the army, must depend upon the nature of the ground, and other circumstances. Both must be able, by their movements, and by the position of their detached posts, to cover all the columns of the army against every hostile attack. In the flank-march, troops must be placed on that side where the army has any thing to apprehend from the enemy, in order to cover it; and light troops must carefully reconnoitre at a distance towards the enemy. 2. The baggage in a march must always be covered by the army; in marching forwards, it should be placed behind, and in marching backwards, before; in the flank-march, it should be placed on that side on which no hostile attack is to be dreaded. When no attack whatever is apprehended, it may be placed close behind or before the columns; or even, when in perfect security, between the regiments. 2. At other times, however, it is frequently sent forwards to a distance, or left entirely behind. 3. When marching in full expectation of an attack, the artillery is distributed by brigades among the columns of the troops, in order that it may deploy at the same time with them. At other times, the park has its peculiar column. 4. The columns must never cross each other on a march, nor approach too close, nor remove too far, from each other; the engineers who direct the route must attend to the former,—the commanders of the columns to the latter. 5. A defile is, every road, or part of a road, where it is not only necessary to break off, but where it is impossible to form in order of battle. In breaking off, upon these occasions, a stoppage is always occasioned: Hence the other columns must regulate themselves by that which has to pass such defiles. But if the whole army must pass them, no part must be allowed to proceed, until we are certain that nothing is to be apprehended from the enemy, so long as we are occupied with the passage.

For the convenience of the march, it is requisite, 1. To prepare as many good roads as can be got ready for the army, and to avoid defiles as much as possible. The artillery, indeed, must have the firmest and most convenient road; but the cavalry also must avoid morasses, woods, steep hills, ravines, and such like, and rather take a circuitous route. With infantry, on the other hand, regard is principally had to the shortness of a road, and to the facility with which the soldiers can march upon it. 2. Care must be taken in passing defiles, that the troops pass speedily, and in regular order; and the head, when out of the defile, should not be allowed to run on, but should shorten their pace. For nothing fatigues troops more than the constant change from halting to running, which is unavoidable in the irregular passage even of the most trifling defile. 3. The marches ought not to be too long, nor too rapid; and all unnecessary circuits should be avoided. 4. All the columns, so far as is possible, should march out of the old encampment, and into the new one, at once; and no part of the army should have a perceptibly longer or shorter route than the rest. 5. For the convenience of the army, the fourriers and sharp-shooters are sent on with the advanced guard, in order to mark out the camp, that the troops may march into it without delay.

On every march, an order is issued, containing an exact description of the number of the columns, and the troops of which they consist; of the strength and composition of the advanced or rear-guard, or the flank covering parties and patroles; of the precise route of each column, and all else that is to be observed during the march.

Sect. V. *Of Convoys.*

An army does not always carry all the necessary supplies along with it; nor is it always in a situation to receive these supplies from a distance, without the apprehension of their being cut off by the enemy. When supplies, therefore, are to be brought by a road to which the enemy has access, the convoy must be covered by a party of troops. This is one of the most difficult operations in war; because even a small convoy—suppose one hundred waggons—will occupy a line too considerable to be easily covered by a small body of troops. The strength of the covering party, however, must be regulated chiefly by the probable operations of the enemy. It consists generally of cavalry, infantry, and light troops; but the description of troops must depend much upon the nature of the ground.

An advanced guard precedes the convoy, which bears a certain proportion to the whole covering party. The infantry occupy all the villages, bridges, woods, &c. through which either the convoy is to pass, or an attack is to be apprehended from the enemy. The light troops scour the country in front, as far as they can with safety, and examine every place in which the enemy might conceal themselves. In a flat open country, the cavalry of the advanced guard spread out, to cover the convoy in front, and to support the advanced parties of hussars; but always in such a manner, that they can easily draw together, and unite to oppose the enemy. A part of the covering party marches in small sections beside the convoy, either on both sides, if both are exposed to an attack from the enemy, or, as is generally the case, only on one side. While the convoy is passing along, all the approaches are kept occupied, and the light troops continue to examine the country around.

The convoy must also have a rear guard, which follows at a proper distance, and has its light troops behind. The infantry relieves all the posts of the advanced guard and the flank-covering party, and occupies them as long as is necessary. On plains, the cavalry covers the rear of the convoy by its manœuvres.

A large convoy occupies so much ground, that it is only possible to cover it against an attacking enemy, when the latter approaches by a way which is known in sufficient time to admit of their passage being opposed. Otherwise, it is necessary to make the convoy drive up, in order that it may occupy less space. In this case, the different posts and detached parties must be at such a distance from the convoy, as to give sufficiently early intelligence of the approach of the enemy; and they must also do every thing in their power, by defensive operations and manœuvres, to detain him. In passing a defile, the convoy must drive up before entering it. An investigation must then be made, as far as possible, to ascertain whether any attack is meditated by the enemy, and if none is apprehended, the passage commences, after a proper proportion of the covering party has been advantageously posted on the other side of the defile. The waggons, as they effect their passage, drive up again, the remainder of the covering party then passes, and the whole proceed in their march. In all situations where it is intended to rest, the waggons must be driven up, and form a barricado; the horses placed within, and all the necessary dispositions previously made for the protection of the convoy.

When an attack is to be made by the enemy, the convoy should be formed into a barricado, in an advantageous position, as, for example, with one or two of its sides leaning on a village, on a large strong building, a river, a wood, a ravine, &c. or upon a height, which the enemy must climb before he can make an attack. In order to form this barricado, the carriages are driven up close to each other, and the troops place themselves behind, and fire. The cavalry are advantageously placed in the vicinity, in order to molest the enemy during the attack. Shold the enemy, however, attack with cannon, more especially with howitzers, the defence of the convoy in this manner could hardly prove successful. The best plan, in such circumstances, would be, to advance towards the enemy, to take an advantageous position between him and the convoy, in which he would be compelled to attack us, and there to fight him. But even upon this plan the convoy must be driven up; for to cover it on a march by such a manœuvre could only be practicable in extremely favourable and rare circumstances, in respect to the situation of the ground, when the enemy had only one approach to the convoy, and that one capable of being occupied and defended.

Sect. VI. *Of Detachments.*

By a detachment is meant a body of men sent to act separately from the main army on some particular service. It may consist of infantry or cavalry, or of both; sometimes it is composed of light troops only; but in general some of these are combined with the others. The number of men comprehended under the name of a detachment cannot be accurately determined; but when several battalions and squadrons are combined, they are called a detached corps.

The object for which a detachment is sent out must determine the description of troops to be employed, as well as the conduct which the leader has to pursue. The reasons for sending out detachments may be reduced to the following: 1. To carry a reinforcement to some particular quarter. 2. To occupy a post which is necessary for the security of the army, or to keep up the communication. 3. To execute some enterprise against the enemy. 4. To procure information by means of prisoners, or otherwise, and to reconnoitre.

The description of troops to be employed on a detached service must be determined by the nature of the ground, and by the object to be accomplished. If a post, such as a village, a bridge, an entrenchment, &c. is to be attacked or occupied, the detachment should consist of infantry. If rapidity be the chief requisite, it should consist of cavalry. When the situation and the object seem to require a different kind of troops, dragoons, who can serve on horseback or on foot, may be employed with advantage.

The general rules for every detachment are: 1. To obtain correct information relative to the views of the enemy, in order to provide for our own safety. 2. To form an advanced guard, in proportion to the strength of the detachment, for the purpose of reconnoitring in front. For this service, as well as that of flank patroles, light troops are especially useful. The nature of the ground must determine to what distance this advanced guard should proceed, but at all events it must not run the risk of being cut off. 3. Such objects as woods, villages, ravines, heights, growing corns, &c. must not be passed, without being certain, from a strict examination, that no party of the enemy is concealed among them. 4. On entering a defile, the whole troop must be drawn together, and not venture in, until all the neighbourhood has been searched, and we are sure of being able to pass and form, before the enemy can attack us. 5. In retiring through such a defile, the detachment should leave a party behind to occupy it, which is afterwards drawn off. The duties of such a post are, to investigate and give notice of every thing that can interest the detachment, and to oppose every attack as long as possible.

I. With regard to the object in view, the special directions for a detachment which is sent somewhere as a reinforcement are, 1. To march secretly, if necessary, which requires a very accurate knowledge of the country, in order that the troops may proceed under cover of woods, or other objects. The patroles, too, should be instructed to observe the enemy without being themselves seen. 2. Should the detachment fall in with the enemy, it should, whether stronger or weaker, employ all kinds of skilful manœuvres, and even artifices and stratagems, in order to avoid fighting. 3. If it be impossible to avoid fighting, the detachment must endeavour, by a skilful, prompt, and determined attack, to beat even a superior enemy. 4. The following reasons only can justify a commander in retiring or abandoning his object: An order to do so, on the occurrence of certain circumstances; the obvious impossibility of a successful result, in consequence of the superiority of the enemy; or if the object could no longer be accomplished, even after a successful attack on the enemy. 5. Should the attack succeed, and the enemy be put to flight, the detachment should not think of a keen pursuit, but should immediately proceed to the accomplishment of its object.

II. A detachment intended for the security of the army, or to occupy a post with the view of keeping up the communication, must observe the rules above given on its march, and also the following, when it has arrived at its destination. 1. It must secure itself by entrenchments, according to circumstances, against every attack. 2. It must place its out-posts so as that none of the enemy may pass unperceived along any part of the district which it is intended to cover. 3. When the out-posts are insufficient, this object must be effected by means of patroles. 4. The small detachments of the enemy which would interrupt the communication must be dispersed; the larger ones must, if possible, be opposed; and the advance of a much superior enemy should immediately be notified at the proper quarter, the retreat made on orders received, or the post defended until reinforcements arrive.

III. A detachment may be sent either directly against the enemy, or may accidentally encounter him, in attempting to accomplish its proper object. In the latter case, all the rules above-mentioned must be observed. In the former case, the detachment must carefully avoid all the enemy's parties, excepting that against which it is directed. Great caution must be used in marching during the night, in order that the enemy may not be unexpectedly encountered, so as to frustrate the whole plan. If an enemy's party is met, and cannot be avoided, all means must be used to surprise it, without firing a shot. When the time for attack has arrived, it must be made with promptitude and resolution, in order to bring the affair immediately to a decisive issue. If any obstacle occurs, a determination must quickly be formed, whether it be of such a nature as to frustrate the whole plan, and render a retreat necessary, or whether the plan may still be accomplished, and in that case the attack should be made without loss of time. The object of the detachment should be steadily kept in view, and the commander should suffer nothing to divert his attention from it, even should an opportunity offer of striking a blow unconnected with that object; for in this one may often be dreadfully deceived; and the best praise of an officer is, to execute well and faithfully what he has been commanded to do.

IV. Detachments sent for the purpose of collecting information respecting the enemy, by reconnoitring, or by means of prisoners, must approach the enemy directly, but cautiously; and when they meet any of his parties, if not too strong for them, they should immediately attack and beat them, and make prisoners; but beware of a blind pursuit, lest they fall into an ambuscade. Should they encounter a party superior in strength to their own, they should keep up a skirmish, without being drawn into an engagement, and, if necessary, in retiring; and by every sort of artifice, they should endeavour to make prisoners, with the view of accomplishing their object.

All detachments, on returning from the execution of their object, should secure their retreat by marching in close and regular order, and keeping their men together, by appointing a rear guard to cover their rear and flanks. Should the rear guard announce the approach of the enemy, the detachment must immediately endeavour to gain a place of safety, by some skilful manœuvre, such as a retreat *en echiquier*, if the troops are of the same description, or forming into empty or solid square, when infantry have to retire before cavalry; or they must take advantage of the ground to continue their retreat; or, finally, endeavour to get rid of the enemy by a sudden and resolute attack.

Sect. VII. *Of the Attack of Foraging Parties, Convoys, and Detachments.*

In all such attacks, it is necessary that we should be well informed of the dispositions of the enemy, that we may take our measures accordingly. Two general rules are particularly to be observed. In the first place, we should make the attack with a superior force; and, secondly, we should make it unexpectedly, which is best accomplished by laying an ambuscade.

An ambuscade is a concealed body of troops, who wait the approach of the enemy, and fall upon him by surprise. The choice of a place for an ambuscade, as well as the number of troops to be employed, must depend upon circumstances. Buildings, woods, heights, ravines, corn fields, are fit places for laying an ambuscade; but care must always be had, that the troops may be able to sally out upon the enemy without defiling. The place must be approachable by a concealed way, or occupied during the night. Every thing must be avoided that can tend to betray the ambuscade; such as the glancing of arms, neighing of horses, &c. and sentinels must be placed in such situations as enable them to see to a distance round them; but they must lie upon their bellies, without hats or caps, or other covering for their heads. The ambuscade must be surrounded at all the approaches by outposts, to guard them carefully, and stop every thing that comes near them. Not a shot, however, must be fired; and the posts must be regularly visited, but without noise. Should the ambuscade be discovered, it must be transferred, if possible, to some other place; but if that is not possible, and an attack is in any degree practicable, it should be made without delay. Otherwise, the enemy must be allowed to approach as near as possible, and should not be attacked until he is entirely in the hands of the ambuscade. In all cases, the attack must be made as rapidly as possible, but in perfect order; and with this view the troops should be previously taught how and where they are to sally out. The cavalry must attack with their swords at a gallop; and the infantry with the bayonet, without firing.

In consequence of the multitude of light troops employed in modern warfare, it is not so easy to lay an ambuscade now as formerly. For this reason, such attacks are often made without attempting an ambuscade. The following are the special rules to be observed in these different kinds of attack.

The number and description of the troops to be employed in the attack of a foraging party must be determined by the time and place, and by the strength of the enemy's covering party; its green foraging is generally performed in plains; a numerous cavalry will here be most useful; but infantry must also be employed to support them, and likewise for the attack of posts. Whether an ambuscade has been laid or not, an attack is generally made first at one place, in order to induce the enemy to weaken his chain at other points, where a second attack is then made. If the enemy be cautious, more than one attack must be made simultaneously, in order to distract his attention, and enable us to penetrate some parts of the chain, which is always the main object. The attacks must, therefore, be made in a very lively and vigorous manner. Having succeeded in penetrating the enemy's chain, the light troops should endeavour to take as many prisoners as possible, and particularly horses. If the enemy, however, has made good dispositions, and placed the foraging party in safety, they must be pursued so far in their retreat, as to render it impossible for them to return and complete their foraging.

The attack of a dry foraging party requires farther dispositions, and a stronger body of troops, especially of infantry. The principal object here is, to attack the villages in which the enemy is foraging, and which are all occupied by infantry. To do this successfully, it is necessary to attack them all at once. A great object has been gained, if we prevent the enemy from completing his foraging; and this much may be accomplished by a vigorous attack: For it will probably happen, either that the enemy shall send his foragers back to quarters, from apprehension; or they will escape of themselves. When this has been accomplished, and the covering party do not retire, they must be kept in constant alarm, until the foraging can no longer proceed; but care must be taken not to engage so deeply as to run the risk of being beaten, especially if the enemy has, in the mean time, received reinforcements. Should the covering party retire, they must be pursued so far as possible, in order that they may give up all thoughts of returning; and then all sorts of carriages should be put in requisition, in order to carry off the forage, which the enemy had collected, to our own quarters.

In attacking a convoy, without laying an ambuscade, the attack must be made, if possible, before the enemy is fully prepared. If he be on the march, an attack is made first on the advanced or rear guard, in order to draw the troops towards that quarter. Several attacks are afterwards made at different points, particularly such as the enemy has weakened, in order to oppose the first attack. Should he, however, be prepared at all points, several attacks must still be made, with the view of distracting his attention, and in order that the light troops may have an opportunity, in the intervals, of penetrating the convoy, and inflicting as much injury as possible. These attacks may be the more easily hazarded, because, if unsuccessful, there is no chance of farther loss; for the enemy's attention being occupied by the protection of the convoy, there is no difficulty in getting away from him.

If the convoy be encamped, the first thing to be done is to get rid of the supporting cavalry; and then, by means of a superior fire, or a vigorous attack upon a weak part, to penetrate the barricado, as in the case of an entrenchment. But if the covering party have taken up a position in front of the convoy, and there await the attack, we should examine whether it be possible to get round behind them, in order that, while we make a feigned attack, a part of the troops may in this way get among the convoy, and destroy it. Should this be impossible, the covering party must be attacked like any other post.

In attacking a detachment, it may be proper, in the first place, to make use of an ambuscade, because the leaders do not always take the necessary precautions. The enemy should then be enticed into the ambuscade by means of a body of troops, who first advance and then retire, or even betake themselves to flight. If the enemy have to pass a defile, we should endeavour, by occupying it, to cut off his retreat, and then, under cover of a ravine, height, wood, &c. to get on his flanks or rear, in order to attack him suddenly in front and rear, or in the flanks. This must never be neglected, when the enemy, by the slightest degree of carelessness, gives us an opportunity for executing the stratagem. Such are the measures to be taken by a detachment, which has been sent out for the purpose of attacking another. The commander, however, although his march may have been ever so well concealed, must not neglect any of the necessary precautions for his own safety. If two detachments, however, which have been sent out for different purposes, should happen to encounter each other, a prudent commander will endeavour notwithstanding to secure all the advantages above described, and will also employ every means of obtaining early and correct information respecting the views of his antagonist, in which the attachment of the people of the country will be of the greatest service. But when two hostile detachments suddenly encounter each other in front, without either having taken the necessary precautions, the numbers, valour, and discipline of the troops, must decide the victory, which will generally be in favour of the party that makes the most determined attack. Should a weaker, however, encounter a stronger detachment, the former must put on a good face, and endeavour, by taking every advantage of the ground, and executing skilful manœuvres, either to hold out until reinforcements arrive, or to make a good retreat. But when a stronger detachment encounters a weaker, the former, indeed, should circumstances permit, ought to endeavour to beat the latter, but at the same time to beware of too much keenness, for fear of falling into an ambuscade.

When prisoners and booty are made in such enterprises, they should be sent forward for security, and the troops should follow, in order to protect them against a possible pursuit, but without engaging farther with the enemy, unless in a case of necessity.

Part II. STRATEGICS.

Sect. I. *Of the Knowledge of the Country.*

As no military enterprise can well succeed without a knowledge of the country in which the operations are to be carried on, it is necessary that we should say something respecting the best means of obtaining this information. The knowledge of a country embraces three things, viz. its political, economical, and military circumstances. All the three are in some measure useful to the soldier; the last may be considered as indispensable.

This information may be obtained by means of printed, manuscript, or verbal descriptions; maps, charts, or drawings; or by personal enquiries. There are few printed descriptions of countries, indeed, so minute and accurate in their military details as is requisite for warlike operations; but in other respects they are often extremely useful; and should be studied, on account of the other material points of useful information which they contain. Historical works, especially such as are written with a view chiefly to military operations, and also the lives of celebrated generals, are of much use, and should be studied with great attention.

No opportunity should be neglected of collecting written and oral accounts of lands, whether in time of war or peace. It must be observed, however, that during war the sources of oral accounts are frequently suspicious, and little to be depended upon, either from ignorance or design in the individuals from whom the information is obtained. To expiscate the truth, therefore, requires much care, skill, and knowledge of human nature.

Maps and charts, plans and sketches, are of singular use in a military point of view. Their value must depend much on the greatness of the scale upon which they are constructed, and the accuracy and minuteness with which the objects are laid down. Maps afford a view of entire countries, their limits, the position and distance of the principal towns, the course of the rivers, &c. and are indispensably necessary towards obtaining a general knowledge of the relative situation of all the parts. Plans and sketches are more limited; and when accurately constructed, they should give a faithful portrait of the objects. A good military sketch should represent every object in its real position and proportion; it should distinguish the nature of the ground, the position and form of the heights, the size of the plateau, the woods, rivers, with their windings, bridges, fords, &c. Also the roads, defiles, towns, villages, churches, and even single buildings, &c. The name of each individual object should likewise be marked. The more minutely the nature of the several objects is described, the more useful will the sketch be; because an apparently trivial circumstance is frequently of importance in a military point of view.

Individual investigation may consist in the preparation of a sketch or description of the district, or merely in making a reconnoissance. In both cases, a practised eye, and a knowledge of the military application of objects, are essentially necessary.

Sect. II. *Of the Plan of Operations.*

Before an army takes the field, it is necessary to draw up a general plan of operations, otherwise much time would be lost at every step in deliberating upon what was to be done next. The perfection of a plan of operations depends almost entirely upon an accurate knowledge of the country in which the war is to be carried on.

War may be conducted either offensively or defensively. The former plan is generally adopted by the stronger power, the latter by the weaker.

The strength and composition of the army to be employed must be determined according to the strength of the enemy, the nature of the undertaking, and also the nature of the country. If it be intended to act offensively, the force employed must be stronger than that of the enemy—the more so the better. But even in a defensive war, the force employed ought never to be so small as to be incapable of contending with the enemy. In an open champaign country, it is necessary to have a considerable force of cavalry, especially, to enable us to carry on defensive operations with success. In mountainous districts, on the contrary, a numerous and effective infantry are required; and a light infantry will be found particularly serviceable. In general, according to circumstances, the cavalry form from an eighth to a fourth part of the whole army. The quantity of artillery must depend upon the nature of the undertaking. If there are many fortresses, a large battering train will be required; and in a country possessing many tenable posts, it is necessary to have a numerous field train, which must be drawn by good horses, in order not to detain the army in its movements. An army should always have a large body of light troops; and although the nature of the ground may make some difference necessary in the proportion of these to the troops of the line, yet it is not easy to determine the proportion according to any precise general rules, because light infantry are useful on many occasions, and light horse may be extremely serviceable even on broken ground.

In conducting offensive operations, two cases are to be distinguished. In the first place, the object may be to surprise the enemy, either at the commencement of the war, or on the opening of a campaign. Secondly, it may be intended to make an attack upon an enemy who is prepared to receive us. The first case is evidently the most advantageous; but, in order to insure success, it is necessary to keep the enterprise secret, and to execute it with the greatest possible celerity.

When it is proposed to surprise the enemy at the commencement of a war, it is necessary not only to have a considerable number of troops constantly on foot, but that these troops should be in a state fit for immediate service. Baggage and artillery horses must be in readiness; a large store of war ammunition must be prepared in the neighbourhood of that quarter where the war is to be commenced; and magazines must be formed for the maintenance of the troops. All these preparations, too, must be made with such care, that the enemy may not be able to discover the object. When all the necessary preparations have been made, it must then be determined what are the most decisive measures that can be accomplished by a surprise; how far we can get the start of the enemy; and whether we shall have sufficient time to execute the most decisive measure, or must be content, from want of time, with something less decisive. These questions must be determined according to the circumstances of each case. Among the objects to be accomplished by a surprise are the following: To seize the enemy's capital; to take possession of one of his most important provinces; to separate his army, so as to prevent it from being drawn together; to attack one of his principal allies, and force him to make peace. When none of these most important objects can be accomplished, we must endeavour to obtain possession of the means of prosecuting the war with advantage, by occupying the passes which lead into the enemy's country, or making ourselves masters of a river which opens into it; or by carrying a fortress which affords the key to it, &c.

In all such enterprises, however, we must keep in view the means of defence which the enemy can oppose to us. These, in general, are: 1. Fortresses; 2 Rivers; 3. Defiles; and 4. The army itself. In the first case, the whole undertaking will commence with a siege of the most important fortress. The importance of a fortress depends upon the advantages which the possession of it will afford us, or the disadvantages to which the loss of it will subject the enemy. Sieges, therefore, must never be formed, unless, 1. When the fortresses are placed on the passes which lead into the enemy's country, and in such a manner that you cannot penetrate till you are masters of them. 2. When they are on your communication, and the country does not furnish the necessary subsistence. 3. When they are necessary, in order to cover the magazines you form in the country itself, to facilitate your operations. 4. When they contain considerable magazines of the enemy, and such as are essentially necessary to him. 5. When the conquest of them is necessarily followed by that of some considerable district, which enables you to separate your armies into winter-quarters in the enemy's country. All fortresses, which are of no essential use in our farther advance, or to our safety in case of a retreat, should be demolished as soon as they are taken.

Rivers and defiles may be passed without difficulty in the case of a surprise; but they should be passed at such places as lead most safely and directly to the great object, where posts may be established, to enable us to advance, or, if necessary, to secure a retreat. If the nature of the country be such, that it can be covered by the army alone, that is, if it be an open country, we must immediately push forwards towards that object, which, if attained, will prove decisive of the war,—as, for example, the capital; or, if that be impossible, we must begin by occupying some tenable place, for the purpose of establishing magazines, of enabling us to advance, or to maintain the conquered country, or to secure a retreat.

In the case of a surprise at the opening of a campaign, we can never expect to find the enemy so unprepared as at the commencement of a war. It is necessary, therefore, that such an undertaking should be previously well considered; for as troops are called upon, in such a case, to act at a season when they are exposed to great hardships in the field, we ought to calculate whether the probable success will compensate the certain expence of men and money. There are occasions, indeed, when the advantage of a few days over the enemy may be decisive; and these should never be overlooked. But when several weeks are required, it will be found much better in most cases to let the troops rest, and wait for the time when the war may be prosecuted without any such evident waste of our recources.

If we cannot attack the enemy otherwise than in a state of preparation, we must endeavour to penetrate into the country in spite of his army. For this purpose, it will be necessary for us to force his army at that point, which will lead us most safely and immediately towards the object we have in view. This may be effected, 1. By a diversion, that is, by causing an attack to be made in some other quarter, so as to make him draw off his troops, or weaken his army at that point where we wish to penetrate. This method is generally adopted, when the enemy has taken up a strong position which covers the whole country; or when we wish to undertake a seige, but are prevented by the strength and advantageous position of the army opposed to us. In order to render this method effectual, however, it is necessary that we should have a sufficient superiority of force, and that our diversion should threaten great danger to the enemy. 2. By intercepting and cutting off his supplies. This may be done, by establishing posts on the rivers or passes, by which he receives his provisions; or by constant attacks on his convoys and foraging parties, which requires a great superiority in light troops, especially cavalry. 3. By means of detachments, which is a species of diversion. 4. By manœuvring, that is, by marching and countermarching in such a manner as to threaten the enemy in some other quarter, and, while he makes corresponding movements in order to oppose us, to seize the occasion of his weakening the point at which we wish to force him. 5. By bringing the enemy to a battle, which is the most simple of all methods. But as a battle is, in many respects, more liable to chance than any other military enterprise, and the enemy will naturally always endeavour to take up a strong position, a prudent general will rather try every other means, if possible, unless he perceives the probability of obtaining extraordinary advantages from fighting.

To lay down a plan of operations for a defensive war, and to carry it into execution, are matters of much more difficulty. A skilful general, therefore, will always endeavour to seize some opportunity of converting a defensive into an offensive war, by striking such a blow as will give him the superiority over the enemy. As in a defensive war the difficulty consists in our being generally obliged to regulate our movements according to those of the enemy, of which we cannot always obtain sufficiently early intelligence, it is necessary, in laying down a plan of operations for a defensive war, to anticipate the probable undertakings of the enemy, according to the nature of the country, and to take proper measures for opposing them. If, for example, the defence of a country depends upon fortresses, these must be previously supplied with all necessaries, and the positions must be determined from which they are to receive succour, when threatened. If it depends upon the defence of a river, or other defile, the positions necessary for its defence, as well as the means of defending it, must be previously taken. When the defence rests upon the army itself, posts and tenable places must be prepared for it; and much prudence will be required in selecting such as are most advantageous; otherwise the covering army must be made sufficiently strong as to enable it, under a skilful commander, to assume an offensive attitude. In a defensive war, the following general rules are also to be observed: 1. We must be in a situation to take the field in such good time as to oppose any enterprise on the part of the enemy. 2. Every precaution must be taken, in order that the army may find supplies at every point to which they may be called by the enemy's movements, which is often a matter of great difficulty. *Lastly*, We have already observed, that a prudent commander must avail himself of every good opportunity to convert a defensive into an offensive war; the various possibilities of such an event, therefore, must be anticipated, and all measures taken to make the most of such an opportunity when it occurs.

SECT. III. *Of Collecting, or Drawing the Army together.*

An army is drawn together, either for the first time, at the commencement of a war, or during a war, at the opening of a campaign, with the view of acting either offensively or defensively.

If it be intended to surprise the enemy, at the commencement of an offensive war, the troops are marched rapidly out of their quarters towards the appointed place of rendezvous. This place may be either on our own frontier, in order to penetrate, with our combined force, into the enemy's country; or in the enemy's territory itself, in which case the troops march into it at once in columns, or in divisions following each other. The first plan is generally adopted, when the enemy is not strong enough to oppose our combined force, but might annoy particular portions of the army. In other cases, the latter plan is generally preferred.

If, at the commencement of an offensive war, a surprise is impossible, the troops are drawn together gradually, for their convenience, to accustom them by degrees to the hardships of war, and to enable us to complete our measures for the campaign. It is often necessary, too, to conceal the real point of attack; and for this purpose the army is drawn together in several separate corps, which can be united at any time; or a considerable extent is given them in their quarters, in order to unite them on any part of the line at pleasure. In these measures, we must be guided very much by a skilful calculation of the distance of places, the nature of the roads between them, and the capability of the troops in performing marches.

In drawing an army together for a defensive war, we must be guided by the means we possess for conducting it, and by other peculiar circumstances. 1. If the post to be defended has been determined upon, we may then advance towards it, strengthen it, if necessary, by the labour of the troops, or of peasants, and cause it to be occupied by a detached corps; or it may be occupied by the whole army, whether the enemy's army be united or not. 2. The choice of the post depends upon the measures of the enemy. In that case we must follow his movements, and keep our quarters as much extended as is consistent with the possibility of concentrating, whenever the enemy's motions render it necessary, and with the safety of the army. If the defence of the country depends upon fortresses, the army may be drawn together in the following manner:

1. A post is chosen, from which the investment of each fortress may be prevented, or from whence, at least, it may be succoured. In this case, however, it is necessary that the army be in a condition to cope with that of the enemy. 2. The army may be divided into several corps, occupying strong camps under the cannon of the fortresses, in order to prevent the enemy from besieging them. In such a case, the cavalry is frequently formed into a separate corps, and endeavour, by constant enterprises, to put every kind of obstacle in the way of the enemy.

But if the defence depends upon a river, or other defile, a central post is generally chosen and occupied, from which the passage may always be opposed; or, if there be no such post, the movements of the enemy must be accurately observed and followed, from the first approach of the quarters, until the entire junction of the army; or separate corps are drawn together in front of the defile, which must always be able to unite sooner than the enemy, or at least to maintain their ground until they receive assistance; and which must be occasionally reinforced, in proportion to the means employed by the enemy.

The same rule may be applied to the drawing together of an army at the opening of a new campaign. It must be observed, that the attacking party is generally the first to collect his army: while the party acting on the defensive must almost always wait to see the enemy's object before he can do any thing. On some occasions, however, the latter party may be the first to collect his army; if, for example, he wishes to consume the provisions in a district before the enemy comes into the field, in order to frustrate the enterprise he may have in view; or when he is going to perform some work necessary for his defence, which must be covered by the army. In drawing an army together, attention must be paid to the season of the year, and also to the comfort of the troops, who ought not to be exposed to great hardships, until they have become habituated to active service.

Sect. IV. *Of Lines of Operation.*

Modern writers on the art of war have denominated the chain of magazines established at the commencement of a campaign, the *Basis of military operations;* and the roads by which an army receives its supplies from the magazines, are called *Lines of operation.* The situation of the principal magazine, and the length and direction of the lines of operation, are considered of the highest importance.

Single lines of operation are preferable to double ones, especially when the latter have an eccentric direction, which exposes the different parts of an army to be attacked and beaten in detail. It is always of advantage, therefore, to give to our own operations an interior direction, and, if possible, to induce the enemy to adopt exterior lines of operation. If it be necessary to form two interior lines, in order to oppose two lines of operation of the enemy, we ought not to separate them too far; because the army acting upon that which is weakest, might be attacked and beaten, with such effect as no advantage obtained on the other line could compensate. For a similar reason, a double line ought not to be presented against a single line, nor an extended line against one that is concentrated. In forming lines of operation, the chief object to be attended to is, the facility of conjunction and simultaneous co-operation. Lines of operation ought to be direct,—consequently such as will enable our troops to march with greater rapidity towards any point that is in danger, than those of the enemy, and thus to present a mass to isolated parts.

A twofold line of operations may be considered good, when the enemy shall likewise have formed a double line; provided the parts of his line have an exterior direction, while yours have an interior one; and his divisions being at greater distances than your own, cannot unite without being previously attacked by yours in mass. An army possessing lines of operation more contracted than those of the enemy can, by strategical movements, overpower the enemy's divisions successively, by alternately collecting the mass of its forces, and attacking them one after another. In order to insure the success of these movements, it will be necessary to leave a small division to oppose that of the enemy, which it is intended to keep in check; with orders not to engage, but to use every art to arrest or suspend its advance, by defending the defiles, heights, and rivers; and lastly, to fall back towards the army.* Hence it follows, that a twofold line of operations, embracing the extremities of a more contracted line, will inevitably be ruined, if the army, acting on the shorter space, know how to profit by the advantage of its situation, and the rapidity with which it can act within its own line. A twofold line of operations, opposed to a single one, will be exposed to still greater danger, if its parts are several days' march asunder, because the difficulty will then be much greater of uniting to resist any concentrated effort of the enemy. All interior and single lines of operations, therefore, will be the most secure. They offer no advantage to the enemy, but, on the contrary, should he have the imprudence to adopt a contrary system, are calculated to bring their whole mass into action against his isolated divisions.

Two interior lines of operation, possessing the means of reciprocally sustaining each other, and destined to face, at a certain distance, two exterior lines of an enemy, must avoid being encompassed by him within a space so contracted as to enable his divisions to act simultaneously; and they must equally avoid the opposite extreme,—that of pushing their operations too far asunder,—because the enemy would have time to crush that division which has been weakened to reinforce the other, and might then make such progress and conquests as might become irresistible.

Let us suppose an army, equal in force to its opponent, but acting in two or three isolated corps, upon lines of operation having an exterior direction, while the enemy operates in a body upon a single line; the army so divided will never gain any real advantage, unless the several corps can attack simultaneously; because the enemy will always have it in his power to oppose double or triple the number of troops to each of their separate corps. Hence, two interior lines are advantageous, because they can concentrate their forces at will, and with greater rapidity than the enemy, and consequently double their numerical strength. For the same reason, single lines, such as have their parts united, and can mutually sustain each other, are to be preferred.†

From these observations we may deduce the gene-

* The wars of Frederick of Prussia afford numerous illustrations of this principle. Bonaparte, too, almost constantly manœuvred in this manner, and with almost invariable success. He practised it at the battles of Quatre Bras, Ligny, and Waterloo; but failed, partly in consequence of bad calculations, and partly from the activity, skill and courage of his adversaries.

† Had the French Directory been aware of this fundamental combination, and appreciated its importance, their armies of the Rhine, the Sambre, and the Meuse, would not have been expelled from Germany in 1796, because they would not have formed a twofold line of operations acting in exterior directions. The armies of the Danube and of the [illegible] would likewise not have been sacrificed in 1799 to an erroneous plan of combinations. Had Wurmser reflected on the sublime lessons of Frederick, he would not have divided his army by a lake, and thus occasioned the defeat of each corps in detail; nor scattered his forces to cover every thing, while the enemy made the

ral principle upon which all combinations in war ought to be constructed. This principle consists in congregating upon the most important point of a line of operations, or of a field of battle, a number of forces superior to that of the enemy. To effect this on lines of operation, marches and strategical movements must be employed; and on fields of battle, we must adopt proper manœuvres, or select judicious modes of attack.

As the principles we have just laid down respecting lines of operation are also applicable to the manœuvres on a field of battle, we shall have occasion to illustrate them still farther in a subsequent section. Meanwhile, we shall only observe that lines of operations have their keys as well as fields of battle; upon these lines there are decisive strategical points, which command the remainder, and have the same influence on operations, as certain points of ground have on battles.

Sect. V. *Of Positions.*

We have already had occasion to lay down some general rules on the subject of positions, while treating of the principles of castrametation. A camp, however, may be in itself exceedingly strong, and yet totally useless with respect to the object in view. The science of positions, on the other hand, exhibits the principles applicable to the choice of a camp the best adapted, according to circumstances, to the proposed object.

In the case of an offensive war, combined with a surprise, there is no great difficulty in chusing positions. An attack in these circumstances presupposes superiority, and all the art, therefore, which is necessary, consists in the ordinary precautions for the safety and supply of the troops, which are determined by the dispositions of the enemy; and with respect to positions, there is almost nothing farther required, than the art of selecting the best routes.

But the art of positions becomes much more difficult and important, when we have to act offensively against an enemy who is fully prepared. It is then necessary to determine the best means by which we may be enabled to break into his parallel. 1. If this is to be effected by a battle, the art of positions is of less importance; because, in that case, we must attack him in the position which he has chosen; or, if it be too strong, we must endeavour to force him out of it by skilful manœuvres. 2. If it is to be done by cutting off his forage and supplies, we must establish ourselves in a strong position, near the enemy—if possible, quite on his flank, but, at all events, somewhat obliquely, in order that our light troops may get into his rear, and intercept his convoys. No pains should be spared in procuring intelligence respecting his foraging parties, which must be constantly annoyed by all possible means. At the same time, we must beware of exposing our own parallel, which should always be secured by fortresses, or posts, or detached corps. Or we should endeavour to out-flank him in his position, by occupying tenable places, or positions for separate corps on his flanks, to enable us to get into his rear, and attack all his convoys and foraging parties. 3. If our purpose is to be executed by means of detachments, we must previously observe upon what grounds the effect of a detachment rests. So long as our main army remains on the spot, it is presumed that the enemy cannot move; for otherwise the position must have been ill chosen. A corps is then detached from the army, as strong as is required and can be spared, in order to execute some enterprise injurious to the enemy. This enterprise may consist either in a particular blow, such as the attack of a post, the cutting off a convoy, the destruction of a magazine, &c.; or in preparation for some blow, which is to be executed afterwards by the whole army; such as the investment of a fortress, throwing bridges over a river which the army is to pass, occupying the entrance and *debouche* of a defile, &c. It is not always necessary that the corps should actually execute the enterprise, but only that it should be so placed as to be able to execute it, if the enemy takes no measures to oppose it.

The following general rules are to be observed, with respect to the position of the main army and its detached corps. 1. The main army must never weaken itself so much by detachments, as to be under any apprehensions for its own safety. 2. No corps must be detached in such a way as to be exposed to danger. 3. In sending out detachments, we must always provide for the junction of the whole army on the necessary point, to secure its safety, or to execute the proposed enterprise, or any other that may offer. Besides, the position of every detached corps must be chosen, so as to enable it to execute an enterprise dangerous to the enemy, and at the same time, if opposed, to have the means of executing some other.

In a defensive war, the art of positions is of the greatest consequence. 1. A position may be chosen which covers the whole parallel. Such a position must be strong in itself; the enemy must not be able to get round it at all, or only with his whole army, and that not without exposing his own parallel or communications. 2. The position may cover the greater part of the parallel. Such a position, besides being strong, must have obstacles on both sides, which, although they do not reach to the end of the parallel, force the enemy to make a large circuit to get round, while he can be opposed by a much shorter movement. 3. The position may be such that the parallel can be covered only by manœuvres. This may be done in three ways. In the first place, a central position is chosen for the whole army, from which the object of every movement made by the enemy may be frustrated by a shorter movement. In the second place, we may follow the enemy in all his movements, always choosing positions of proper strength, and so near to him, that, from fear of being himself attacked, he can undertake nothing, unless with his combined force. In these circumstances, we must endeavour to beat, or at least annoy, all his convoys, foraging parties, and detachments. Thirdly, we may extend our line in proportion as he extends his. When he makes a movement in his parallel, we

decisive march upon Trent and Bassano. Had Alvinzi, Cobourg, the Prince of Lorrain, and Brown, not mistaken these precepts, and operated without combination, they would not have been beaten in detail. Looking to still more recent events, we find that the same causes have uniformly produced the same effects. The governments have constantly caused their armies to act on the same erroneous drinciples, and the results were accordingly such as might have been anticipated. Thus, Mack was isolated at Ulm; the movements at Austerlitz were too extensive; the three corps of Prussians, at Jena, Weimar, and Auerstadt, were without connection; Buxhovden and Benningsen were not united at Pultusk; the Austrians were divided at Abendsburgh, Eckmuhl, and Ratisbon. These instances afford most convincing proofs of the truth and importance of the above observations.

make a corresponding one in ours; when he detaches a corps, we do the same, always calculating the time it will require to join the main body, in order that we may always be in a situation to unite more rapidly than the enemy. Should he expose a detachment, a communication, or magazine, we must endeavour to take advantage of the opportunity, and to change the relative situation of the war. We must beware, however, of committing any such fault ourselves, and that is a matter of great difficulty; for as the enemy begins all movements, and we must regulate all ours by his, it is scarcely possible to avoid some dangerous exposure. Hence, this method is the most hazardous of all.

An army with both flanks secure against the possibility of being turned, is in a most advantageous post; but where defensive measures are to be literally followed, such positions will seldom occur. It is more easy to gain a flank in an open country, it is more decisive where there are mountains; because, in mountainous ground, the enemy may be hemmed in, and cut off from its magazines. These are, indeed, manœuvres of a delicate nature, which require to be conducted by a general possessed of more than ordinary abilities, and commanding an excellent army. With these advantages, the assailant certainly has the best chances of success, provided he is sufficiently cautious in chusing positions which do not expose his own communications to a counter operation on his flank or rear, by which the enemy might force him to fight on disadvantageous terms. No corps whatever must be posted in a valley, unless we are masters of the mountains which form it; and if we cannot occupy both sides, we must at least occupy one; for though, at first sight, mountains, rocks, and woods, may appear impassable, yet, upon a diligent inquiry, the contrary will be always found; for in every country that is well peopled, there are, and must be, communications between the villages, at least for infantry. We ought, therefore, to occupy the mountains and woods with our infantry, and the valley beneath with our cavalry, which will hinder any enemy from passing through it.

The conduct of a defensive war is always a matter of great difficulty. In defending a province, it is necessary that our movements in every direction along its frontiers may be made with facility; or, that a position be selected, which the enemy cannot attack with the prospect of success, nor turn without being exposed to be cut off from his own magazines and line of operations; in short, a position from which he cannot force us to retreat. Posts of this description, however, are rarely to be found; for if the enemy be active, resolute, fertile in resources, and possessed of an army well versed in manœuvres, he will constantly find means to penetrate, at least with infantry, and turn our flanks. The attempt to cover every town and village will always be found impracticable. The perfection of defensive war consists in preventing an enemy from obtaining any advantages, which may enable him to accomplish his main object. When, therefore, the precautions are so carefully taken, that at the end of the campaign he finds himself no nearer the attainment of this object than he was at the beginning, then a defensive war has been properly conducted, notwithstanding any other advantages or acquisitions of territory he may have obtained.

There is in every camp some one essential point, or hinge, which may be called the key of it; and on which the strength of it most immediately depends; while you keep this, the enemy has nothing, and when you lose it, all is lost. The same holds good as to positions. The choice of this point, with regard to positions, depends entirely on, and must be regulated by, the object which the general has in view; by the situation of his magazines, and by the number and species of his troops, that he may not only have a good position, but likewise a good field of battle, in case he is attacked. On the talent of discovering these points, depends the science of camps and positions, and the method of attacking and defending them.*

We may conclude this branch of the subject with the general observation, that no position, however strong, can secure an army remaining immoveable within it from being overwhelmed, or turned at one or other of its extremities; and that the only certain method to prevent such a misfortune is by manœuvring in the same sense as the enemy, that is offensively, and by threatening his own line.

Sect. VI. *Of Movements.*

An army ought never to make a movement without having some object in view, and measures should always be taken to secure that object with as much safety and convenience as possible. A movement may be made forwards, or towards the enemy; to the rear, or from the enemy; aside, in our own, or, at the same time, into the enemy's parallel: and the object of all these movements may be, to give battle; to avoid a battle; to change our camp for the better maintenance of the troops; to prevent such a design in the enemy; to entice him into some other quarter, or prevent him from establishing himself there; for the purpose of passing a river or defile, or of preventing the enemy from passing it; to invest a fortress, or prevent the enemy from investing one; with the view of making a feigned march, in order to deceive him, and then to attain our object by another movement.

In every movement, two things are especially requisite to enable us to attain our object. In the first place, celerity; and, secondly, good arrangements. Celerity is of two kinds; it consists either in the rapidity of the movement itself, or in its continuance. Both are called forced marches. Cavalry perform a forced march in the one way, and infantry in the other. But as both are destructive to men and horses, they ought never to be undertaken without urgent necessity; and a skilful general will not often be obliged to have recourse to them. The arrangements consist, first, in lightening the army, by removing all heavy carriages that can be dispensed with; secondly, in preparing the roads; and, thirdly, in the occupying of posts, and sending out detachments, in order to facilitate or secure the march.

A movement is rendered secure, 1 By concealing it from the enemy; which may be done by breaking up suddenly, by marching at night, by avoiding every thing that can betray the march, such as drawing in the posts, extinguishing the fires, striking the tents, &c. or by de-

* These decisive points are neither numerous nor difficult to discover. On a scattered line, we must look for them in the centre, from whence one of the extremities is overpowered—as at Prague, Marengo, Austerlitz. On a contiguous line, they are on the extremity of that flank which has most connection with the general basis of the operations—as at Leuthen, Castiglione, Ulm, and Wagram.

ceiving the enemy with illusory appearances, such as smoke, dust, &c. 2. By providing against every accident. For this purpose, the ordinary dispositions for a march, which we formerly noticed, are to be observed; and we may calculate in what points of the march we can take up positions, and how much time will be required to place the troops in order of battle in every point; posts and detachments may be sent out, in order to obtain early intelligence of the enemy's motions, that we may have time to form in order of battle in every such position. We may cover the march by occupying the passes through which the enemy could reach us, or such objects, under the fire of which the enemy would be obliged to pass, should he wish to attack the army in march; or we may place cavalry in such a situation as would enable them to fall upon the flank of the enemy on his approach. For the convenience of the march, it is necessary that we have good roads, and make no circuits, nor expose the troops to any unnecessary fatigues.

We shall afterwards have occasion to treat of the march forwards, for the purpose of giving battle, as well as of the movements in passing and defending defiles. In marching to the rear, in order to avoid a battle, we must pay particular attention to our own situation and circumstances, and to the probable enterprises of the enemy. If he be quite close to us, and can immediately attack us, we must take every possible precaution to conceal our march, and to perform it in safety, especially if we have a discouraged army. All the heavy artillery and baggage must be sent to a distance before us; the march must be performed rapidly, but without disorder; and we must endeavour, before the enemy can attack us, to gain some defiles into which he cannot follow us. If he be at such a distance from us, that he cannot follow us with his whole army, but only harass us with a corps of cavalry and dragoons; in that case we may, according to circumstances, diminish the hardship and fatigue which the troops would otherwise have to undergo.

The other kinds of movements are such as are made with a view to the attainment of some particular object, or to prevent the enemy from executing some design. In marching with a view to attain some particular object, we must take especial care that our own parallel remains covered, and for this purpose three things must be observed. 1. That our communications be not cut off. This rule, however, may be overlooked, as long as the army carries a sufficient supply of necessaries along with it, or finds those necessaries at the place of its destination. 2. That the enemy do not carry any place, or destroy any of our magazines. 3. That the enemy be not in a situation to prevent us from returning, if necessary, into our own parallel, a thing which might easily happen, if he were to take up a strong position between the army and our own territory.

When sufficient precautions have been taken, with respect to the points above mentioned, movements of this kind may be made in a three-fold manner: 1 With the whole army. 2. With divisions at the same time, which is called a combined movement, and is often employed in marching towards the enemy, with the view of giving battle, or to force a defile, or invest a town. 3 With divisions following each other. In every movement, two things are to be apprehended,—an attack while on the march, and an anticipation on the part of the enemy. We have already spoken of the dispositions which ought to be adopted, with a view to prevent our being attacked while on the march, or to render such an attack harmless; and we shall have occasion to revert to the same subject in a subsequent part of this article. To prevent the enemy from anticipating us, it is necessary that we should keep our design concealed; that our movement should be made with celerity; and that previous arrangements should be made for removing all obstacles which might obstruct or detain the army, as well as for enabling it to accomplish the march, and attain its object with safety. Secrecy, indeed, is not always consistent with these previous arrangements; and it will require much skill and knowledge of the country to combine both in as great a degree as possible Favourable circumstances, too, are requisite to enable us to secure the means of success by previous arrangements; but it may sometimes be done by occupying some place or post with a detachment, or some defile which the enemy must pass, in order to prevent the object of our movement. In this case, it is necessary that the place or post which we have occupied, or the defile, be so situated as to prevent the enemy from occupying the position which he means to take up; and then all the rules which we formerly laid down, with respect to detachments, must be observed.

A combined movement is one, in which the divisions of the army march without being able to form one contiguous order of battle. It is often employed, because it enables us to execute the movement with greater rapidity; it has the effect of diverting the attention of the enemy; and it gives us an opportunity to make an attack in more places than one, either upon the whole of the enemy's army, or on some large corps, or to hem in some of his troops. In such operations, it is necessary that all the divisions of the army should be secure during the march; and this may be the case, 1. When we are certain that the enemy is ignorant of our movement, either because it has been kept completely concealed, or because all the passes have been secured, so that we can obtain immediate intelligence of all his motions on any of the marching divisions. 2. When every division has a route which secures its retreat, in case of the enemy's approach. 3. When each division is always certain of finding positions on its march, which will enable it to maintain itself until others come to its assistance. 4. When the enemy, in attacking one of our divisions, would be certain of being himself attacked by another on his flank, before he could beat the first.

The march by divisions following each other is adopted, when great defiles prevent the march of the whole army; when one part of the army, which can move with greater rapidity, is previously dispatched in order to secure the means of performing the march with the whole army; or, when we have not wholly determined upon performing the movement, but wish to have a start. In the first case, there must be no chance of the divisions being exposed to an attack, either in the defile itself, or in the *debouche* from it. In the second case, the division in advance must either be able to maintain its ground until the army comes to its assistance, or to make its retreat without any disadvantage to itself or the rest of the army. To which we may add, with regard to the third case, that the dispatching the division in advance must not interfere with, far less render impossible, any other movement of the army, which may be afterwards found necessary.

In order to prevent the enemy from attaining his object by any movement, we may remain obstinately in our position, if it be such as gives us an opportunity of inflicting such injury upon him as must necessarily detain him; or we may move ourselves to the place of his destination, or to an opposite quarter, either with the whole or a part of the army. We should march with the whole army towards the place of the enemy's destination, when we know for certain that he will, or that he must move to that point; or that we should risk a great deal by suffering him to accomplish his object, but would be in no danger should he afterwards relinquish it, and even make some other movement. In this case, the army must be prepared for battle, if it should not be thought preferable merely to encamp opposite to that of the enemy, with a defile between. We should march with a part of the army towards the enemy's point of destination, either when the enemy himself employs only a part of his force, or when a part of the army is sufficient to frustrate the enemy's design; for example, when the object is to prevent the passage of a defile, which a part of the army can defend against the whole force of the enemy; or, in case of the investment of a fortress, where the mere reinforcement of the garrison with one or two thousand men is frequently sufficient to frustrate the whole enterprise.

We may move with the whole army in an opposite direction, 1. When we are certain of being able to inflict upon the enemy a blow, which will be of more consequence than any advantage which he could derive from his movement. 2. When we are equally certain that the apprehension of the blow which we may strike will compel him to abandon his design. We may employ only a part of the army in such a movement, if a part be sufficient to inflict the intended blow; if it be necessary that we should be prepared, after executing the blow, to move in the direction which the enemy has taken; if we be uncertain whether the enemy may not abandon his design, from apprehension of the blow which we threaten; or if, by withdrawing the whole army from the position which it occupies, we should expose ourselves to danger.

Feigned marches are such as are made, not for the purpose of accomplishing our real design, but in order to induce the enemy to make some movements, which shall enable us more effectually to attain our object. These may also be performed, either with the whole or a part of the army. The design with which we blind the enemy, must be a probable one, and such as he may easily take for our true object. The more probable the better; and best of all, when it may be converted into the true one. When such a movement is made with the whole army, we must take care that it do not lead us too far from our real object, much less give the enemy an opportunity of rendering it entirely abortive. For this reason, the movement is frequently performed slowly, the army is extended, and the advanced guard, especially the light troops, spread far out in front. The movement is generally performed by dispatching a division of the army towards that side on which the feint is made, with a number of light troops to conceal its real strength. And should the enemy follow this division, we may then move with the rest of the army, or a part of it, towards the true object. In this case, it will be of advantage if it be not necessary for the detached corps to form a junction with us before we commence our movement; but that we begin at once, and at the same time, send an order for its return. Meanwhile, false reports with respect to our designs may be circulated, but in such a way as may induce the enemy to believe them to be true. The corps which is detached for the purpose of executing the feigned movement must, of course, be under no apprehensions for its own safety.

An army, weak in numbers, cannot make detachments while near a superior enemy; because they may be cut off, and beaten in detail. With a small army, it should be a maxim to act constantly in a body; for it cannot attempt to form any enterprises but by the observance of this rule. The system of covering every point must be abandoned, and our endeavours solely confined to the preservation of that object, which eventually must determine the success of the campaign. If, for example, the enemy should detach a corps to operate a diversion, capture a magazine, or undertake a siege, opportunities may arise of attacking him with a force otherwise far inferior. Should he be defeated, his detachment must likewise retreat, and his whole project is rendered abortive. A small army is also sometimes enabled to fall upon these detachments before they can retire, or be sustained by the main army.*

SECT. VII. *Of the Passage of Rivers and other Defiles, and the Means of Defending them.*

Every place where is is necessary to march with a very small front, including, of course, bridges, is called a defile. It is necessary to distinguish the entrance, the defile itself, and the outlet, or *debouche*. Now, as troops, so long as they are in the defile, are in a defenceless state; and if one part be on one side, and the rest on the other, neither can come speedily to the assistance of the other; the passage of a defile is difficult, and easily opposed. Defiles, therefore, have always been of great importance in war.

There are two descriptions of cases in which the passage of a defile is attended with difficulty. 1. When the enemy is posted on the other side, and we wish to march towards him. 2. When we are on the same side with the enemy, and our object is to place the defile between him and ourselves. In the first case, the enemy may either be aware of the point at which we wish to pass, and be prepared to dispute the passage; or he may be in doubt with respect to the point, and we endeavour to pass unperceived. It must be observed, that a defile cannot be said to be passed, until the whole troops are through it, or, at least, until so many are placed, and in such order, on the opposite side, that the enemy cannot prevent the passage of the whole.

In the case of most defiles, the roads are already prepared. But rivers have generally this peculiarity, that the passage must first be prepared by throwing a bridge over them, which is commonly a bridge of boats or pontoons. But, in order to enable us to throw over those bridges, and to defend them, it is necessary to have a body of troops on the other side. And as, in almost all cases, the fire of our artillery, and sometimes even of our small arms, can reach the opposite

* Prince Henry of Prussia gave two examples of this kind in one year (1759,) by defeating General Vehla at Hoyerswerda, and General Gemmingen at Dommitch. Two such prosperous events often give the superority to a weaker army, and compel a stronger antagonist to act with great circumspection.

side, and thus cover the construction of the bridge, the passage, and the deploying of the troops, a river may often be passed, but any other defile seldom, by force.

In order to effect the passage of a river by force, it is necessary,—1. That we should have a convenient situation for constructing more than one bridge; and hence the bank should neither be too high nor too low. 2. That we should have an advantageous position for the artillery, and also, if possible, for the small arms, so that they may have a cross fire at the place where the bridges are constructed. The heights, therefore, on the side from which we are to cross, must be more elevated than those on the opposite side; at the place where the bridges are formed, the river should have a bend inwards; and the river itself should not be too broad. 3. That there be no new defiles on the other side of the river, but a good free space where the troops can easily form under their fire, and then proceed to attack the enemy.

The following dispositions are then made for the passage. 1. The artillery and troops are stationed at those points where they can act with most effect upon the opposite side, and, if possible, they should be placed behind breast-works. 2. Troops are sent over, partly for the purpose of constructing the bridge, and partly in order to throw up entrenchments before it, which must be the more strongly constructed and occupied, the less we can depend upon the effect of the fire from our own side for protecting the entrenchment, the bridge, and the deploying of the troops on the opposite side. These troops must get over by means of fords, boats, or rafts. In fording, the cavalry generally cross over, carrying the infantry behind them. The cavalry remain on the opposite side, if they have nothing to apprehend from the enemy's fire, and, under the fire of their own people, keep themselves ready to attack all that approach the entrenchment or the bridge itself. As soon as the bridge, and the works on the opposite side are completed, the troops commence the passage, in such order as circumstances require, rapidly, but without too much haste. The order depends upon the nature of the ground. If the country be level, and favourable for cavalry manœuvres, the horse must pass first, in order to cover the passage of the infantry. If it be necessary to occupy an advantageous position with artillery, a corps of infantry, with a brigade of the park, takes the lead. The situation may be so favourable for the passage, that the troops, as soon as they arrive on the other side, can deploy and march forwards; it frequently happens, however, that they must first place themselves in the entrenchment, and gradually advance and deploy as they receive reinforcements. 4. When the enemy perceives that the passage is certain, he generally retires. If he does not, as soon as the requisite number of troops arrive, he must be attacked according to the nature of the ground and of his position; and he must be beaten, otherwise we should be in a most perilous situation; and therefore such a passage must never be attempted without a moral certainty of being able to accomplish it.

In order to effect the passage of a river by stratagem, it is necessary, 1. To choose a position from whence we can speedily reach several places where a passage may be accomplished; and in such a manner, that when the enemy places himself so as to oppose us at some of these points, he will be obliged to make a circuit before he can reach the others. 2. To make all kinds of feigned dispositions, and feigned movements, with the whole or a part of the army, in order to mislead him. 3. Should he expose any part, we must endeavour to send over a corps of cavalry and infantry, with the articles necessary for forming an entrenchment, at such places where they can best effect a passage. 4. These must construct bridges, and entrench themselves as rapidly as possible, and, at the same time, occupy, as far as their force will permit, those places from which the debouche can be covered. 5. If these measures succeed, the army prepares for the passage, and the support of the corps. 6. When the dispositions have been so far completed, the army passes, after having previously occupied all those points, which can cover and secure the passage and the debouche. 7. As the troops arrive, they must be so placed as to protect the passage of the rest, and to secure all the further advantages. 8. Should the enemy, notwithstanding, still attempt to dispute the passage, our movements must depend upon circumstances. If we are too weak to drive him back, we must stop and observe his motions, and make our dispositions accordingly, either to continue the passage, should he neglect the proper opportunity, or to secure a safe retreat for those who have already passed. In the latter case, the enterprise has failed, and we must attempt it in some other manner. But if we are strong enough to bid defiance to the enemy, we must either prepare to receive his attack, if our position be a strong one which covers the passage; or if the passage cannot be completed without driving back the enemy, we must attack him without hesitation, with the troops which have got over, before he is aware.

In the case of other defiles, the dispositions are much the same, only that, in general, we have no occasion to be detained in preparing roads. Almost every thing, therefore, must depend upon our having secured the debouche; which must be done by throwing forward a corps to take possession of some tenable place, or good position, at the outlet of the defile. If this has been effected, we have gained every thing. But the longer the defile, and the more difficult the roads through it, the less easy will it be to effect this object. Hence, the passage of this description of defiles is considered as much more difficult than that of rivers; especially if the enemy has fortified the passes, because these must first be forced, and then the debouche secured.

In opposing the passage of a river, it is presupposed that the enemy can find no points at which he can effect the passage by force, or, at least, that he has not the superiority necessary to enable him to accomplish that object. The following are the general dispositions for preventing the passage of a river. 1. We must break down all the bridges in the neighbourhood, and destroy all the fords, and secure all the boats and vessels above and below, as far as we can reach. Should any bridge be left standing, it must be sufficiently secured by a strong entrenchment, or *tete-de-pont*. 2. We must occupy all those posts from whence we can obtain intelligence of the enemy's movements, and at the same time obstruct his passage. 3. If we have sufficient time and means, we should throw up entrenchments at all important points which command the passage, in order to occupy them as soon as we learn that the enemy intends to pass at that place. These entrenchments must be so situated, that if the enemy had suddenly occupied them, we should still be able to drive him out. After these preparatory dispositions, we may adopt one of two plans. In the first place, we may take a position on the river, opposite to the enemy, and follow all his motions with the whole or a part of the army, in order to oppose his passage at every point. Or, secondly, we may take a position with the whole army, not quite close to the river, but at a distance to be determined by its course, which will enable us to arrive at any point where the enemy might attempt to pass, before he can accomplish his object. The country on and about the river must be strongly occupied with posts, in order to obtain early intelligence of every one of the enemy's motions. As soon as we are assured that the enemy is seriously attempting the passage at any particular point, we must march thither, and attack all that have already crossed, or destroy the bridges, or at least prevent him from persevering in the enterprise, if we can do nothing more. We must beware, however, of allowing ourselves to be drawn too rapidly to any one point, as the enemy might then really effect the passage at some other place. So long as we are in a state of uncertainty, we should merely hold ourselves in readiness to march, or send a corps in advance, for the purpose of obstructing the operations of the enemy. The advantage of this method of defending a river consists in this, that the army is not separated in consequence of the passage of the enemy, nor receives any serious blow, nor is forced to expose a great part of its parallel, in order to unite at a great distance behind. There is still a third method of defending the passage of a river, but which can only be employed by an army which is nearly equal to that of the enemy, when the course of the river does not admit of our adopting the second method, in consequence of the river presenting a convex bend to the defending party. This method is, to pass the river ourselves, to take up a strong position close to the enemy, and then hold ourselves in readiness to beat him while he is engaged in the passage. Bold as this method may appear, there is no doubt that it may be attended with singular success under proper precautions. In all enterprises of this nature, indeed, especially where troops can only be brought successively into action, much will always depend upon activity, boldness, and decision; and the fortunate issue will generally be determined by the first attack. When the leading columns have crossed a bridge, or penetrated through a defile, and have maintained their ground until the army is come up and enabled to support them, the success of the event is determined. Hence, it is always of essential importance to prevent the deployment of the leading columns; not a moment must be lost in charging them; the least hesitation may produce irretrievable ruin. The attack being resolved upon, it must be made with impetuosity, because, should it be repulsed, there can be little hope of making a second more successful.

The defence of all other defiles may also be conducted according to all the three methods above described: and the two first always depend upon preventing the *debouche*. But in the case of these other defiles, another method still remains; which is, to establish ourselves within them, by means of fortresses or redoubts. If such posts cannot be turned, or when placed on hills, if they are not commanded by higher eminences, they render the passage of the defile impossible. In establishing such posts, therefore, we must have these circumstances particularly in view, and also to keep the road itself completely under their fire.

The passage of a river or other defile, with the view of placing it between us and the enemy, is, on this account, a matter of difficulty, because there is a period at which the army is divided, and the enemy can attack it at the greatest possible advantage. In such a case, we may either conceal our intention, or we must effect it in the face of the enemy. The following are the general rules applicable to both cases. 1. All the baggage, heavy artillery, and all the carriages that can be dispensed with, should be sent far before us, to some secure place. 2. A strong position should be taken close to the river; and the more close, if we can conceal the time only, and not the place where the passage is to be effected; but, at all events, in such a manner that we may be able to march upon several points of it. 3. Behind this position, bridges should be thrown, shortly before the march, and secretly, if we wish to conceal the place; but otherwise, at the most convenient points, and without any attempt to conceal our intentions. 4. If there be positions on the opposite bank of the river which can cover the passage, they should be occupied with troops and artillery, and strengthened, if necessary, by redoubts. 5. The passage should be made in a continued and orderly manner, but without hurry, until all have passed, except the detachment which is destined to break down the bridges, and which must afterwards pass over in boats. 6. In case of being attacked by the enemy, we must make a proper use of all the means of defence which we have prepared, without engaging with him farther than is necessary to secure the passage. Besides, we must endeavour, in the first case, to seize the first favourable moment to effect the passage, and, if possible, to deceive the enemy by fallacious movements, with respect to the real point. When this cannot be done, we should endeavour to conceal the time, by breaking up during the night, or in the midst of a thick fog, a storm, &c. and employing all kinds of warlike stratagems. Notwithstanding all these precautions, we must not neglect to take every measure for securing the passage against accidents. The rear guard must occupy all the posts that can cover and protect it, and all must be prepared to assist it, in case of necessity.

When it is not possible to conceal from the enemy either the place or the time of the passage, and he has it in his power to attack us at any time, it will be necessary to adopt the additional precaution of entrenching ourselves in several lines, so that when the army has beeen weakened by the passage of a part, the rest may not have too extensive a line of defence. Nothing should be neglected that can tend to conceal the retreat. In the case of other defiles besides rivers, there is little difference in the dispositions, except that the precautions employed to cover the passage at the opposite side are unnecessary, and all our attention, therefore, must be turned to the rear guard, which can only be slowly succoured.

It is unnecessary for us to say any thing of the means of passing a defile, when the enemy is master of both sides, and the army, in attempting the passage, must cut its way through; because this is quite a desperate situation, out of which it is almost impossible to extricate ourselves, and into which no general can fall, without gross errors and incapacity. In such a case, we should have to contend with the twofold difficulties of a retreat, and the forcible passage of a defile. Success in such a case must be ascribed to good fortune, and not to good conduct.

In order to prevent the retreat through a defile, it is necessary, 1. That we should be vigilant, to prevent the enemy from effecting the passage secretly. 2. That we have an accurate knowledge of the enemy's situation, that we may regulate our project of attack accordingly, and carry it into execution before he has time to effect his object; for which purpose we must drive him as close to the river as possible, in order that he may not be able to conceal from us the point where he means to pass. 3. That we should make such dispositions as will enable us to make an attack every moment, especially during the night, by keeping the troops, cavalry, infantry, and artillery, constantly in readiness.

Sect. VIII. *Of Battles.*

A combat between two entire armies is called a battle; when a part only of the one army is engaged with a part of the other, it is called an action. It is not necessary for us, however, to make any such distinction here, as the disposition and arrangements for both are the same, and the number of the combatants makes the whole difference. We shall only observe, that one is more easily induced to risk an action than a battle, because the former is not so decisive.

In this section, we propose to consider the reasons which should induce us to give or refuse battle; the arrangements for battle, including the order of march and disposition of the troops; the different modes of attack and defence, and the consequences of victory and defeat.

It is a general rule, that we should never give battle, unless when we have no other means of attaining our object; or when we have much to gain, and little to lose by it. The following are some of the principal reasons which should induce us to give battle. 1. To relieve some important place. 2. To enable us to besiege some important place belonging to the enemy. 3. To cover a seige which has been already commenced. 4. To drive the enemy out of a country, or, 5. To defend a country against him. 6. To deprive the enemy of an ally; or, 7. To induce an alliance with others. 8. When the army is on the point of getting into an awkward situation, from which it can only be saved by a successful battle. 9. If we foresee, that if we do not give battle now, a period will come, in which we shall be compelled to do it under much more unfavourable circumstances. 10. When we perceive, from the situation of the enemy, or from some errors which he has committed, that we have it in our power to beat him.

To avoid a battle is to place ourselves in such a situation as to make it impossible, or at least very dangerous for the enemy to attack us. We act in this manner, 1. When it is more probable that we shall lose than that we shall gain the battle. For instance, if our troops are not in a good state of discipline; if we are posted on ground which is not adapted to the kind of troops of which our army consists; if we are weaker than the enemy, or if the enemy has taken a very strong position. 2. If we foresee a future opportunity of giving battle in more favourable circumstances; as, for example, when we expect a reinforcement ourselves, or that the enemy's force will be diminished; or that the enemy will be obliged to take up a bad position. 3. If, in general, we can expect less advantage from gaining the battle, than we should suffer injury by losing it; as, when the enemy's fortresses are in a better state of defence than our own; when every step which he makes in advance is laborious and expensive, while a successful battle would lay every thing open to him; when his retreat is easy, while ours is dangerous; or when, by a defeat, we should be deprived of our resources, while the enemy would still retain his. 4. In all cases where we can attain our object without a battle.

When we have resolved upon a battle, we must endeavour to give it under the most favourable circumstances. For example, when the enemy are inferior to us; when his troops are discouraged, and in bad order; when his generals are not agreed, or when we have an understanding with one of them; when the enemy is placed in a bad position, or when he is ill encamped or entrenched in a position which is otherwise good; when he is ill provided against an unexpected attack, whether in his camp, or on the march; or when his retreat is difficult, and ours easy.

When an army is desirous of giving battle, it advances towards the other in order to attack it; but if it wishes to avoid a battle, it selects a position, which must be the stronger, the more reason it has to avoid an engagement, and there awaits the attack of the enemy. It is possible, however, that both parties may be equally desirous of giving battle, and therefore advance, and attack each other wherever they meet; or, the army that wishes a battle may await the attack. In the latter case, the army takes a strong position, from which the enemy must expel it, without being able to do so without a battle.

In a battle there are three things to be considered, each of them in a double relation, viz. to the attacking and defending party. These are, the arrangements for battle, the battle itself, and the pursuit and retreat.

Among the arrangements for a battle some are common to both parties; some are peculiar to the attacking, and some to the defending party. The following are those which are common to both parties. 1. Every disposition must be made to render a victory as profitable as possible, and to diminish, as much as we can, the evil consequences of a defeat. 2. The arms must be accurately inspected. 3. We must have a sufficient supply of ammunition, and take care that it be not wanting at any place where it may be necessary. 4. We must get rid of all the baggage. 5. We must endeavour by all means to inspire the troops with courage and confidence. 6. The troops must be previously allowed to take sufficient rest and food. 7. We must have a sufficient supply of medicines, bandages, and surgeons.

The arrangements to be made by the attacking party must be regulated, in a great degree, according to the measures adopted by the defending army; we shall therefore speak of the latter first. 1. A good field of battle must be chosen, where we are to await the enemy's attack. The field must be adapted to the number and description of our troops; besides presenting obstacles to the assailants, it should afford us the means of following up a victory; it should admit of such manœuvres, as, in case of our being compelled to retire, will prevent a total and ruinous defeat; and, at all events, it should afford us the means of a safe retreat. For this reason, positions with strong projecting angles, or with defiles, especially a river, in the rear, must be carefully avoided, because the loss of a battle in such situations must be absolutely ruinous. 2 Having chosen our field of battle, we must endeavour to make the best use of the advantages which it affords; our cavalry and infantry must be posted in such situations where they can best act, and mutually support each other; the artillery, in particular, must be placed so as to produce the most decisive effect. 3. All the posts in front, which are calculated to obstruct or break the attack of the enemy, or cover a flank, should he attempt to turn our position, (such as houses, villages, heights, &c.) must be rendered as strong as possible, and occupied by the proper description of troops, in order to produce the expected advantage, and to present a powerful resistance to the enemy's attack. The possession of villages, in front, provided they are at a proper distance to be sustained, is one of the most advantageous circumstances that can occur in a field of battle; but all the advantages are lost and turn against you, if you do not sustain them. Villages, when situated as above described, and properly occupied and sustained, are so very advantageous, that a general will seldom chuse to attack them, but will rather mask them, and set them on fire with howitzers, and chuse some other point of attack, which, though in appearance less proper, will, generally speaking, succeed better.* 4. All the generals must be well instructed with regard to the nature of the position, especially that part of it, the defence of which is committed to them, and also with regard to their conduct in every event that can be anticipated, and how they are to give and receive assistance. These, again, must give similar instructions to the officers under their command.

The attacking army endeavours to obtain, by all means, the most accurate knowledge of the dispositions of the enemy. If his position be found very advantageous, we must endeavour to entice him from it, or cause him to weaken himself by detachments. For the art of a general, when he is desirous of giving battle, consists in enticing the enemy to ground where he can fight with advantage; but, at the same time, he must take care not to lose in manœuvring, the proper moment of attack. If the ground be determined upon, the army marches to it in several columns; the general being commonly with the advanced guard, for the purpose of reconnoitring the position and arrangements of the enemy. This position may be of a fourfold nature. 1. The front of the position may present no advantages to any part, and may be attacked along its whole extent. This is the case in large plains, and such ground, therefore, is sought by two armies, who are desirous of coming to a decisive action. 2. There may be an obstacle before the front, which must first be surmounted. 3. The position may be such that we can only attack certain parts of the front. 4. The enemy may be placed behind entrenchments.

In a case where it is in our power to attack the whole of the enemy's front, those who are skilled in military science notice several modes of attack, or orders of battle. 1. To attack the whole of the enemy's front with the whole of our own. 2. To throw forward one of our wings, with the view of attacking the opposite wing of the enemy. 3. To throw forward both wings, in order to attack both of the enemy's wings, and keep back the centre. 4. To advance the centre, and keep back the wings. The first is very rarely employed with our large armies in modern times, and can only take place with small corps. It is never advisable, unless we chuse to place every thing at hazard. The second is universally acknowledged to be the best mode of attack, because it enables us to concentrate our force upon the point of attack; and, by employing it, we risk less in case of a retreat, because the army can easily be covered by the refused wing. The third mode is only employed when we wish to outflank the enemy; or, when our wings consist of cavalry, who commence the attack by overwhelming every thing opposed to them, in order to fall upon the flanks of the enemy. The fourth mode is bad, because every projecting angle in a position is a weak point, and in this mode there would be two such angles. It can only be employed, therefore, when we have to attack the enemy under circumstances in which we are apprehensive of being outflanked, if the wings should leave their leaning points; for example, if, on passing a river, we were obliged to drive off the enemy, without permitting the wings to leave the *appui* of the river. All attacks, in which parts of the army advance, and others remain behind, thus forming an oblique line, are best made, on the part of the infantry, *en echelon;* the cavalry, on the other hand, rush out of the line, and make a separate attack, supported by the infantry. But we shall have occasion, by and by, to explain more particularly the various orders of attack.

If it be necessary, before proceeding to the attack, to make ourselves masters of some obstacle in front, we must examine wherein the obstacle consists; whether we cannot get round it, or how we can rapidly surmount it. Such obstacles may be of two kinds; 1. Such as from their nature obstruct the approach. 2. Such as are occupied with troops, and, by the fire from them,

* We have a fine example of this given by the celebrated Marlborough, at the famous battle of Hochstead or Blenheim. His Lordship had attacked several times the village of Oberklaw, but was each time repulsed with great loss. He afterwards, very judiciously, having left a body of infantry to mask the villages, advanced, and broke the enemy's line, and thus gained the battle. The French had garnished all the villages before their front, particularly Oberklaw and Blenheim, with a prodigious quantity of infantry, expecting that the generals of the allies would attack them, and by no means presume to advance and leave them behind; but they were disappointed, and beaten, with the loss of all their infantry posted in the villages.

Hence Jomini lays down the following rules respecting positions of this description. 1. That an army, posted behind villages, must protect its front by occupying them. 2. That for this purpose, some battalions of infantry, furnished with artillery, must be employed. 3. That the army must be drawn up at a convenient distance in rear, so as to sustain and be sustained by them; and preserve the means of withdrawing the troops, in case the enemy should threaten to cut them off, by successful movements in another point. 4. That from the danger of being turned in such posts, and the nature of their defence, only a moderate quantity of infantry is required; and that too much importance ought not to be attached to their preservation.

These ideas are justified by the event of several battles, and in particular by that above named. Had the French generals withdrawn the greater part of their infantry from Blenheim and Oberklaw, when they perceived that their line was threatened upon another point, they might have brought them to act upon the flank of the assailants, and probably have gained the victory. Admitting they had still been defeated, they would not have lost twenty battalions prisoners in these villages.

prevent the attack, because we should be compelled to present a flank to them; such as villages, heights, &c. If the obstacles are of the first kind, we must endeavour 1. To force the enemy to leave his position, by a rapid movement towards his flank or rear, by which means we may be enabled to avoid or surmount the obstacle; 2. If that be impossible, we should endeavour to discover some place, which, either from the nature of the ground, or the want of prudence on the part of the enemy, is not exposed to his fire; 3. We should examine whether, from some point, we may not be able to bring a superior fire to bear upon him, and thus silence his fire at those points where our passage is obstructed. At all events, our troops must be supplied with all that is necessary for forming a road over the obstacle; indeed more than one road should be prepared, and the breaking off and deploying ought to be performed in good order, and with rapidity. In the case of obstacles of the second kind, we should, 1. Endeavour, by an oblique attack on the flank or rear of the enemy, to relieve ourselves from the necessity of attacking the obstacle itself; 2. If that be not practicable, we must endeavour to pave a way for ourselves by artillery; in which case, howitzers, used against villages and entrenchments, will be of great service; 3. We must make an attack upon them, according to the nature of the circumstances, supported by the whole army.

If we can only get at the enemy at certain points, where we are sure that he has concentrated his whole force, we must endeavour to ascertain the number, situation, and nature of these points; whether some of them may not have been neglected, and which of them have the weakest fire; whether we may not be able to draw off his attention from some of them, by false attacks or otherwise; or whether, by means of batteries well placed, we may not be able to silence his fire on the points of attack. Our dispositions must be made accordingly, and we must determine the number of attacks, and the time at which each is to be made; the number of troops to be employed, with the order in which they are to attack, as well as the position of the troops which are to sustain each attack; as also, what is to be done after a successful or unsuccessful attack, and how a false attack, which has made good progress, may be sustained.

The following dispositions are necessary in the attack of an entrenched camp. In the first place, we must examine the whole entrenchment, in order to find out its weak parts. These may have been occasioned by the fault of the enemy; as, for example, when the flanks are not secured; when, at some points, the works are not complete, of a weak profile, or are so constructed, that we can approach them without being exposed to their fire; or the weakness may be occasioned by the nature of the ground. It is also necessary to ascertain the means which the enemy possesses within his entrenchments, to renew the contest, or to make a good retreat. In the second place, having sufficiently investigated these matters, we proceed to make our dispositions for the attack. These consist, 1. In determining the number of attacks, false and real, with the time at which they are to be made; the number of the troops, their order, &c. as above. 2. The troops must be supplied with all things necessary for the accomplishment of their purpose, such as hurdles or fascines, if there are wolf-holes,* or marshy places to be passed, or ditches to be filled up, and axes, when pallisades, &c. are to be attacked. 3. We must determine the signals, and the time of the several attacks. With regard to the latter, we may observe, that night attacks have the following advantages: We can the more easily surprise and alarm the enemy; while we conceal our own dispositions, and have little or nothing to apprehend from his fire until we come up to the entrenchment. But this mode of attack has likewise great disadvantages: the columns may easily lose their way, and miss the time and place of attack; we must dread the most dangerous kind of defence, by the enemy mounting the breast-work, and preventing us from climbing up. The troops cannot be kept together at night; many remain behind; and terror and disorder spread as easily among the assailants as among the defenders. In a night attack we lose the advantage which might be expected from a previous cannonade on the enemy's works; and even if we should succeed in penetrating the works, it is probable that we may not be able to follow up our advantage, and to render it decisive. On account of these disadvantages, most attacks on entrenchments are made by day. In general, we would recommend the following rules as the safest with respect to the time of attack. A night attack should be made only when we expect to take the enemy by surprise; or when he has bad, discouraged, or ill-disposed troops. It is always advisable, however, to march, and make our dispositions during the night, in order to commence the attack by day-light, unless we have reason to dread confusion and disorder. At all events, we should attack as soon after dawn as possible, in order that we may have time to follow up a victory.

Hitherto we have taken it for granted that the defending party had made good dispositions. It is possible, however, that he may have committed errors, which must also be taken into the account. The troops may be ill posted or disposed upon the field of battle; the troops, or the different kinds of arms, may not be able to sustain each other; the reserves may be ill placed, or at too great a distance; a part of the line may form a projecting angle, perhaps not very well covered; we may be able, by a rapid movement, to compel the enemy to change his order of battle; or, he may be, as it were, nailed to his position, from the fear of losing some essential advantages by attempting to advance.

When in this way all the necessary dispositions for the attack have been made, the following general rules are to be observed: 1. The army, which had previously been marching in columns, is placed in order of battle, generally by deploying. This manœuvre must not be performed at too great a distance, in order that the army may not have occasion to break off again, while marching to the attack; nor too near, lest it should be performed under a dangerous fire. 2. The artillery is moved up to those points required by the plan of attack. 3. At the proper time, the command or signal for the attack is given, and the troops immediately march upon the enemy.

In case we are to attack the whole of the enemy's

* Round holes, generally about two feet in diameter at the top, one at the bottom, and near two deep, with a sharp pointed stake driven into the bottom.

front, we proceed in the following manner: 1. The army is commonly drawn up in two lines, with the necessary reserves, and in complete order of battle, if the ground admit of it, otherwise the intervals are extended, but never beyond the half order, which must not be exceeded. 2. The army then move forwards, according to the pre-determined mode of attack, either under the fire of the artillery, or after the latter has done the expected execution, taking care not to break the line. 3. The nature of the ground, and other circumstances, must determine whether the attack is to be made first with cavalry or infantry, or with both at once; and whether troops of one kind are to be opposed to troops of the same or a different description. But whatever is to be done must be done resolutely. 4. If we have thrown the troops opposed to us into disorder, we must immediately form and prepare to receive or to attack the second line or reserve. 5. If there be no second line or reserve, or if these also have been beaten, the victors should not give themselves entirely up to the pursuit, but send a detachment for that purpose, sufficient to prevent the enemy from forming again; while the rest endeavour to improve the advantages obtained, by falling on the enemy's flank, or taking such a position as will cut off his retreat. 6. The artillery must fire upon those batteries which most annoy the troops in their advance, or upon the points chosen for the commencement of the attack.

If there be some obstacle in front which must be previously surmounted, the cannon must play upon it, while the troops destined to attack it, march upon it in column at those points where they are least exposed to the enemy's fire. The rest of the artillery endeavour partly to interrupt the communication between the enemy's army and the posts, and partly to secure the debouche, and to silence the batteries which would prevent it. The whole strength of a position frequently consists in such a post in front, and the enemy retire as soon as it is forced; but if they do not, the whole line must be formed, as rapidly as possible, for the attack, as soon as we have got possession of the post, in order to profit by the disorder which the flight of the troops which have been driven out of it may have occasioned in the enemy's army.

If we can attack the enemy only at certain points, we must ascertain the best method of making the attack, whether by the fire or the bayonets of the infantry, or with cavalry. If by means of fire, we should endeavour to unite as much fire as possible, both from great and small arms, on the points of attack; and the troops and cannon should be so placed as to have a cross fire. But if the attack is to be made with the bayonet, our troops in column must approach the enemy cautiously, in order that they may not suffer much from the enemy's artillery, and then attack with vigour. The cavalry must attack with that fury in which the force of their charge consists. When our fire, which, if possible, should always take place during the advance of the troops, has made an impression upon the enemy, the troops nearest them, or those who receive orders, must immediately push forwards, and avail themselves of his confusion, to make a rapid charge with the view of penetrating his line. Those who have succeeded must follow up their success, and overthrow all that advances to sustain the broken line. The troops that follow those who made the attack must fall on the flank of that part of the enemy which has not given way, and form front in order to oppose any attempt that may be made by the second line, or the reserve, to restore the combat. If we have completely succeeded in establishing ourselves on those points of the enemy's line, he retires from the field. Our more advanced troops then endeavour to occupy positions for the purpose of cutting off the retreat; the others who were engaged in the attacks, endeavour to unite as rapidly as possible, to form in line, and to support the troops engaged in the pursuit.

In the attack of an entrenched camp, the troops must be made acquainted with the obstacles which they have to encounter in each attack, and be supplied with the means of surmounting them. As many of these obstacles as possible should be previously removed by the artillery. The troops which are destined to form the attacks then march in open columns to the points of attack, and endeavour to avail themselves of all the advantages of the ground, to avoid the enemy's fire. The troops destined to support the attacks follow at a moderate distance in front. The columns should not be too strong, nor consist of more than two battalions. It were better to make several attacks than to form too deep columns. To arrive in front of the entrenchment—to spring into the ditches and climb up, must be the work of a moment. While the foremost are thus engaged, those following them must, if necessary, keep the breast-work clear by means of their fire. As soon as a part have surmounted the breast-work, the rest must immediately follow, place themselves on the top of the breast-work, drive off every thing with their fire, and even turn the enemy's cannon against himself. Under cover of this fire, the workmen clear the entrances in the neighbourhood, or make new ones, if necessary, to admit the troops. If cavalry are employed, (which is always the case when the ground will admit of it,) they charge such of the enemy as attempt to make a stand, as soon as a few squadrons are formed. If infantry, they always endeavour to gain more and more ground, and to drive off the enemy with their fire, until he leaves the entrenchment entirely, when the different attacks can unite and form line. In all attacks, it is of advantage to conceal from the enemy the true points at which they are to be made; and for this purpose all possible feints and stratagems should be employed that are consistent with the attainment of our main object.

The party acting on the defensive must first take care that his flanks be secure, and his front strong and well covered. He should then endeavour to discover the point or points against which the enemy's attack is directed; and when he perceives that a reinforced attack is intended, he must strengthen that point in such a manner as the nature of the ground, and of the troops employed by the enemy, require. All the artillery that can be brought to bear upon them must play upon the enemy's columns, and particularly endeavour to harass them while deploying. If the enemy make the attack with infantry, he must be opposed by a strong fire along the whole way to the attack, which, when properly executed, should compel him to turn to the right about. If with cavalry, they must either be charged by our own horse, or opposed by infantry; and, in the latter case, we should endeavour to manage matters so, that the cavalry, while in full charge, shall present the flank to a corps of infantry posted near them, whose fire may easily bring them into disorder. Otherwise, infantry must await such an attack without firing, until the enemy come within twenty paces, when a well-timed general charge will certainly drive back the cavalry. Our own sustaining cavalry must then break through the intervals, and convert the disorder occasioned by the fire of the infantry into a complete flight. If the enemy, while marching to the attack, should give us an opportunity of attacking him in flank, it should by no means be neglected; for in this way an attack can frequently be effectually and decisively repulsed. But, in such a case, we must take good care not to expose our own flank.

When we have beaten back a part of the assailants, we must not pursue them too keenly, but only endeavour to prevent the beaten troops from forming again, which may be done by means of light horse, or detached troops. If the enemy, on the other hand, has penetrated any part of our line, the troops appointed to sustain it must immediately come up, and endeavour to profit by the confusion which is occasioned even by a successful attack. The beaten troops must hasten to form again, and attack the enemy. If we can fall upon his flanks, we shall the more certainly force him to retire. It is very easy to apply these general rules to the particular cases.

Before leaving this subject, it may be proper to explain more minutely than we have hitherto done, the mechanism of the different orders of battle; a perfect knowledge of which is of the very first importance in military science.

All the seven orders of battle which tactical writers, since the days of Vegetius, have described, may be reduced to these two—the *parallel* and the *oblique*. The order is said to be parallel, when our front is developed in a direction parallel to that of the enemy, and can engage along its whole extent. This is the most simple and natural disposition, and must have been generally adopted in the infancy of military science. As knowledge increased, armies superior in numbers would endeavour to avail themselves of their superiority by turning the enemy's flanks; hence the disposition in form of a crescent, which is still practised in the Turkish and Asiatic armies. On the other hand, skilful generals, at the head of inferior armies, would endeavour to discover the means of compensating the disadvantage of inferior numbers by a more perfect system of tactics. They would perceive that, by presenting a front parallel to a superior enemy, they exposed themselves to be surrounded and beaten; and they would consequently be led to adopt some other disposition, some science of movements, by means of which they could bring a part of their forces to bear upon some point of the enemy's line, while the rest were kept back out of the reach of the enemy. Hence the oblique order of battle; the advantages of which were at length found to be so great, that it was generally adopted by all armies, whether superior or inferior in numbers, to the utter exclusion of the parallel formation. The advantages of the oblique order are, that since its introduction war has become a science of judicious combinations, instead of a game of chance; and that, as it does not admit of a general engagement along the whole line, the result of battles depends upon the ability of the commanders more than upon the quantity of blood that is shed. This order of battle was well known, and very celebrated among the ancients; but the King of Prussia was the first commander, in modern times, who executed it upon scientific principles, and adapted it to modern tactics.

In the oblique order of battle, it is not necessary that the front should precisely describe an oblique line with respect to the enemy's front; for it seldom happens that the nature of the ground, and other circumstances, will admit of such a perfectly regular formation. Every disposition, then, may be called oblique, in which we bring a part of our forces to act against the enemy, while the rest of the troops are kept out of his reach; every disposition, in short, in which we attack, with superior numbers, one or more points of the enemy's line, while the rest of our troops are placed beyond the reach of being attacked by him. The advantage of this order of battle consists in this, that, by attacking some part of the enemy's line with superior numbers, we are enabled to penetrate and overwhelm it, to fall upon his flank and rear, and thus force him to retire from the field.

From the nature of the oblique order, the attack must be directed against one of the enemy's wings. The main object to be attained by its means is to make an impression on the point assailed, to continue to outflank it, and to turn its rear. To render these results practicable, it is necessary to reinforce the attacking wing, so as to give it a decided superiority over the enemy; and to prevent him from reinforcing the point about to be attacked, the assailant must have recourse to every delusive art to mask his real design, until the onset is actually commenced. Then the attack must proceed with vigour and rapidity; no time must be suffered to elapse which might allow the enemy an opportunity to recollect himself. The onset must be as furious as it is unexpected, and he must be overthrown, even before he has had leisure to fire a shot.

In operating thus with a concentrated effort upon one of the extremities of the enemy's line, measures, as we have already hinted, must be taken to make this attack practicable, by masking the preparatory movements; for, without this precaution, it would be in the power of the hostile army to move in a corresponding direction with the columns intending to turn its flank, and to continue to present a front to them, or even to turn their own flanks. Hence it is necessary to conceal the march of the columns by the obscurity of the night, the conformation of the ground, or by a false attack upon the enemy's front. The two last methods are to be preferred, especially if they can be employed both together, because movements by night are more liable to uncertainty and irregularity than those made by day. In order to alarm a greater extent of front, it may be preferable to act with a corps of light troops, distributed in platoons, rather than with a continued line in the shape of an advanced guard. This skirmishing force might, according to circumstances, be augmented to six or eight battalions; and a point should be indicated to them upon which they are finally to close, and where they will be sustained by cavalry and light artillery. This method has the twofold advantage of perplexing the enemy, in regard to the real importance of the false attacks, and the number of troops employed in them; and also of attracting the attention, and keeping in check the greater part of his front, while the columns are marching to their destination.

The oblique order may be executed either in line, or *en echelon*. When formed in line, the disposition presents an oblique front in a half quarter of conversion, (Plate CCCLXXXIII. Fig. 39.) When formed by *echelons*, each battalion and squadron is out-flanked on the side where the attack is made by the battalion or squadron next it, to the extent of a certain number of paces, more or less considerable, according to the number of troops of which each column is composed, and the degree of obliquity required in our disposition. All that part of the army, however, which is destined for the attack, forms a sort of hammer in front, placed in the common order, (Fig. 40.) This disposition by *echelons*, instead of being formed by battalion and squadron, may be taken by regiment or brigade, and even by more considerable corps; these corps being placed by *echelons* at some distance from each other, so as to be able to support each other mutually when necessary, and to occupy the positions which can best prevent their being exposed to an attack, and enable them to deceive the enemy. Of these two modes of forming the oblique order, in line, or by *echelons*, the first is merely elementary and methodical. It may be well to practise it in camps of instruction, in order to make the officers acquainted with the nature and object of the oblique order. The second mode, which is derived from the first, is more simple, easier in its deployment, more applicable to all sorts of ground, and more susceptible of manœuvre and action when the disposition is formed. There are various ways of forming these oblique dispositions, which the reader will find described by Guibert and other tactical writers. Meanwhile, we shall notice another species of the oblique order, in which the army, although not drawn up obliquely in front of the enemy, places itself, either from the nature of the ground, or the skilfulness of its movements, in such a situation as enables it to make an attack upon one or more points, while it is itself out of reach of the enemy upon those parts of its line which it is desirous of refusing. This is the order which is most generally adopted in actual warfare, because it seldom happens that battles are fought on plains absolutely smooth and open, where, consequently, the dispositions may be made without regard to the nature of the ground, and in the regular obliquity established by principles. We are almost always compelled to abandon this regularity, in order to avail ourselves of the advantageous positions which are presented by the nature of the country, either to favour the illusion which we wish to practise upon the enemy, or to secure the weak parts of our line. Thus, the order of battle at Lissa, or Leuthen, may be called an oblique disposition, although certainly the army of the King of Prussia was not drawn up obliquely to the front of the Austrians; but he attacked with a strong body their left wing, took it in flank and overwhelmed it, while, at the same time, he availed himself of a chain of heights, opposite to their right and centre, in order to deceive them, to keep them in check, and to place in an excellent defensive position, the rest of his army, which was weakened by the reinforcements he drew to his right.

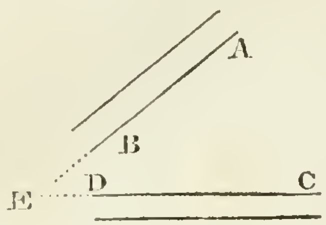
The methods of marching and fighting invented and carried into execution by the great Frederick, form an admirable study for all who would acquire a perfect knowledge of military dispositions. On examining the Prussian orders of march, at the battles of Kollin, Rossbach, and Leuthen, (Plates CCCLXXXIV. CCCLXXXV. CCCLXXXVI. and CCCLXXXVII.) it will be seen that the armies moved in columns by a flank,* each line forming a column; and that this order of march was obtained by simply breaking the lines into open columns of companies. It will be equally easy to perceive with what facility these columns again formed in order of battle, by wheeling into line. The following are the advantages which this method offers for all kinds of marches and orders of battle. 1. By means of this order of march, the army can make all its movements without being disunited; and, consequently, it is not liable to have its right or left columns successively overpowered, since the whole is formed in two only, with no more distance between them than is usual between the first and second lines. 2. The enemy cannot penetrate between these columns, or cut them off. 3. By taking the direction which the line of battle is to occupy, the army, on arriving upon the ground, can be formed in a few minutes; that is, in the time required for all the divisions to wheel into the allignement. It is only necessary to cover this march with an advanced guard, which will answer the double purpose of protecting the army, and of keeping the enemy in suspense respecting the real point of attack. 4. The army having no other distances to observe to form into two lines, than the two hundred or three hundred paces between the two columns, and that between platoons, there can be no difficulty in executing the manœuvre with precision. 5. When the army intending to outflank the enemy has reached the proper point, by a concealed movement, and is in the necessary direction for that purpose, by suddenly forming into line, the enemy will neither have time to form a *potence*, nor to change front entirely; and consequently, he will be overpowered on one of his extremities by a mass of forces which it will be impossible for him to resist. This was more clearly proved at Leuthen than in any other battle. 6 If it be not advisable to form the army into two columns, of the same length as the line of battle, they may be converted (if the ground will permit) into four, by doubling the lines, or by marching by wings, without, on that account, embarrassing the formation of the line. When the four columns moving in the order of doubled lines, have arrived within a short distance from the point where they are to form, the even columns (second and fourth) will halt, and protect the further movement of the others, until their heads are disengaged; when the first platoons will immediately fall in at a proper distance from the last of the leading columns; and thus they will be in position to wheel up, and form a contiguous line, (Plate CCCLXXXIII. Fig. 41.) If they are formed by wings, to draw up in two lines is executed by a simple change of direction, simultaneously made by the head and rear of each column. The order of march at the battle of Leuthen explains this at first sight.

To the method above described, we may attribute the facility which Frederick displayed in manœuvring upon the flanks of his enemy; and the means of keeping his army in columns until the moment of attack, when they formed line in an instant. The system of keeping his army constantly united, of opposing a mass to isolated parts, a whole line to a single extremity of a line, could only be put in execution by means of the order above described, which united promptitude of formation, with connection and simplicity.

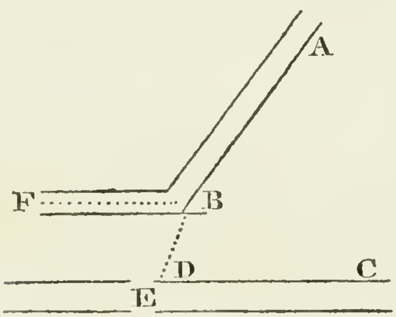
We have already observed, that in making an oblique attack upon one of the extremities of the enemy's line, measures must be taken to make this attack practicable, by masking the preparatory movements; otherwise it will be in the power of the hostile army to move in a corresponding direction with the columns intending to turn its flank, and to continue to present a front to them,

* It is not meant as a movement made in files, but a march by platoons, divisions, or companies, in column of the whole army, right or left, in front.

or even to turn their own flanks. As, for example, when two armies march in the directions CD, and AB, they will form an angle in the point E.



Whence it follows, that whichever first reaches the point E, will have gained the flank of the other, and will consequently turn it. Let AB be the army marching by divisions, or otherwise, with a strong corps of cavalry at its head, to attack and gain the flank of CD with all possible speed: if CD be vigilant, there will be no difficulty in frustrating the manœuvre, by reaching the point E before the enemy. For, having timely information, AB cannot anticipate his antagonist, because the distance from D to E is less than that from B to E; consequently CD has the advantage, and AB may be considered as defeated, provided proper care is taken to profit by the circumstance, and the attack is made boldly. To be convinced of this, we need only examine how AB can oppose it. As soon as the cavalry CD has passed the point E, the army AB has no other resource than to



form an angle or *potence* BF. This movement being executed in haste, will not be very orderly: while the cavalry in E, having already formed in line, will advance, and gain still more on the flank by continuing to incline to the left, while moving to the attack. Hence they will outflank, and make the onset before the enemy's horse in BF can be ready. Another inconvenience arises from the formation *en potence*. The army, having previously marched with proper distances between the columns or lines, is thus suddenly thrown together by the lines forming to the rear, which may produce such confusion, that both the first and second line may be routed together before they can be disengaged.

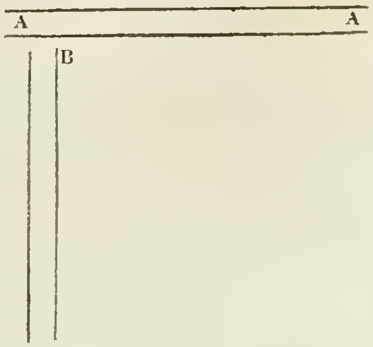
While the cavalry CD is making the attack, the infantry will have time to reach the point E; and should they be only a few battalions, they must nevertheless advance, without waiting until others are come up. Nothing would be so injurious as to lose time by irresolution, because it is evident that they can march forward without standing in need of being supported by the army; for, supposing CD to have marched by divisions to the left, and the cavalry by superior speed to have gained, during the movement, six or eight hundred paces in advance, the infantry will arrive at E, about the time that the cavalry, after having made the shock, will be engaged in forming anew, and will thus be in readiness to protect it while busied in that operation; after which they can march on both together against the enemy, who, finding his cavalry overthrown in the first charge, will be found endeavouring to form his right wing of infantry *en potence*, or with an angle thrown back; but as in this manœuvre his disordered cavalry will obstruct him, he will order them to move off to the right. If at this moment the infantry CD advance, they will find the enemy still in the act of forming, and defeat him with ease. Admitting that these battalions have preceded the others by some hundred paces, they will soon be followed by the succeeding, who, having in their turn, reached the point, will advance in a kind of *echelon* of battalions, and thus come gradually, and in proper time, into action; and if the whole take the precaution to incline towards the left, while advancing, the enemy, in a short time, will be so completely taken in flank and rear, as to make it impossible for him to take any effectual measures of resistance.* Besides, the angle at B offers an excellent mark for the artillery to enfilade and beat in reverse. In this manner a great army may be so compressed by an inferior force, as to seem totally surrounded.

The principles of the oblique attack on an enemy's flank may be farther illustrated, by considering the effects of an attack directed against an army while marching. To attack an army on the march, indeed, is advantageous, for the same reason that it is desirable to engage an extremity of an enemy's line; because the

* Jomini allows that these views, originally suggested by Tempelhoff, are sufficiently just; but adds, that he is grossly mistaken when he asserts, that two columns being brought close together, by a change in their direction, will be enfeebled, and on that account more easily defeated. Besides, it is not absolutely necessary to make this change of direction, in the case above supposed. Two brigades might be made to change front, and thus the two lines would not crowd upon each other.

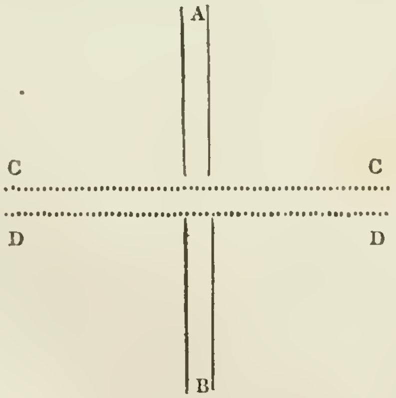
Jomini and Tempelhoff are not quite agreed with regard to the effect of an angle or *potence*, in resisting a flank attack. The latter observes, that to protect a flank by a *potence*, against an active and manœuvring enemy, is to employ a remedy more dangerous than the inconvenience intended to be avoided; and that it should never be adopted, unless the flank can be securely posted upon a point which the enemy cannot turn. Another disadvantage, he adds, attends projecting angles; namely, that the troops forming the point cannot make a retrograde movement, without crowding and causing confusion; nor can they advance, but by leaving such an opening in the position, as the troops posted to the right and left can with difficulty close; and this they can only perform by movements, which, producing a fluctuation in the whole line, are apt to cause general disorder, if attempted in the presence of the enemy. To conclude, an angle is the object upon which an experienced enemy will endeavour to accumulate a raking fire of artillery. Jomini, on the other hand, admits, that an army manœuvring with ability, will be able to turn the flank of an angle, as well as of a straight line; but he observes, that it will be necessary to make a more considerable movement; that this movement will require time, and give the enemy an opportunity to change front, and present his whole line on the point where his flank only was expected. The one, in short, will march on the arch of a circle, while the other moves on the chord; and therefore the army acting on the straight line will have completed its movement, before the other which describes the curve. Thus, while checked in front by the angle, the flank and rear will be turned by the line, and the enemy will be compelled to lose ground.

army attacked on the heads of its columns is placed, relatively to its opponent, in the same situation with that assailed in flank. This is demonstrated by the following figure.



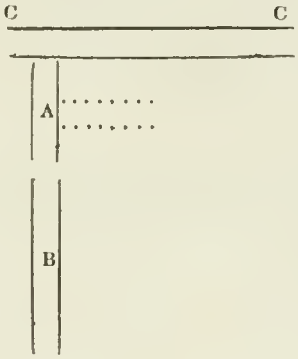
Supposing both armies in line; B will be found to be attacked by a perpendicular line, with one of its extremeties outflanked, in the same manner as the heads of its columns would be, if the army were on march.

Both manœuvres produce similar advantages; which are, that the army attacked can only bring its battalions successively into action, while the attacking force, pressing forward with vigour, is enabled to overthrow them one after another. In order to secure this result, it is not enough to attack an army on march, but the corps A must, besides, move in a corresponding direction; that is, by prolonging the march horizontally, if the advance of the hostile columns be perpendicular, and prolonging the perpendicular movement, if that of the enemy be horizontal. The object of these directions must be, to present a whole line to the head of a column, and, consequently, to a single extremity of the enemy's line. It is obvious, that if the heads of two hostile columns were to meet in similar directions, and began reciprocally to deploy, the consequence would produce a parallel order of battle, and a shock between two equal fronts, totally devoid of combinations.



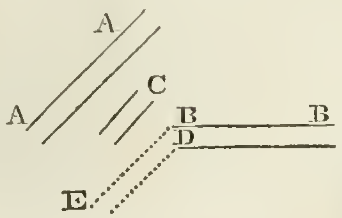
The army A, marching in two columns, is met by B, moving in a similar direction, (both perpendicularly) the first will immediately deploy, for fear of being attacked; and if the second do not instantly perform the same evolution, it will be defeated, as appears from the former figure. A, consequently, will form the line CC, B the line DD. But this reproduction of parallel fronts, of battalion opposed to battalion, unquestionably results from incapacity on the part of the commanders. The armies, thus drawn up, may destroy each other, without either gaining a decisive advantage; and whichever gains the victory, it will not be owing to the skill of the general.

An army, therefore, which is attacked on the march, will immediately endeavour to form an angle; or, in other words, the leading brigade of the columns will instantly deploy; and this deployment being either to the right or left of the columns, will constitute an angle or *potence*, as may be seen by the following figure.



A forms the advanced guard, or the head of the columns B; if it be attacked by the enemy, it will deploy to either hand, according to the direction of the attack, and occupy the dotted lines, which form an angle or *potence* with respect to the columns. This manœuvre is necessary to oppose the first efforts of the enemy C. But being secure from immediatee danger, does it follow that the army must imitate the movement of the leading brigade, and restore the parallel order? At first sight, the manœuvre appears natural, and it is most commonly the refuge of generals possessed of inferior talents; yet it is not, on that account, the most advisable. If it be proved that an attack upon a flank is most appropriate, why should not an army, of which the vanguard, or the brigade on the flank happens to be engaged with the enemy in front, endeavour in its turn to gain the flank of the assailant, and exchange defensive for offensive measures—a probable defeat for almost certain victory? Nothing can prevent a commander, when attacked in this manner, from ordering the brigade in action to defend its post inch by inch, and to retire gradually upon

A is the army attempting to turn the left flank of B, which forms the angle C; and the columns D are immediately prolonged in the direction E, by which means they turn the right flank of A. If it be objected that the enemy will not allow the manœuvre to be executed, it is answered, that to prevent it, he must either fall back or charge front. This latter movement will not be easy, in the presence of the angle, and under the momentary expectation of the columns wheeling into line.



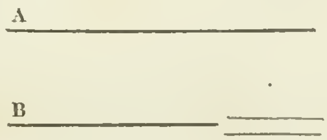
Hence are deduced the following maxims: 1. Between armies equally well versed in manœuvres, an angle may be used with success, against attacks directed upon a flank. 2. In order to make this movement without detriment, the angle or *potence* must be used only as a momentary resource; the army must follow it up by changing front, in the same direction, in order to be prepared to repulse the enemy with its whole line. 3. If the army attacked be sufficiently strong to act offensively, after forming an angle to check the enemy's front, and cover the menaced flank, it will, instead of changing front with the rest of the line, alter the direction, and march in column to a flank, so as to turn the extremity of the enemy's line in its turn. 4. An angle, with the extremity projecting to the front, does not cover the flank of the army so effectually, as when turned to the rear; for the enemy, in the former case, would readily turn the extremity of the angle, and throw it upon the line, merely by prolonging the direction of his leading divisions; while, in order to attain an angle to the rear, he would be obliged to make the circuitous march above explained.

another intermediate brigade, placed echelon-wise in its rear; and while these are engaged, he can change the direction of his columns, by facing the platoons to the right or left, and move by their flanks, until he has in his turn outflanked the enemy's line. (See Plate CCCLXXXIII. Fig. 42)

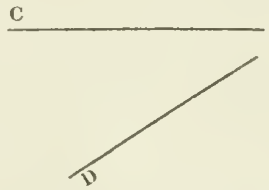
The platoons nearest the enemy will prolong their file movement considerably more than at a greater distance behind, the latter gradually taking less ground; so that the last forms the pivot, or has only to continue its original perpendicular march. From this disposition an oblique formation will result, which outflanks the enemy, and prevents his pressing forward upon the retreating brigade, because, in consequence of the new order of battle, he is in danger of being himself attacked to great disadvantage, if the enemy operates with vigour and unison. The manœuvre is both more simple and more rapid in the execution. It offers the singular advantage of placing the whole army upon an extremity of the enemy's line; while the change of front, if permitted to be performed, only restores the parallel order of battle. If this manœuvre, of an open column moving by files to a flank, appear complicated, others may be substituted in its stead, provided they are conducted on the principle of throwing the mass of the forces on the flank of the enemy.

To conclude the subject of flank attacks.

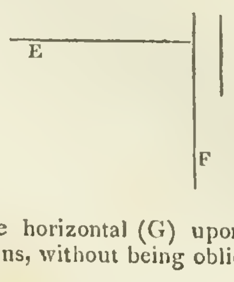
1. An army (B) may be placed out of the reach of the enemy's artillery, and consequently be ranged in a line parallel, and having one wing greatly reinforced without being oblique.



2. The line (D) may be greatly inclined, with its head towards the attack, and consequently be positively diagonal, without being reinforced.

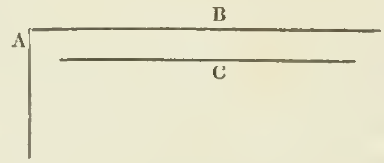


3. It may be perpendicular (F), with a wing reinforced upon the flank of the enemy, without being diagonal. Such was the disposition of the Prussians at Kunersdorf.



4. It may be horizontal (G) upon the heads of the enemy's columns, without being oblique.

There are several modifications of these different orders; as, for instance, of the third. The flank may be reinforced by an angle, or *potence*, perpendicular to the front, such as the Austrians adopted at Prague and Kollin.



The potence A, being perpendicular to the enemy's line C, reinforces the right wing of the line B, without being oblique. The same observation is applicable to an angle towards the rear.

It is probable, that the ancients, in general, preferred the parallel order, reinforced on a wing, to the oblique order. Among the moderns, Turenne employed the former at the battle of Ensheim, and the latter at Sinsheim; but these manœuvres being executed by one division only, without celerity, and in sight of the enemy, they had time to form a parallel line, and to reinforce the point attacked. The king of Prussia seems justly entitled to the honour of having first appreciated the advantages of such an order of battle as he displayed at Leuthen, because, until that moment, it had never been applied in a similar manner.

A parallel line, strongly reinforced on the most important point of attack, is unquestionably good, and coincides with the principle which we consider as the basis of all operations. It may therefore conduce to victory, but is nevertheless subjected to several inconveniences. The weak part of the line, being so near the enemy, may be drawn into action against the intentions of the commander, and be defeated, and thus frustrate the advantages which might have been gained on the opposite flank. The reinforced part of the line may defeat its opponent; but it cannot, on that account, take the enemy's line in flank and rear, without making an extensive movement, which would cause a separation from the other divisions, if they happened to be engaged. But if those divisions were not engaged, and therefore enabled to follow the movements of the reinforced part of the line, still, as this manœuvre would be circular, the enemy, by marching on the chord of the arch, would oppose to it a direct and more rapid counter-movement, which would place the offensive on his side, and bring his mass of forces first on the principal point of attack. But the disposition of the king of Prussia at Leuthen has quite a different effect; not only is the extremity of the attacked wing overpowered by a whole line, but the flank of that wing is turned, and its rear taken in reverse; and all this is performed without manœuvre, or prolonging the diagonal direction, by simply marching the whole front from its oblique position straight forward. The divisions not destined to form the first attack cannot, from their distance, be engaged with a superior enemy. They incur no such risk, and yet they are in a situation to render successively their support to the wing which is engaged.

Having thus attempted to explain the arrangements for battle, and the different modes of attack, we shall now proceed to consider what measures ought to be taken, after the termination of the battle, by the victorious, and by the defeated army. The army which has attacked and beaten its opponent should observe the following rules: 1. The light and other detached troops must instantly pursue the enemy, with the view of increasing his disorder; the whole army follows more leisurely, and in good order. 2. As soon as we can perceive the direction of the enemy's retreat, we must determine what is to be done to increase his loss; as, to cut off the retreat of a part of his force, or to place artillery in such a manner as to obstruct the retreat, and render it more confused and bloody, and prevent the enemy from rallying. 3. All the posts which have been placed for the purpose of covering the retreat, must be instantly and vigorously attacked, in order to avail ourselves of the panic among the troops. 4. We must pursue the enemy as long as day-light and the strength of the troops will permit, in order to push our victory to the utmost. For the maxim, that we ought to make a golden bridge for a flying enemy, is only to be put in practice when we can do no better. 5. As every battle is fought on account of some ulterior object, we should immediately proceed to the accomplishment of that object, as soon as we have made the necessary arrangements for the care of the wounded, &c. For every thing ought to be previously in readiness for the maintenance of the troops in their farther advance; and we must be prepared to take advantage of all the errors which the enemy may commit in his retreat.

If the victory has been gained by the army acting on the defensive, the same rules, upon the whole, are to be observed, but with more caution. For the same reasons which forced it to select a position, and there await the attack of the enemy, generally prevent it from pursuing him, and following up the victory farther. They must beware, indeed, of leaving their position too soon, and pursuing too keenly, because the enemy might otherwise turn round and attack the troops which had given up their advantages, beat and pursue them, and enter the position along with them.

If the attacking party have been beaten, the following rules are to be observed: 1. So long as there is any chance of victory, the repulsed troops must be formed again, and led on anew to the attack; or their place supplied by fresh troops; and the moment must be accurately determined, beyond which the retreat cannot be delayed without danger. 2. As soon as this moment arrives, the dispositions previously determined upon must be made. These consist in occupying with troops and artillery all tenable places, such as villages, houses, woods, heights, &c. lying at the distance of a short gun-shot from the roads along which the army is to pass, in order that the troops may securely retire under their fire. These places must be so much the stronger, if the retreating troops have a defile to pass. And, if possible, the retreat of the troops which have been thrown into them must not be allowed to be cut off, after they have accomplished their object. 3. When these dispositions have been made, the cannon are to be marched off the field of battle, in order to save our artillery. But should there be decisive batteries, which cover the retreat; we should rather sacrifice them than expose ourselves to the loss of a great number of troops: but we should also consider how the enemy can use them when he has got them. For if he cannot immediately turn them against the retreating troops, it is the less necessary to hesitate to sacrifice a few pieces of cannon to the safety of the army. 4. The troops follow the artillery; and in broken ground the cavalry march off first; on plain ground, the battalions which have been engaged in fighting fall back and march off, and the cavalry, in the mean time, take up a position, from which they can fall upon the flank of the pursuing enemy. When the infantry have thus marched off, under cover of the cavalry, the latter also retire in the best possible order. 5. A rear guard, as in every march, must be formed of those troops which have suffered least; but much stronger than upon ordinary occasions; and they must proceed with much more caution. The infantry of the rear guard occupies all that can cover the retreat; and calls in all its posts as it proceeds. The cavalry always marches in such a manner, that it can easily form in order of battle; it retires, therefore, *en echequier*, or in such other order as the nature of the ground will permit; so as to combine rapidity with order. When an obstacle occurs in a retreat, the rear guard forms in order of battle, and takes up the best position for covering the army, by which it must be supported, should it be too violently attacked.

Nearly the same rules must be observed by an army which has been attacked and beaten; only that it must commence by again forming in line, before proceeding in the retreat, at least if it is to be conducted with order. For the line of an army acting on the defensive, and beaten, is always broken; although this does not hold in the case of an army acting on the offensive. In such a retrograde movement, the points where the army is to form, and upon which it is to lean its flanks, must have been previously determined. If from this position it be possible to deprive the enemy of his advantage by a general attack, a spirited commander will not hesitate to attempt it. Otherwise the enemy must be kept in check, in the new position, until all our dispositions are made for the retreat.

Both parties, after the loss of a battle, must immediately endeavour to take up and maintain a strong position, to repair the loss they have suffered, and then proc·d again to the execution of their design. The farther we retreat, we not only lose a greater tract of country, but the army becomes more discouraged, a circumstance which is always of much greater consequence than the loss of a battle.

General Lloyd, the celebrated commentator on the military occurrences of the seven years war, has laid it down as a rule, that an army retreating ought to be divided into as many strong corps as the nature of the country will admit of; because, in this case, the enemy can do you no very essential damage. If he separates his army likewise into many corps, none of them will be strong enough to undertake any thing of consequence; and if they keep too close, they may receive some considerable check. Another advantage arising from this method of retiring is, that the enemy cannot intercept any of your corps; because he can neither push between them, nor go so far about as to come before them, without exposing his own troops to be hemmed in between your different corps. If he follows you with his whole army, one division only can be in danger; which may be easily avoided by forming a strong rear-guard, who will get time for the remainder to march off in safety; and the more so, as a small corps marches much more lightly than an army. Care must be taken not to engage the whole corps; because, if the enemy is near, and acts with vigour, it will be entirely lost.

These ideas of Lloyd, which are contrary to the principles upon which most of his own maxims are established, have been wrought up into a system by Bulow, under the title of *eccentric retreats*, in opposition to *concentric movements*. A contrary system, however, is with greater propriety, we think, maintained by Jomini. We have already observed, that an army inferior in numbers to its antagonist ought always to endeavour to act in a body; because it is only by so doing that it can hope to obtain any advantage over the enemy. It cannot be disputed, that an army compelled to retreat is already sufficiently weak, without being besides divided. All the divisions, indeed, cannot be ruined when thus separated; but one or two will certainly meet with such a fate; and the most disastrous concentric retreat cannot produce any thing more calamitous. When we shall have compared the system of Lloyd and Bulow with events, and, in particular, with the result of the concentric retreat of the Archduke Charles of Austria, in 1796, we have no doubt but the propriety of drawing opposite conclusions to their's will be universally admitted. Lloyd, indeed, is already in contradiction with himself; for he allows that the dividing of the pursuing forces exposes them to defeat. How then can he advise the pursued to commit the same fault?

Sect. IX. *Of Cantonments and Winter Quarters.*

When the weather becomes so bad that the body cannot withstand it, the troops ought not to be exposed to it in the open field, but should be placed in quarters, where they may find shelter and protection. And, as active service in the field is extremely fatiguing, they ought to be placed at the end of a campaign in extensive quarters, where they may find subsistence and comfort, in order to refresh themselves. Hence arises a twofold mode of placing troops in quarters: 1. When the only object is to shelter the troops from the weather. 2. When they are distributed in extensive quarters, with a view to their subsistence and comfort. The former are called cantonments, the latter winter quarters.

As the army is incapable of withstanding the enemy in its quarters, the general principle, whence all the rules for the distribution of the troops in quarters is derived, is this: That in case of an attack from the enemy, we should always have it in our power to draw the army together in order of battle, upon an advantageous field, before the enemy can attack us.

Rain and nightly cold force us first to place the cavalry, on account of the horses, in the villages. Their quarters must be so disposed, that the camp of the infantry completely covers them, and the enemy cannot fall upon them from behind; and that either the distance of the out-posts, or the obstacles which the ground or the resistance of the infantry presents to the enemy, should leave time for the cavalry to unite and assist in beating off the attack. The same principles must be followed, when we are compelled to place the infantry in quarters.

We place our troops in winter quarters when we perceive, 1. That we ourselves can no longer undertake any enterprise of importance; and 2. When the enemy cannot attack our troops in their quarters. The first may occur, when the capture of a fortress would be necessary to enabled us to advance farther into the enemy's country, but the badness of the weather prevents us from undertaking the siege; when no post or pass is to be carried, which would be of use in opening the following campaign, or in securing our quarters; when there are no provisions any where to be consumed, which the enemy might want; or when no blow is to be executed against his magazines, &c. The second case occurs, when our fortresses are sufficiently provided with all necessaries; or when our quarters are so disposed, that the enemy either cannot penetrate into them at all, or only with the greatest danger, or when an attack would be of no use to him, but only ruin his own army. Excepting these cases, we must wait until the enemy places his troops in quarters, and then the campaign sometimes continues during a great part of the winter.

For the security of the quarters, of whatever kind they may be, it is required, 1. In general; that the whole of the enemy's army may not be able to make an attack upon our whole quarters, without finding them prepared. 2. In particular; that the enemy's troops may not be able to attack and carry one or other of the quarters.

The general security of the quarters depends, 1. On the nature of the country between the enemy and the quarters; as when they are covered by a river, a chain of mountains, or other objects forming defiles. In such cases, we have the additional advantage, that the natural obstacles are generally still more effectual at that season of the year. 2. On the nature of the ground in the quarters, and on their situation. There must be no defiles within the quarters which can interrupt their connection; and in case the quarters should be attacked at one or more points, the troops must have the means of retiring and uniting with the army, without the risk of being cut off; which might happen, if any one part were to form a projection, not covered by tenable posts or otherwise. 3. On the measures taken to protect them. All the approaches through the defile which covers the quarters, must be destroyed or fortified. The quarters must not be too far distant from each other; and a common rendezvous must be chosen, where they can all arrive with rapidity and safety, and find an advantageous position. The proper distribution depends upon the time in which the enemy can approximate his quarters, and make an attack upon ours; for otherwise, the more they are extended, the more comfortable will it be for the troops. The rapid junction of the army on approximating the quarters, should be facilitated by improving the roads and communications, removing the obstacles, establishing signal posts, &c. The light troops in front, should constantly send out small patroles, in order to obtain notice of all that is going on among the enemy; and for the same purpose, the army should be provided with good spies.

The security of the individual quarters depends, 1. On posts being well placed on all the roads by which the enemy might approach. 2. On the judicious use of patroles towards all points from whence the enemy might approach. 3. On the good disposition of the quarters for defence against every surprise and open attack. 4. On the discipline of the troops under each commander, and the regular performance of their duty. The troops, in quarters, however, should never be unnecessarily subjected to fatigue.

There is scarcely any operation in war more delicate and difficult, than the distribution of the troops into winter quarters; it requires a perfect knowledge of the country, and must be regulated by a prodigious variety of circumstances. 1. Regard must be had to the enemy's disposition; 2. to his general plan of war, and to the particular object he has in view for the ensuing campaign; and, 3. to the object you have yourself in view for the following campaign. If you propose to be on the defensive, the distribution of the troops must be made in such a manner, as to be able to unite in different points, without leaving even a possibility of their being intercepted in their march to the place of rendezvous; that these points be chosen as near the frontiers as possible, in order to cover the country; and that they be so well chosen, that the enemy can neither force you in them, nor leave you behind. If you propose being on the offensive, the troops must be so distributed, that, in one march or two, they may form several great corps on the enemy's frontiers, and pass them, so as to separate his quarters, and run no risk of being intercepted before they join, and form one body in the enemy's country. Above all things, care must be taken that they are not exposed to be inquieted during the winter, which the troops must enjoy in peace and safety, as well to refresh themselves, as to form the recruits, &c.

The following is the manner in which the army is generally distributed in quarters: 1. The troops of the right wing are placed in the villages lying to the right, those of the left wing in the villages to the left, in the same order in which they encamp. 2. The troops of the first line are placed in the more advanced villages, those of the second in the villages lying behind, in proportion to the extent of ground occupied by the army. 3. The whole of the infantry, however, is placed in the first and second line, and the cavalry in the third; for the latter has no security in villages. 4. The light troops are placed in front and on the flanks of the army, but, if possible, so as to be in some degree covered against the enterprises of the enemy, in order that they may not be obliged to provide for their security by hard service, otherwise the chief object of the winter quarters, viz. the refreshment of the troops, of which they have so much need, would be rendered nugatory. They are, therefore, placed in front, but on this side of the defile which covers the army; from whence they may watch over the security of the army by constant patroles, consisting of only a small number of troops. This is called the *cordon* of the quarters. 5. The light infantry, or detachments of the army, occupy the entrenchments on the bridges, or other passes: but there, likewise, all proper measures must be taken for the maintenance and comfort of the troops.

The petty war which the troops carry on against each other along the *cordon*, is of little consequence; for although they endeavour to attack every individual quarter, as soon as they find that the commander has neglected any of the measures of security; yet such an attack, even if successful, would have little influence, if the quarters were otherwise well disposed; and several attacks could only succeed against useless troops. The following, therefore, are the only things worthy of attention. 1. Attacks upon a principal post in the quarters; and, 2. A general attack on the whole quarters. Both enterprises may have a strong influence on the attacking army, and therefore should not be wantonly undertaken. In the first case, we must inquire, 1. Whether the object be worth the trouble. For example: Can we compel the enemy to raise his whole quarters, and transfer them? or can we maintain the place, and does it open to us the way to further enterprises? or, finally, are we so certain of success, that the hope of making prisoners is sufficient to induce us to undertake it? 2. Is it probable that we shall succeed? This probability must result from the bad disposition of the quarters, which enables us to approach them undiscovered; from the neglect of proper measures on the part of the commander to prevent a surprise. The situation and circumstances must be such as to afford us the means of a safe retreat. When the attack has been determined upon, the same rules are to be observed as in the case of all other detachments; and we may also observe, that it is almost necessary to success, that we should get into the rear of the quarters, either with the whole or a part of the detachment; partly because the attack from thence will be more unexpected by the enemy, and therefore have a greater chance of success; and partly, because we may thus attack him on more than one side, raise his whole quarters, and cut off his retreat.

A general attack upon the whole quarters of an army is, in all points, similar to an attack on an enemy's country, in order to surprise it. The following reasons may induce us to make such an attack. 1. A bad disposition of the enemy's quarters. 2. Measures ill taken among his troops for the performance of their duty. 3. A well founded hope that we shall be able to drive the enemy out of the country in his possession, either immediately, or upon the opening of the campaign. This may be the case, if the enemy have neglected some tenable places, and left it in our power to make ourselves masters of them; or if he has enclosed some of our fortresses within his quarters, which the lateness of the season prevented him from taking, and which will serve us as *points d'appui* in our advance; or, lastly, if his whole quarters consist of an open country, from which we can drive him behind defiles, which he will afterwards in vain endeavour to pass. 4. The success of such an enterprise will be greatly promoted by a skilful disposition of our own quarters, by good and secret arrangements within them, by which we shall be enabled to draw them rapidly together, and move into those of the enemy.

Sect. X. *Fundamental Principle in Military Combinations.*

In this concluding section, we propose to lay before our readers a summary of the essential principles of military combinations, extracted from Jomini's excellent *Treatise on Military Operations.*

The fundamental principle which ought to regulate all military combinations, consists *in operating with the great mass of our forces, a combined effort on the decisive point.* We may easily conceive, that a skilful general may, with 60,000 men, beat an army of 100,000, if he can but contrive to bring 50,000 men into action upon one part of the enemy's line. The numercial superiority of the troops not engaged, in such a case, is more hurtful than advantageous, because it only tends to increase the disorder, as was proved at the battle of Leuthen. The rules for applying the principle above laid down are by no means numerous, and we shall endeavour to point them out.

I. The first rule is, to originate, or take the lead in all movements. The general who succeeds in placing this advantage on his side, has it in his power to employ his forces wherever he thinks it most advisable; on the other hand, he who waits for the enemy cannot be master of any combination, because his movements are subordinate to those of his adversary, and because he has no longer the power of arresting them when they are in full execution. The general who takes the lead, knows what he is going to do; he conceals his march, surprises and overwhelms an extremity, a weak part. He who waits, is beaten on one of those parts, even before he has been informed of the attack.

II. The second rule is to direct our movements on that weak part which can be most advantageously attacked. The choice of this part depends upon the enemy's position. The most important point is always that of which the occupation would procure the most favourable chances, and the greatest results. Such, for example, would be the positions which should enable us to gain the communications of the enemy, with the basis of his operations, and to throw him back upon an insurmountable obstacle, such as a lake, a large river without a bridge, or a great neutral power.

In double and scattered lines of operations, our attacks will be most appropriately directed on the central points. In carrying the mass of our forces to that quarter, we overwhelm the isolated divisions which guard them; the scattered corps to the right and left can no longer operate in concert, and are forced to make those ruinous eccentric retreats, from which the armies of Wurmser, of Mack, and of the Duke of Brunswick experienced such terrible effects. In simple lines of operations, and in contiguous lines of battle, the weak points, on the contrary, are the extremities of the line. Indeed, the centre is more within reach of being sustained, at the same moment, by the right and the left; while an extremity attacked would be overwhelmed before the arrival of sufficient means from the other wings to sustain it, for these means would be much more remote, and could only be employed one after the other.

A deep column, attacked on its head, is in the same situation with a line attacked on its extremity; the one and the other will be engaged and beaten successively, as has been demonstrated by the defeats of Rossbach and Auerstadt. At the same time, it is easier to make new dispositions with a column in depth, than with a line of battle attacked on an extremity.

In executing a general strategical movement on the extremity of an enemy's line of operations, we not only bring a mass into action against a weak part, but from this extremity we may easily gain the rear and the communications, either with the basis, or with the secondary lines. Thus, Bonaparte, when, in 1805, he gained Donauwerth, and the line of the Lech, had established the mass of his force on the communications of Mack with Vienna, which was the basis of this general in respect to Bohemia, and rendered it impossible for him to unite with the Russian army, which was his most important secondary line. The same operation took place in 1806, on the extreme left of the Prussians by Saalfeld and Gera. It was repeated in 1812, by the Russian army in its movements on Kaluga and Krasnoi; and again in 1813, by Bohemia on Dresden and Leipsic against the right of Bonaparte.

III. The result of the preceding truths proves, that if we ought to prefer an attack on the extremity of a line, we should also beware of attacking the two extremities at once, unless indeed our forces are greatly superior. An army of 60.000 men, which forms two corps of about 30,000 each, for the purpose of attacking the two extremities of an army equal in numbers, deprives itself of the means of striking a decisive blow, by multiplying uselessly the number of the means of resistance which the enemy can oppose to its two detachments. Such an extended and disunited movement may even expose it to the enemy, who may collect the mass of his force upon one point, and annihilate his adversary by the terrible effect of his superiority. Attacks multiplied in a greater number of columns are still more dangerous, and more contrary to the great principles of the art; especially when these columns cannot be brought into action at the same instant, and at the same point. As a consequence of this maxim, it is proper, on the contrary, to make an attack upon both extremities, when we have masses greatly superior to those of the enemy; we may thus bring more troops into action upon each of his wings, while, by keeping very superior forces accumulated upon a single point, our adversary might perhaps be able to deploy and bring into action an equal number. We must take care, in this case, to throw the great body of our force upon that wing, where the attack promises the most decisive success.

IV. In order to operate a combined effort with a great mass upon a single point, it is necessary, in strategical movements, to keep our forces collected upon a space nearly square, in order that they may be more disposable.* Large fronts are as contrary to good principles, as scattered lines, large detachments, and isolated divisions.

V. One of the most efficacious means of applying the general principle above laid down is, to make the enemy commit faults contrary to that principle. We may threaten him with some small corps of light troops on several important points of his communications; and it is probable, that not knowing the force of these corps, he may oppose them with numerous divisions, and scatter his forces. These light troops, at the same time, serve the essential purpose of collecting intelligence for the army.

VI. It is of great importance, when we originate any decisive movement, to neglect no means of informing ourselves respecting the enemy's positions, and the movements which he may make. The system of *espionnage* is very useful, and no pains should be spared to bring it to perfection; but it is still more essential to procure accurate intelligence by means of partisans. A general ought to scatter small parties in all directions, and to multiply their number with as much care as he would avoid such a system in great operations. For this purpose, some divisions of light cavalry are organized, which are not admitted into the line of battle. To operate without these precautions, is to march in the dark,

* By this is not meant a full square column, but that the battalions be disposed in such a manner as to be able to arrive, with the same promptitude, from all points, towards that which may be attacked.

and to expose ourselves to all the disastrous chances which a secret movement of the enemy might produce. We have already observed, that these partisans would contribute, at the same time, to alarm the enemy upon some important points, and thus induce him to divide his forces. These means are too much neglected; the system of *espionnage* is not sufficiently organized before hand; and the officers of the light troops have not always the experience requisite to enable them to conduct their detachments.*

VII. In conducting the operations of war, it is not enough to carry our masses skilfully on the most important points; we must also know how to bring them into action. When we have established ourselves upon these points, if we remain inactive, we have lost sight of the principle entirely. The enemy may make countermanœuvres, and to deprive him of the means of doing so, we must immediately engage him, as soon as we have gained his communications or one of his extremities. It is at that moment especially that we ought to combine a simultaneous effort of our forces. Battles are not decided by the masses present, but by the masses engaged. The former decide the preparatory strategical movements; the latter determine the success of an action. In order to obtain this result, a skilful general ought to seize the moment when it is necessary to carry the decisive position of the field of battle, and he should combine the attack in such a manner as to engage all his forces at the same time, with the sole exception of the troops destined to form the reserve. If an effort founded upon such principles shall not be successful, we cannot hope to obtain the victory from any combination, and we shall have no other resource but that of making another attempt with this reserve, in concert with the troops already engaged.

VIII. All the combinations of a battle may be reduced to three systems.

The first, which is purely defensive, consists in awaiting the enemy's attack in a strong position, without any other object than that of maintaining ourselves in it. Such were the dispositions of Daun at Torgau, and of Marsin at the lines of Turin. These two events serve to demonstrate how vicious all such dispositions are.

The second system, on the contrary, is entirely offensive. It consists in attacking the enemy wherever we can find him; as Frederick did at Leuthen and Torgau, Bonaparte at Jena and Ratisbon, and the allies at Leipsic.

The third system is in some degree a middle term between the two others. It consists in choosing a field of battle, determined according to its adaptation to strategical purposes, and the nature of the ground, in order to await the enemy's attack, and to seize, during the battle itself, the proper moment for assuming an offensive attitude, and to fall upon our adversary with every chance of success. The combinations of Bonaparte at Rivoli and Austerlitz, those of Wellington at Waterloo, and in the greater part of his defensive battles in Spain, may be classed under this head.

It would be difficult to lay down precise rules for the employment of these two last systems, which are the only ones that can be successfully adopted. We must always have a view to the moral disposition of the troops of each party, to the peculiarities of the national character, and to the nature of the ground; and these circumstances alone may direct the genius of a commander. We shall confine our remarks, therefore, to the three following general observations. 1. With experienced troops, and on open ground, the absolute offensive, the *initiative* of attack, is always the best system. 2. In ground of difficult access, whether by nature or from other causes, and with well-disciplined troops, it is perhaps better to allow the enemy to arrive in a position which we have previously reconnoitred, in order to take the lead of him when his troops shall have been exhausted by their first efforts.

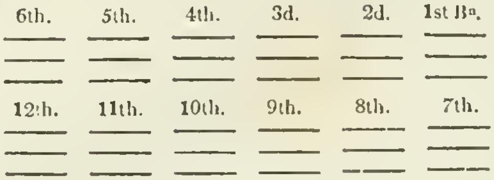
3. Nevertheless, the strategical situation of both parties may sometimes require, that we should make a lively attack upon the positions of our adversary, without regard to local circumstances; for example, if it were of consequence to prevent the junction of two hostile armies,—to fall upon a detached part of an army, or upon a corps isolated on the other side of a river, &c.

IX. The orders of battle, or the most proper dispositions for conducting troops into action, ought to have for their object to give them, at once, activity and solidity; for they ought neither to be too extended nor too crowded. A spare order is weak; troops crowded into too dense an order are in a great degree paralised, because it is only the head that can be brought into action, they are easily thrown into disorder; and artillery makes dreadful ravages amongst them. It appears to us, that in order to fulfil both conditions, troops remaining on the defensive may be partly deployed, and partly in columns by battalions, like the Russian army at the battle of Eylau; but the corps drawn up for the attack of a decisive point ought to be composed of two lines of 'battalions each, instead of deploying, being

* The immense advantages which the Russian armies derived from the services of the Cossacks, afford sufficient proof of the truth of the above observations. These light troops, insignificant in the shock of a great battle, are terrible in a pursuit. They are the most formidable enemy for all the combinations of a general, because he can never be certain of the safe arrival and execution of his orders, and his convoys are always in danger, and his operations uncertain. So long as an army had only a few regiments of these partisans, the whole of their value was not known; but when their number was increased to 15 or 20 thousand, an idea could be formed of their importance, especially in a country, the population of which was not unfavourable to them.

For one convoy which they intercept, we must cause them all to be escorted; and the escort must be numerous in order to insure safety. We are never certain of performing a march unmolested, because we know not where the enemy are. These incidental duties require an immense force; and the regular cavalry are soon rendered totally unfit for service, in consequence of the fatigues to which they are exposed. The Turkish militia produces nearly the same effect on the Russians, as the Cossacks on the other European armies; the convoys are not more secure in Bulgaria, than they were in Spain and in Poland. In other armies, perhaps, some thousands of volunteer hussars or lancers, levied at the commencement of a war, and directed by enterprising leaders, on well chosen strategical points, would accomplish nearly the same object; but we should always have to look upon them as detached and independent troops, for if they were to receive their orders from head-quarters, they would no longer be partisans. It is true, they would not possess precisely the same qualities; and, in the long run, they could not contend with good Cossacks; but, to an unavoidable evil, we must apply all the remedies in our power.

formed in columns by divisions, in the following manner:*



This order presents infinitely more solidity than a deployed line, whose fluctuations prevent the impulse necessary for such an attack, and put it out of the power of the officers to carry on their troops. At the same time, with a view to facilitate the march, to avoid the too great depth of the mass, and, on the other hand, to increase the front, without at all injuring its consistency, it would perhaps be more proper to place the infantry in two ranks. The battalions would thus be rendered more moveable; for the march of the second rank, pressed between the first and third, is always fatiguing, fluctuating, and, consequently, less firm and lively. Besides, they will have all the requisite force, as the three divisions will present six ranks in depth, which is more than sufficient. Finally; the front enlarged to the extent of a third will present more fire, if it should come to firing; and at the same time that it appeared more formidable to the enemy, by shewing him more men, it would be less exposed to the fire of artillery.

X. In ground of difficult access, such as vineyards, enclosures, gardens, and walled heights, the defensive order of battle ought to be composed of battalions deployed, and covered by numerous platoons of sharpshooters. But the attacking troop, as well as the reserve, could not be better drawn up than in columns of attack by the centre, as in the preceding observation; for the reserve must be ready to fall upon the enemy at the decisive moment, and attack with force and vivacity, that is to say, in columns.† Nevertheless, this reserve may be left partly deployed until the moment of charging, in order that the extent of its front may appear the more formidable to the enemy.

XI. In a defensive battle on open ground, we may substitute, for these columns, squares of battalions, by doubling the lines of the two ranks, so as to form them on a depth of four. Each battalion would thus present a sufficient mass, as it would have only a front of from forty to fifty files.

This order seems advantageous, when we have to fear grand attacks of cavalry; for it gives, at once, security to the infantry, and shelter to the cannoneers and to the train of artillery. At the same time, as it affords less activity and less impulse than that of columns of attack, the latter appears preferable, because, with troops well exercised, it is easy to form the square in each battalion, by a simple conversion to the right and left of the centre division. The general's plan of battle, the nature of the ground, the description of troops, must determine the preference to be given to these two orders.

XII. If the art of war consists in concerting a superior effort by a mass against weak parts, it is incontrovertibly necessary to push a beaten army vigorously.

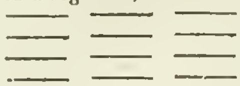
The force of an army consists in its organization, in the whole resulting from the connection of all the parts with the central point which sets them in motion. After a defeat, this whole no longer exists; the harmony between the head which combines, and the body which ought to execute, is destroyed; their relations are suspended, and almost always dissolved. The whole army is then a weak part; to attack it is to march to a certain victory. Abundant proofs of these truths will be found in the march on Roveredo, and the defiles of the Brenta, to complete the ruin of Wurmser; in the march from Ulm to Vienna,—from Jena to Wittemberg, Custrin, and Stettin,—from Waterloo to Paris. This maxim is often neglected by generals of inferior talents. It would appear that the whole effort of their genius, and the scope of their ambition, were limited to gaining the field of battle. Such a victory is a mere displacing of troops, without any real utility.

XIII. In order to render the superior shock of a mass decisive, the general must spare no pains in forming the moral disposition of his army. To what purpose should we place 50,000 men in order of battle against 20,000, if they wanted that impulse which is necessary to carry them forward, and to overwhelm the enemy? We do not allude merely to the soldier, but still more particularly to those whose business it is to lead. All troops are brave, when the chiefs shew the example of a noble emulation and perfect devotion. The soldier must not remain exposed to fire from the mere dread of a rigorous discipline; he must rush into it by the desire of not being outdone by his officers in honour and bravery, and, above all, by the confidence with which he has been inspired in the wisdom of his leaders and the courage of his companions in arms.

In all his calculations, a general must be able to reckon upon the zeal of his lieutenants; he must be assured that a vigorous attack will take place wherever

* A division consists of two platoons; thus the battalion being composed of six companies, or six platoons, will have three divisions, which, in fact, will cause it to form on three lines.

This remark, however, refers to the French constitution of battalions and regiments; but it is obvious that the idea could be easily modified so as to apply to our own, by forming our battalions into columns of four grand divisions (supposing the flank companies absent) closed to half distances, and a whole brigade, as a regiment, is formed in the above order. Thus:



Or if the ground would not admit of the depth of these columns, they might be made only of two grand divisions in rear of each other.

† It has been said that the Duke of Wellington always fought with his troops deployed. This may be true in so far as relates to the troops who were to remain on the defensive, but for his offensive and manœuvring wings, we think he must have formed columns. Otherwise, those must have been greatly to blame, who allowed themselves to be beaten, with equal forces, by such a system; for a General could desire nothing better than to have an adversary who should always employ it.

It must not be thought, however, that in presenting an order of battle as the most advantageous, we mean to assert that a victory would be impossible, unless it were strictly followed. Local circumstances, general causes, superior numbers, the moral disposition of the troops and of the commanders, are considerations which must also be taken into the account; and in reasoning from a general maxim, we must assume that all these chances are equal.

he orders it to be made. In order to attain this end, he must render himself at once beloved, esteemed, and feared; and he ought to have the choice and the fate of his lieutenants in his own hands. If they have arrived at this rank by the right of seniority alone, we may conclude beforehand that they will scarcely ever possess the qualities necessary to enable them to fulfil their important functions. This circumstance alone may cause the failure of the best planned enterprises.

It will be seen from this rapid sketch, that the science of war is composed of three general combinations, each of which presents but a small number of subdivisions. The only perfect operations will be those in which these three combinations shall be properly executed.

The first of these combinations is the art of embracing lines of operations in the most advantageous manner, or what it commonly called *the plan of a campaign*. We do not well understand, indeed, what is meant by this term; for it is impossible to lay down a general plan for a whole campaign, the first movement of which may overthrow the whole scaffolding, and in which it may be impossible to foresee beyond the second movement.

The second branch is the art of conducting our masses in the most rapid manner possible to the decisive point of the primitive or accidental line of operations. This is what we commonly understand by strategy; which is nothing else than the means of executing this second combination.

The third branch is the art of combining the simultaneous employment of our greatest mass on the most important point of a field of battle; or the art of battles, which some authors have called the order of battle, while others have treated it under the name of Tactics.

EXPLANATION OF THE PLATES.

PLATE CCCLXXXI.

Fig. 1. Represents a battalion forming Front to the Rear by a Counter-march of the whole.
Fig. 2. Forming Front to the Rear by a Counter-march of Platoons.
Fig. 3. A Battalion forming Front to the Rear by wheeling about.
Fig. 4. One half faced to the Right-about, previous to wheeling.
Fig. 5. Forming Front to the Flank, by facing to the Right or Left, and marching up.
Fig. 6. The same, by Deploying.
Fig. 7. The same, by a single quarter Wheel.
Fig. 8. The same, by an eighth Wheel, by Companies, the Flank Company only making an entire Wheel.
Fig. 9. The same, by wheeling round the Centre.
Fig. 10 & 11. Forming from Line into Columns.
Fig. 12. Forming, or Deploying, from the Centre.
Figs. 13, 14. A Battalion in Column marching off to the Right and to the Left.
Fig. 15. Marching forwards in Columns.
Fig. 16. Marching to the Rear in Columns.

PLATE CCCLXXXII.

Fig. 17. A Counter-march by Columns.
Fig. 18. Columns breaking off on a narrow road, or defile, without halting.
Fig. 19. The Oblique March by Columns.
Fig. 20. Close Columns forming Front.
Fig. 21 Deploying from the Centre.
Fig. 22. The Movements reversed, the last Division forming the Head.
Fig. 23. Forming Front to the Rear by counter-marching and deploying.
Figs. 24, 25. Close Columns forming Front to the Flank.
Figs. 26, 27, 28. Columns formed by wheeling placed in order of Battle to the Front.

PLATE CCCLXXXIII.

Figs. 29, 30, 31, 32, 33, 34, 35, 36. Columns forming Front to the Rear.
Fig. 37. Columns deploying close to a Defile.
Fig. 38. Passing Obstacles, and forming Line.
Fig. 39. The Oblique Order in Line.
Fig. 40. The Oblique Order by *Echelons*
Fig. 41. An Army, in four Columns of March, forming Line.
Fig. 42. An Army attacked on its Flank, changing the direction of its Columns, and gaining the Flank of the Enemy.

PLATE CCCLXXXIV.

Order of Battle at Kollin.

PLATE CCCLXXXV.

Order of Battle at Rossbach.

PLATE CCCLXXXVI.

Order of Battle at Leuthen.

PLATE CCCLXXXVII.

Lines of March, 1. At Kollin ; 2. At Rossbach ; 3. At Leuthen.

MILITIA. See Britain, and England.

MILK. See Dairy.

MILL. See Barley Mill, Drug Mill, and Hydrodynamics.

MILLAR, John, Professor of law in the university of Glasgow, was born on the 22d of June, 1735, in the parish of Shotts, of which his father, Mr. James Millar, was then minister. His mother was the daughter of Mr. Hamilton of Westburn, a gentleman of considerable estate in Lanarkshire. He received the rudiments of his education at the grammar-school of Hamilton; and, in 1746, he repaired to the college of Glasgow, where he formed an acquaintance with the celebrated Mr. Watt, afterwards of Birmingham, Dr. Adam Smith, and other eminent characters.

Mr. Millar was originally destined for the church, but he afterwards resolved to devote himself to the profession of the law. About the time he had finished his studies at Glasgow, he received an invitation from Lord Kames to reside in his family, and superintend the education of his son. In this situation he continued about two years; during which period he had an opportunity of cultivating the acquaintance of Mr. Hume, the historian, and was entrusted with the education of his nephew, the present very eminent professor of Scotch law in the university of Edinburgh.

In 1760, Mr. Millar was called to the bar; and he was soon looked upon as a very rising young lawyer. Circumstances, however, soon afterwards induced him to abandon his prospects at the bar, and to solicit the vacant appointment of professor of law in the university of Glasgow, which he obtained in 1761. About the same time, he married Miss Craig, a lady nearly of his own age, to whom he had formed a strong attachment. In the discharge of his duties as a professor, Mr. Millar delivered several courses of lectures in the university on the Roman law,—on the general principles of jurisprudence,—on government,—on Scotch law; to which, a few years before his death, he added a course of lectures on the law of England. He never wrote his lectures, but was accustomed to speak from notes, containing merely his arrangement, his chief topics, and some of his principal facts and illustrations. For the transitions from one part of his subject to another, the occasional allusions, the minor embellishments, and the whole of the expression, he trusted to that extemporaneous eloquence, which seldom fails a speaker who is well informed and deeply interested in his subject. The ability he displayed as a public teacher soon attracted a numerous concourse of students to his lectures, and contributed to raise the character of the university, of which he was a member, to a high degree of celebrity.

On his coming to Glasgow, Professor Millar became a member of the *Literary Society*, consisting chiefly of professors, together with some clergymen of the city and neighbourhood, which had been instituted in 1752; and he immediately proved himself a very active and zealous promoter of its views. He continued to attend its meetings with a punctuality of which there are few examples, during a period of forty years; reading discourses in his turn, and taking a lively interest in all its discussions. Having employed himself, for some years, principally in collecting materials for his various lectures, he afterwards found, that, notwithstanding his public duties, it was in his power to do justice to such young men as might be entrusted to his care as domestic pupils; and to their instruction he accordingly dedicated a very considerable part of his time.

Such were his regular and stated occupations during the winter. For some years after he was settled at Glasgow, he was in the habit of spending a great part of the summer with his father at Hamilton; but as his family increased, this plan became more inconvenient; and his uncle, Mr. Millar of Milheugh, ever attentive to the comfort of his nephew, gave him the small farm of Whitemoss, near the village of Kilbride, about seven miles from Glasgow, where he amused himself with agricultural improvements.

In the year 1785, Mr. Millar lost both his uncle and his father, who died within a few days of each other, and in consequence, he succeeded to the property of Milheugh, where he had an opportunity of gratifying his taste for agricultural pursuits and rural embellishment. During his residence in the country, however, he also employed a great part of his leisure in perusing such books as his other avocations in winter prevented him from reading, and in preparing his own works for the press. In 1771, he published his treatise *On the Origin of the Distinction of Ranks*, which was very favourably received, both in this country and on the continent; and in 1787, he gave to the world his *Historical View of the English Government, from the Settlement of the Saxons in Britain to the Accession of the House of Stewart.* These two are the only works to which Mr. Millar prefixed his name; nor does it appear that he published any other tracts, except one or two anonymous pamphlets on political subjects, and a few articles in the *Analytical Review*.

Amidst his other avocations, Mr. Millar found time for some limited practice as a lawyer, giving opinions, as a counsel, previous to the commencement of law-suits, and acting occasionally as an arbiter. He was also in the habit, for many years, of acting as counsel for criminals at the circuit courts of justiciary, where he exhibited uncommon skill and acuteness in the examination of witnesses, and a powerful and manly eloquence in his addresses to the jury.

Mr. Millar paid two visits to London, one in 1774, and another in 1792; at which latter period he arrived in sufficient time to be present at several very important debates in both houses of parliament; and he also enjoyed the satisfaction of becoming acquainted with Mr. Fox, and the other leaders of opposition, to whose principles he was warmly attached. The chief part of his time, however, was spent in the society of his former pupils, Lord Lauderdale and Mr. Adam, now Lord Chief Commissioner of the Jury Court in Scotland, and in the family of his old and much esteemed friend, Dr. Moore, author of Zeluco and Edward.

Mr. Millar had been uniformly zealous in his attachment to the party of the Whigs; and the French Revolution, at its commencement, rivetted his attention, and in its early progress excited his fondest hopes. When a similar spirit seemed to be called into action in this country, by the force of example, Mr. Millar became a member of the association known by the name of the Society of the Friends of the People, and he took a warm interest in all the political discussions of the times. Of course, he was decidedly hostile to all the measures of Mr. Pitt's administration, and in particular to those connected with the contest between this country and revolutionary France, which, with many other individuals, he regarded as injurious to the cause of liberty.

In 1791, he lost his second daughter, who was carried off by consumption; and in 1795, his wife died, after a long and painful illness. In the spring of the last mentioned year, his son, who had passed advocate, and got into business at the bar, emigrated to America; but soon after his arrival, he was struck with a *coup-de-soleil*, of which he almost instantly expired. This succession of melancholy events in his family, could not fail to produce a deep impression on the sensible mind of Mr. Millar; but after the first shock, he seemed to have recovered his self-possession. About the end of the year 1799, he was himself seized with a very dangerous inflammatory complaint, from which, however, after a few weeks of severe indisposition, he appeared perfectly recovered. In the month of May, 1801, he was again taken ill, after having exposed himself for several hours to a hot sun; and his complaint soon assumed the appearance of the most dangerous pleurisy, which terminated his life on the 30th of that month, in the 66th year of his age.

In his person, Professor Millar was about the middle stature; of a strong, active, and athletic, rather than an elegant form; and his countenance was uncommonly animated and expressive. He was very temperate in his mode of living, and regular in his habits of exercise. His manner, upon first entering a room, was not altogether free from formality and constraint; but this was only of momentary continuance. He possessed a wide range of information; and his conversation, whether upon subjects of a lighter or a graver kind, was lively, animated, and improving. He was completely conversant with literature and the *belles lettres*, took great delight in the Classics, and was familiarly acquainted with English, French, and Italian poetry. He was fond of argument, and exhibited great skill and dexterity in debate. On political subjects he always argued with zeal; and, towards the latter end of his life, with a considerable degree of keenness. In his political professions he was sincere, consistent, and disinterested; and the open and decided expression of his sentiments excited no feeling of personal hostility, even in the breasts of those who differed most widely from him in their opinions.

The style of his writings is very different from what might have been expected by those who had felt the vivacity of his conversation, and the copious diction of his extemporary eloquence. His language, as has been well observed by one of his friends, is the expression, rather than the ornament of his thoughts. Clear, accurate, and precise, it never fails to convey his ideas with a distinctness which precludes all misapprehension; but it frequently conveys them in a manner neither the most striking, nor the most alluring to the reader. Simple correctness and accuracy seem to be the only qualities he aimed at, and attained; even when he rises from plain narration to warmth and energy, the force is almost always in the principal idea, seldom in the accessaries. It is owing to this cause, perhaps, that his works are less popular than they would otherwise have been, had the style of the author been a little more attractive.

See Mr. Craig's account of the life of Professor Millar, prefixed to the edition of his treatise *On the Origin of the Distinction of Ranks*, published in 1806. (z)

MILO, anciently Melos, an island of the Greek Archipelago, about 60 miles in circuit, of a round figure, and penetrated on the north by a spacious bay, where the largest squadron may lie in deep water. The mountain St. Helias, which is the highest part, rises to a considerable altitude above the level of the sea: and another mountain, Calamo, which is supposed to have been a volcano of great antiquity, still emits fetid sulphureous smoke from several spiracles on its summit. Rocks of lava, sulphureous hot springs, mephitic exhalations, and many other circumstances, denote the frequent influence of subterraneous fires. The springs are impregnated with various substances; and, since the days of Hippocrates, they have been thought efficacious in the cure of diseases. Public baths are formed of one in a grotto where the vapour rises as in a natural stove. Porphyry, iron, gypsum, and the finest alum, obtained from a subterraneous gallery, where the thermometer stands at 108°, are among the productions of this island. There are salt marshes, or reservoirs, on the shore, filled by the sea-water in winter, which evaporates during the heats of summer.

The lower grounds of the island are extremely fertile and well cultivated, both in fields and gardens. Grapes, figs, melons, and olives, are abundant; also, wheat, barley, leguminous plants, and cotton. The fruits are said to be the best in the Archipelago, and the wine and honey are esteemed excellent. Besides mules, black cattle, sheep, goats, and swine, the domesticated animals, game is very plentiful.

Notwithstanding these advantages, the insalubrity of the climate is so great as to threaten the island with total depopulation. Little more than a century ago, the inhabitants were computed at 20,000; now they have dwindled down to 500; and were it not from the resort of families from the Morea, allured by the fertility of the soil, it is believed that the human race would become quite extinct.

The inhabitants follow agriculture, or pastoral pursuits; vast caverns throughout the island affording the latter convenient shelter for the flocks. Some are fishermen and pilots. The women are occupied in fabricating coarse stuffs and cotton stockings for home consumption, or for Europeans. Formerly, the hand-mills of Milo were celebrated from the quality of the stone; and were exported to the Turkish continent, the Ionian islands, Italy, and Egypt. But trade is almost annihilated from the decrease of the population, and the French privateers abandoning the Levant.

This island contains two towns, Milo, the capital, and Castro, or Sifours. The inhabitants of the former, who, in the beginning of last century, amounted to 5000, are now reduced to about 200, compared, by their visitors, to so many walking corpses. It is considered dangerous to sleep three nights here, and the town is in ruins. Castro occupies the lofty peak of a mountain, and is approached by a rock overhung by smooth basaltic rocks, which are almost insurmountable. The streets communicate by stairs. The slightest breeze resembles a hurricane; and the inhabitants attain very advanced age in this elevated situation. In the year 1700, Tournefort found 18 churches in Milo, 13 monasteries, besides many chapels, two bishops, and the rest of an ecclesiastical establishment, corresponding to a numerous population. Some of the monasteries still subsist, where later travellers meet an hospitable reception.

The site of the ancient capital is ascribed to an assemblage of ruins between the harbour and Castro, consisting of fragments of walls, some fine columns of granite, vaulted excavations, lined with cement, and the remains of bricks and pottery. On the opposite side of a deep ravine, there is a hill penetrated by an immense number of catacombs, which are gained by a subterraneous flight of steps. In general, seven sarcophagi cut out of the rock occupy each chamber, which are ornamented by sculptures, and exhibit the traces of painting on the cement with which they were lined; as also inscriptions now illegible. Several families have established their cottages above these catacombs, and convert the sarcophagi to cisterns for the winter's rain, which is employed in watering the fields below. The position of the ruins, their extent, the solidity of the walls, and the nature of the fragments, together with the great number of catacombs, are supposed to indicate the previous existence of a flourishing city, with temples, or other sumptuous edifices.

Melos is frequently mentioned in the history of the Grecian States; from which it passed under the dominion of the Romans, and on the decay of their empire was subjugated by the Turks, in whose possession it still continues, scarcely capable of paying an inconsiderable tribute. (*c*)

MILTIADES. See Athens, and Greece.

MILTON, John. This ornament of English poetry, and champion of English principles, was born in Bread Street, London, on the 9th of December, 1608. Few psrticulars are known respecting his family, except that it was respectable and ancient, that it had been long resident in Oxfordshire, and had once possessed considerable property, which was forfeited during the wars of the Roses. John Milton, the poet's grandfather, who was under-ranger of the Forest of Shotover, had disinherited the poet's father, whose name also was John, for becoming a Protestant. The young convert, who was then at Oxford, left the University in consequence of this misfortune, and applied himself to the profession of a scrivener in London, which, at that time, united the two businesses of law and money agency. It appears, from several circumstances, that he was no ordinary man—at least he was so considerable a proficient in music as to hold a considerable rank among the composers of the age. The poet's mother was, according to the testimony of her son, an exemplary women, and highly esteemed in the neighbourhood for her acts of charity. Her name was Caxton. Her family was originally from Wales. Our Milton was her eldest son. His younger brother, a lawyer and a royalist, was saved, during the republican government, by the interest of the poet, and after the Restoration was knighted, and made a Baron of the Exchequer, and a Judge of the Common Pleas, by James the Second. A sister, whose name was Anne, married Edward Phillips, a secondary in the Crown Office in Chancery. From this marriage sprung John and Edward Phillips. Both of them were the pupils of Milton, and one of them was his biographer.

The early genius of our immortal poet was fostered with such marks of judicious partiality as denoted his father's pride in the possession of so extraordinary a son. Aubrey relates, that the portrait of the youthful genius was taken by Cornelius Jansen in 1618, when he was only ten years of age, and that he was then a poet; and Dr. Symmons, in his life of Milton, notices this portrait being at present in possession of the family of Mr. Hollis. We presume that Dr. Symmons is accurate with regard to the date of the picture, though we have never heard of any print of Milton representing him earlier than apparently about his 19th year, and wonder that so curious a portrait should not have been made more known by engraving.

Some part of Milton's early education was committed to the care of Thomas Young, a puritan clergyman, who was compelled, by the persecution raised against the sectaries, to retire to the Continent, and was for some time chaplain to the British merchants at Hamburgh. It is not known at what particular time Young was the domestic tutor of Milton, but it is certain, that before his going to the University, our poet passed an interval of study at St. Paul's school, under the direction of Alexander Gill. The son and assistant of this schoolmaster was the intimate friend of Milton, as we find by three of the poet's familiar letters. He succeeded his father as master of St. Paul's school, but, what is disagreeable to relate of one honoured by such a friendship, was removed from his situation for excessive severity to the boys.

In his 16th year Milton was entered a pensioner at Christ's College, Cambridge, (Feb, 12. 1624) and was committed to the tuition of the Rev. William Chapel, the reputed author of the whole Duty of Man, and afterwards Bishop of Cork and Ross. Milton had at this time exercised himself in the composition both of Latin and in English verses. At 15, he translated and paraphrased two psalms, which he thought in maturer life worthy of the public eye. Dr. Symmons conceives, that in the highly poetical epithets of these boyish compositions, we may discover the first shootings of the infant oak which in later times was to overshadow the forest. We are rather inclined to think, with Dr. Johnson, that these productions excite no expectations—the boy Milton seems at that period not much greater than other boys, when he indites such a couplet as the following:

"The high huge-bellied mountains skip like rams
Amongst their ewes—the little hills like lambs."

The treatment and conduct of Milton at the University has been a fruitful subject of controversy. Dr.

Johnson good-naturedly fears that he was one of the last students in either University who suffered the public indignity of corporal punishment. The barbarous custom of public corporal corrections was no doubt retained at English Universities till about as late as the time of Milton, and from the savageness of the custom, and the utter ignorance of the science of education which it betrays, may easily be conceived to have been often dispensed by brutal tempers for acts of mere juvenile indiscretion. "C'est la crime fait la honte, et non pas l'echaufaud." So that, supposing Milton had been punished, unless the turpitude of his offence were proved, the anecdote needed not to have stirred up the pious concern of either his friendly or inimical biographers. It would only excite the disgust of a reflecting mind, to think that the barbarism of the monkish ages came so far down into the system of modern education; and if Milton was flagellated at college, and if the guardian spirits of human improvement have any thing to do with schools and colleges, they assuredly looked with an evil eye on Cambridge, in that hour when the spirit and pride of genius were exposed to the danger of extinction by a treatment so degrading both to the teacher and the taught. But Cambridge and Milton may both be easily acquitted of the suspicion of this occurrence. The story is a mere exhalation from the calumnies which were heaped upon his name by those who dreaded and felt his political eloquence—such as the son of Bishop Hall, and the Du Moulins and Moruses of his own day. His contemporaries believed not a word of the younger Hall's assertion, when he accused Milton of having been vomited forth from his university for disgraceful crimes; for Milton had unanswerable documents to produce at the moment, to show that he had been an object of regard and partiality among his superiors at Cambridge. But Aubrey, nevertheless, had heard of a rumour of Milton's having been punished at college—a rumour, however, which even Wood, ill-disposed as he was to the poet's memory, rejected as scandal—a rumour distinctly falsified by Milton's appeal in the face of the world to the members of his university, against the charge of ill-behaviour at college—and one which he could not have made without instantaneous detection, if he had ever been the object of ignominious punishment. But Thomas Warton would not let Aubrey's rumour drop, and Dr. Johnson, taking it up, and translating out of Milton's verses to Deodati, the Latin word *et cetera*, (meaning something else by "SOMEWHAT MORE," which it does not mean,) endeavoured to torture out of those verses the evidence of a fact which they will not yield. On Aubrey's rumour, and on Dr. Johnson's false translation, the story rests, and let it there rest in peace.

Early in the period of his college residence, we discover his progress as a writer both of English and Latin poetry. Perhaps the first of his English poems which can be fixed upon as an important date in the history of his genius, is his ode on the death of a fair infant, (his sister's child.) written at 17. He there manages with facility and effect a stanza similar to the Spenserian, though shorter, and evidently formed on Spenser's style. The thoughts rise to tenderness and sublimity, though sometimes blemished by conceit. His *Ode on the Nativity*, written at 22, discloses still greater beauties, and perhaps still deeper defects. The "*Verses at a Solemn Music*" have something peculiarly Miltonic; and his vacation exercise, on the subject of his native language, is pregnant with the first stirring-spirit of Paradise Lost, where he speaks of a subject of poetry.

> "Such, where the deep-transported mind may soar
> Above the wheeling poles, and at Heaven's door
> Look in and see each blissful deity," &c. &c.

Many of his Latin elegies were written as early as his 18th year. Ovid was his model in elegy. It has been regretted that he had not a model of greater strength, but to find power united with tenderness in classical elegy is not an easy task. Among his Latin verses it is interesting to meet with his description of a tender passion which he cherished at the age of 19. The object of it was a lady whom he saw in a public walk near the metropolis. She suddenly disappeared from him among the crowd, and he could never afterwards obtain any intelligence respecting her.

He took the degree of A. M. in 1632, and being now 24 years of age, left Cambridge to reside at Horton in Buckinghamshire, where his father lived after retiring from business. The five subsequent years which he passed under his father's roof may justly be regarded as the happiest of his life. To this favoured period we are indebted for some of the most exquisite productions of his genius. *Comus* and *Lycidas* were certainly written here, the former in 1634, the latter in 1637—and most probably the *Arcades*, *L'Allegro*, and *Il Penseroso*. The composition of the *Arcades* probably preceded that of *Comus*. The piece was written for the Countess Dowager of Derby, who resided at Harefield, in the vicinity of Horton. She was of the same family with Spenser the poet, and had been his patroness and his theme of praise before she was celebrated by Milton.

The *Arcades* is evidently nothing more than the poetical part of an entertainment, the bulk of which was formed of prose dialogue; and the attraction of which, to its spectators, probably depended much upon the spectacular show produced by machinery. But the poem, which was Milton's part of the entertainment, discovers a kindred, though inferior lustre of fancy to *Comus*. *The Mask of Comus* was acted before the Earl of Bridgewater, the President of Wales, in 1634, at Ludlow Castle, and the character of the lady and the brothers were played by the Lady Alice Egerton and her two brothers, the sons of the Earl of Bridgewater. The story of the piece is said to have been suggested by the accident of the Lady Alice having one night lost herself in the forest of Haywood. Dr. Johnson ascribes the origin of *Comus* to Homer's story of Circe; Hayley, however, has made it appear probable that it was derived from the Comus of Erycius Pateanus, which was republished at Oxford in the very year in which Milton's *Comus* was written. The elegy *Lycidas* was written in 1637, on the death of Edward King, one of the fellows of Cambridge, and the son of Sir John King, secretary for Ireland, in the reigns of Elizabeth, James, and Charles. The vessel in which he sailed from Chester for Ireland was lost in a calm sea, and not far from land. His memory was so highly esteemed by his university, that almost all the versifiers of Cambridge paid him a tribute. This was the last of Milton's works written whilst he resided at Horton with his father. *L'Allegro* and *Il Penseroso* were probably written but a short time earlier. Notwithstanding their Italian titles, they afford genuine English landscapes. They seem the works of a mind happy in every sense of the word.

They are little worlds of imagination, exhibiting, as it were, in fairy and concentrated miniature, the whole horizon of our pleasing or pensive associations. They have the truly angelic inspiration of a feeling of happiness, which they breathe and communicate both with and without gaiety. For Milton's melancholy man is as enviable a being as his cheerful one.

In his 30th year, with the concurrence of his father, he resolved upon an excursion to the Continent, chiefly with a view to the classic region of Italy. On the intimation of his design, he received a letter from the celebrated Sir Harry Wotton, who had resided at Venice as ambassador from James the First, and was now Provost of Eton. The compliment which Sir Harry pays to some of the poetry of Milton, which he had lately received from him, and to which he confesses that in its kind he had seen nothing parallel in our language, is remarkable, as perhaps the earliest token of superlative admiration which can be found to have been paid to his poetical genius. Certainly, at the time of his leaving England, we have no proofs of his general celebrity at home being in any degree equal to his genius. It is in Italy that we begin to perceive him adequately appreciated. He left England in 1638, attended by a single servant. At Paris we only learn that he saw Grotius, but have no means of ascertaining with what mutual sentiments they impressed each other. He proceeded from Paris to Nice, and embarking from thence to Genoa, proceeded through Leghorn and Pisa to Florence, at which place he remained for two months. He had studied the language and literature of Italy with the deepest attention, and thus accomplished, he soon obtained admission into the literary academies of the Florentines; became the object of their admiration, and the subject of their encomiums, which he says the Italian is not forward to bestow on men this side the Alps. Carlo Dati, Antonio Francini, Gaddi, Frescobaldo, and several other men, very respectable in Italian literature, were among his eulogists and almost worshippers.

A work entitled "*La Tina*," by Antonia Malatesti, was dedicated to him whilst at Florence; and the dedication of a work of even moderate merit to a stranger passing hastily through the place, and distinguished by neither wealth nor political importance, argues Milton to have then acquired no ordinary celebrity. The Italians thought so highly of his knowledge of their own language, that the academy Della Crusca consulted him on the verbal niceties of Italian. During his visit to Florence, he saw and conversed with Galileo, at that time a victim of ignorance and cruelty, having been imprisoned for his philosophical views by the Inquisition, and greatly reduced by sickness and mental distress. From Florence Milton passed through Siena to Rome, where he spent other two months. Here the kindness of Holstensius opened to him the curiosities of the Vatican, and introduced him to Cardinal Barberini, who at that time possessed the whole delegated authority of Rome, under his uncle Pope Urban the Seventh. At a great musical entertainment which this opulent churchman gave, Barberini looked for our traveller among the crowd at the door, and brought him, as Milton says, almost by the hand into the assembly.* At Rome he was praised in Latin epigrams by Salsilli and Silvaggi. He continued his route from thence to Naples, and falling into company with a hermit upon the road, was by him, from whom such a service could be least expected, introduced to the celebrated Manso, the patron and biographer of Tasso, who received him with flattering kindness and attention. The freedom with which Milton expressed himself on religious subjects was the only circumstance which deprived him of an unlimitedly free and intimate communication with this venerable nobleman, a circumstance which Manso himself commemorated in a well-known epigram. Undoubtedly the complimentary offerings of the Italians to Milton are not distinguished by merit as compositions, but we must regard them as the hasty though sincere effusions of men seeking to express their immediate feelings of enthusiasm, and not attending to what they wrote with the anxiety of authors writing for reputation. From a passage in Milton's address to Manso, we discover what he also mentions in one of his subsequent political writings,† that he already cherished the project of some great poetical work, "*which he should leave so written to after-times, that they should not willingly let it die.*"

The plan of his intended travels extended to Sicily and Greece; but as he was preparing to depart for Sicily, he received letters acquainting him with the near prospect of a civil war in England. He esteemed it dishonourable to be abroad whilst his fellow citizens were contending for liberty at home. He revisited Rome, however, and staid also at Naples for two months, excepting a few days which he passed at Lucca, the native place of the Deodati, the family of his beloved school-fellow of that name. From Florence he crossed the Appenines, and travelled through Bologna and Ferrara to Venice, where he staid a month, viewing the curiosities of the renowned city. Having provided for the safety of the books which he had collected in Italy, by procuring a place for them in a vessel bound to England, he pursued his returning course by Verona and Milan to Geneva. From thence he returned through France to his native country, after an absence of a year and three months. This was at the time of the King's return from his second expedition against Scotland, when his forces had been obliged to retreat before Leslie. The crisis was a striking one. Private griefs, however, must have been at this time mixed with Milton's sensations of interest in the public, as the first news which he heard on coming home was the death of his friend Carlo Deodati. He dedicated to his name his Epitaphium Damonis. From a passage in this poem, it appears that he still frequently thought of some great epic composition, and that Arthur and the heroes of British fable were at that time his meditated subjects.

Coming to London, he hired lodgings in St. Bride's church-yard, and received, as pupils, his two nephews, John and Edward Phillips. It has been asked, whether he took pupils gratuitously or for reward—we may go a step farther back, and ask what is the use of such a question? The business of teaching is still honourable, though it should reward the teacher with subsistence. It is of more importance to inquire how far his plan of teaching corresponded with the superiority of his intellect. It was formed, says one of his most admiring biographers, Dr. Symmons, on an erroneous principle—"It respected things more than words." This descrip-

* Ipse me in tanta turba quæsitum ad fores expectans, et pene manu prehensum, persane honorifice intro admiserit.—*Epist. Famil.*
† Reasons for Church Government.

tion certainly opens not unprepossessingly. He placed in the hands of boys from ten to fifteen years of age, such writers, as, though not remarkable for beauty of language, gave information on some of the departments of science, as, the agricultural works of Cato, Columella, and Varro; the Medical Treatise of Cornelius Celsus; Pliny's Natural History; Vitruvius's Architecture, and the philosophical poems of Lucretius and Manilius. We perceive in this plan the teacher's laudable ambition to imbue the minds of those entrusted to him with an early love of science, as well as the recollection of words and phrases, and cannot agree with Dr. Symmons that it is founded on false principles. Sir William Jones followed the plan of education traced out by Milton; and if we may judge of a system by its disciple, he could not have pursued a better.

From St. Bride's Church-yard he soon removed to a house in Aldersgate Street, which admitted his scholars into his family, and the situation, secluded by a court from the street, and opening behind into a garden, supplied the retirement favourable to literary occupation. Here he gave his pupils the example of close application and abstinent diet. He indulged only in temperate festivity once in the course of a month or three weeks. "His companions," Phillips says, "were the beaux of the times, but they never were so intemperate as those of the succeeding generation."

The state of politics brought his pen into exertion. The long parliament now represented a nation irritated by the flagrant abuse both of civil and ecclesiastical power. The king's treatment of members of parliament, one of whom, Sir John Elliot, had died from the severity of imprisonment; his arbitrary exertions, and the severe sentences of his courts and councils, had made the public ripe for resistance and innovation; and the despotism of the church had walked side by side with that of the state. But Charles's embarrassments after his defeat from the Scottish army compelled him to have recourse in earnest to a parliament; and this legislature released the press from its horrid silence. Milton, on his return from the Continent, found the clamour loud and general against the bishops. He was on this occasion, to all appearance, the leader of the attack on the church, as far as the hostility of the press was concerned. In his two treatises of reformation touching church government, he contended that the reformation of the church had not proceeded sufficiently far; and inveighed against the practical evils which religion and liberty had suffered under the prelatical government. To this and other attacks from puritan pens, the virtuous and learned Bishop Hall thought it proper to reply, in "A Humble Remonstrance to the High Court of Parliament;" and about the same time Archbishop Usher published a work to maintain the apostolical institution of Episcopacy.

In reply to these pamphlets, Milton published two pieces, the first of which bore the title of "*Prelatical Episcopacy*," and the second, "*The Reason of Church Government urged against Prelacy*." The point at issue between these polemics was the divine or the human origin of episcopacy. These opponents of our author, Hall and Usher, were men whose characters reflected honour upon their cause, and who, in their conduct, were not persecutors. This circumstance, however, is not decisive of the truth of the ecclesiastical doctrines which they supported. Milton's productions were the most learned and able on the puritan side of controversy. But the piece which seems to have chiefly attracted the public attention at this time, was one written by five of the presbyterian divines, under the title of "*Smectymnuus*," a word made up of the initial names of the authors. To this book Bishop Hall replied in a "Defence of the Remonstrance," and Milton's formidable pen produced "*Animadversions on the Remonstrant's Defence*." These five pieces of Milton's were written in one year, 1641, when their author was thirty-three years of age, and whilst he was daily occupied with the fatigues of tuition.

In the beginning of the next year, his "*Animadversions*," which unquestionably were rude and personal, excited a deeply vindictive reply (as was supposed) from the son of Bishop Hall. The anonymous publication heaped enormous falsehoods on Milton's head. Our author's "*Apology for Smectymnuus*," was drawn forth by this accumulated provocation. The most objectionable part of this work is the critical attack which he makes on Bishop Hall's literary character, and on his satires: its most splendid and eloquent passage is his eulogy on the first proceedings of the Long Parliament. This publication seems to have closed the controversy; weapons more effectual than pens were now drawn against the church.

About Whitsuntide, in 1643, Milton took a journey into the country, apparently for the mere object of recreation; and, without having communicated his design of marriage to any of his friends, returned, rather to their surprise, at the end of a month, with his wife, Mary Powell, the daughter of a country gentleman, at Forest Hill, near Shotover, in Oxfordshire. His matrimonial choice seemed to be hasty, and was not fortunate. His spouse, strongly attached, like all her family, to the royalist party, and accustomed to the affluent hospitality of her father's house, was soon tired of a studious, recluse, and republican husband. After a month's experience of her new life, she sighed for the gaieties she had left behind, and by the earnest request of her relations obtained permission to pay a short visit to Forest Hill. But when the period returned, (Michaelmas,) when she should have arrived, she shewed no disposition to keep her word; but, on the contrary, treated his letters with silence, and sent back his messenger with disdain. The king at this period was defeating the parliamentary forces, and the Powells were disposed to break as well as they could an inauspicious connexion. On the other hand, Milton determined to repudiate a wife who left him nothing of matrimony but the chain. To justify the intended measure, he published, in 1644, an essay on the *Doctrine and Discipline of Divorce*. This treatise, which was incribed to the parliament, was soon followed by "The judgment of Martin Bucer concerning divorce," and by *Tetrachordon* and *Colasterion*. The two last of these tracts were written in 1645—the latter of them as a reply to an anonymous antagonist, the former as an exposition of the four passages in scripture, which are supposed to relate more immediately to the permanence of the marriage obligation. By these writings, the fury of the presbyterian clergy was instantly excited; they endeavoured to infuse their passion into the legislature, and occasioned Milton to be cited before the House of Lords. But he was speedily and honourably dismissed from this tribunal, and the Presbyterians lost an able friend, and excited a formidable enemy. Milton was serious in his opinions, and prepared to act upon them. Conceiving himself released in conscience from the marriage bond, he paid his addresses to an accomplished and beautiful young lady, the daughter of a Dr. Davis. The lady, it has been intimated, was rather averse from the proposal, but her objections (and her friends seem not to have stated any,) were apparently slight, when the match was prevented by the return of his delinquent spouse. Public affairs were now changed. The tide of fortune was against the royalists, and the Powells, foreseeing, what the event proved, that Milton might protect and assist them, hastened to propitiate his resentment. They concerted with Milton's friends to introduce his wife unexpectedly into his presence at a friend's house, and she supplicated for her pardon upon her knees so effectually as to obtain it. He admitted, along with her, to his house, the family of the Powells, who were now in danger and distress, and saved the bulk of their property by his interest with the victorious party. Whatever gratitude the Powells felt, they never did him the justice to pay his wife's fortune out of their rescued estate. But, it is possible, that in such times the recovery of property might be more nominally than really complete. They remained under his roof for many years, which, unless their spirit was extremely abject, would argue that they were late in regaining their estate, and in the interval it must have suffered much deduction. In the mean time, to accommodate his enlarged family, our author hired a house in Barbican. In the year 1644, whilst immersed in his controversy about divorce, he published his ideas on the subject of education, and not long after sent forth his work Areopagitua, in which he defended the freedom of the press with a degree of intelligence and spirit which has never been surpassed.

The Presbyterians, on their arriving at power, forgot the principles which they had professed in their rising to it, and placed the press under the same controul of which they had of late so indignantly complained. Milton came forward as the champion of free discussion, and made his weapons of reason and fancy as effective by their weight and edge, as they were dazzling by their brightness. Though the presbyterians could practically resist the adoption of his principles, they could not prevent his arguments being heard and felt. The office of licenser of the press was indeed continued throughout the whole duration of their power, but at a subsequent period, (in 1649,) we find the conscientious Gilbert Mabot resigning this invidious office, and in stating the grounds and motives of his conduct, repeating the arguments for a free press contained in Milton's Areopagitua.

In 1645, Milton once more courted the Muses, whom he had so long deserted. From the period of his return to England to this year, his pastoral on *Deodati*, and some occasional sonnets, were the only poetical fruits of his genius. He now prepared an edition of all his English, Italian, and Latin poems. The small volume which they formed was published with his name, and with a preface by their publisher, Humphrey Mosely. The sonnets were the most important novelties of the collection.*

In 1646, his wife brought him their first child, a daughter, named Anne, who was lame, either from her birth, or in consequence of some accident in her early infancy. In 1647, his venerable father died under his roof, having come to live with him since the year 1643, when at the capture of Reading, he left his residence with his younger son in that city. The Powells left him not long after, and his house, (says Phillips,) looked once more like a house of the muses. In this same habitation, in the Barbican, his second daughter Mary was born. In the spring of 1647, he removed to a smaller one in High Holborn, the back part of which looked into Lincoln's Inn Fields.

Phillips relates, that in the course of the civil wars there was a proposal for Milton embracing the military life; and says that, if he was not much mistaken, there was a design of making him an adjutant-general in Sir William Waller's army. Dr. Johnson ridicules this vague allusion to an unfulfilled intention. Yet we may ask, what there is ridiculous, either in the rumour, or in Phillips's taking notice of it. If Milton was not employed in the field, it was because he could fill the post of intellectual warfare with more advantage. His laurels at that post were more honorable than the field of battle could afford him; and in that field there was no combatant but himself who was capable of earning them.

After the works already mentioned, he is not known to have published any thing earlier than his treatise, which appeared early in 1649, entitled *The Tenure of Kings and Magistrates, &c.* maintaining the right of the people to depose and put to death a tyrannical king. The unfortunate Charles I. had suffered on the scaffold. Milton's work therefore came forth, not to accelerate Charles's fate, but, as he expressly declares, to tranquillize men's minds in the agitation which his fate produced. The pity which King Charles's tragic story excites,—a pity, however, by no means irreconcileable in humane minds with the conviction of his conduct having been deeply culpable, should not lead us hastily to regard the attempt at tranquillizing men's minds after his death as unprincipled. On the contrary, Charles had no sooner died, than compassion for him was made the pretext for men avowing slavish principles of the most abandoned nature. It was proclaimed as a fundamental maxim of government, that kings were from God, and not responsible to man; and this maxim too was avowed in some instances by men, who, at an earlier stage of the civil wars, had paved the way for the very dethronement and death which they now hypocritically lamented.

Without denying that Milton, in the sternness of his republican opinions—and, let it be allowed, even in the infectious taint of over-heated party zeal—may have regarded Charles with less humane allowance than the candid eye of an impartial posterity regards him; yet still it must be remembered, that this work professed not to discuss the question personally respecting Charles, but respecting the abstract principle of human rights and regal responsibility, at the root of which the anti-regicides were now striking. Whatever treatment it might have been true and humane policy to have imposed on the fallen monarch, it was not to be tolerated, that his fate should be called in question, on the atrocious principle that kings are not responsible. So that Milton, as far as abstract principle was concerned, is not to be viewed in the light of one contributing to shed Charles's blood, but to be justified for slaying the monstrous opinions that rose out of it.

* The whole of his sonnets, however, were not included in this collection. Some of them were written at a subsequent period.

His next work was a pamphlet on the articles of peace, which the Earl of Ormond concluded at Kilkenney in the king's name with the Irish insurgents.

Without imputing to Charles any participation in the horrible massacre of the Irish protestants, it is clear that the treaty with the Catholics, concluded under the king's name and authority by Ormond, was sufficient to confirm the public prepossession on the subject, and to give an appearance of the tone of truth to republican and puritan invective. Milton, therefore, found it not difficult to be severe on the articles of a peace, which by abandoning the English and Protestant cause in Ireland, permitted their enemies to indulge in sanguinary revenge. When he had concluded this attack, he returned to the more quiet occupations of literature, and finished four books of his history of England. These come down no farther than the union of the heptarchy under Edgar. Two other books, written at a subsequent period, namely, after his controversy with Morus, bring the narrative as far as the battle of Hastings. It is a history unfortunately terminating at the period where our annals begin to be interesting; but the materials are copious and curious, and the style energetic, though occasionally harsh. The first book is abandoned without reserve to the fables of Geoffrey of Monmouth, and was intended, as the author intimated, rather to suggest subjects to the poet, than maxims to the statesman or sage.

On the death of Charles I. the executive power of the commonwealth was lodged in a council of 38 members of the legislative assembly, who made England for a time command the respect and terror of Europe. Resolving to adopt the old Roman language in their intercourse with foreign powers, they appointed a Latin secretary; and the learning, talents, and republicanism of Milton, pointed him out as the person best fitted to fill this office. The younger Vane and Bradshaw, who have both been the subject of his panegyric, are supposed to have first suggested his appointment. His continuance in this office was prolonged to the Restoration; and the state papers in his department were models in the class of diplomatic compositions. Those letters in particular which he wrote in the Protector's name, to mediate for the oppressed Protestants of Piedmont, reflect a lustre on the reign of Cromwell, and on the history of England.

Milton had scarcely entered on the proper functions of his office, when he was summoned by the new government to the discharge of another and peculiar duty. One of the contrivances of the royalists after the death of Charles, to stimulate public enthusiasm in their cause, was to publish the Eikon Basilikè, or portrait of his sacred majesty in his solitude and sufferings. The book was given out to be a collection of the feelings and reflections which Charles I. had at various times during the civil wars committed to writing. It represents him in the constant intercourse of prayer with his Maker, asserting the integrity of his motives before the Searcher of hearts, and appealing to his justice from the injustice of man. There are few men, whose conduct through life would sanction them in writing such a diary, to make conscientiously such constant appeals to the Deity in favour of the purity of their motives, and Charles was neither so pure as to be able to make them with a safe conscience, nor so hardened as to have made them with cool hypocrisy. It has been ascertained, by proofs which no reasonable man can reject, that this book, representing him as a saint and a martyr, was written for the political ends of the royalists by Dr. Gauden; and it is remarkably curious, that the most decided confession of the spuriousness of the Eikon was made by Charles's own sons Charles II. and the Duke of York.* The work. however, was considered as genuine when Milton wrote his remarks on it, although there were internal symptoms against its authenticity which his sagacity could not overlook. The council of state saw the dangerous impression which the Eikon Basilikè was calculated to make. They might have suppressed it by force; but they preferred waging war, by opposing argument to argument, and book to book. Milton, at their desire, wrote the *Iconoclastes*, or image-breaker, in which he disclaims the intention of insulting the memory of Charles, but confronts the monarch's actions with the piety ascribed to him, and has even hinted at the work having been manufactured for him by his household rhetorician,—a suspicion which time has verified.

Milton's memory has been charged with three several offences in the *Iconoclastes*, or *Image Breaker*. In the first place, with having too rudely blamed the king for making use of a prayer which he borrowed from a romance, namely, Sir Phillip Sydney's *Arcadia*; in the next place, with having interpolated the *Eikon Basilikè* with that prayer, in order that he might establish a ground of censure; and, in the third place, with having uncharitably insulted Charles's *memory*, on account of his intimacy with the plays of Shakespeare. The first accusation is true, the two others are absurd. He did, with unnecessary harshness, animadvert on Charles's having borrowed a prayer from a romance, but he did not interpolate the Eikon; for in the first edition of the Eikon, printed by Royston a royalist, the prayer in question is to be found. His animadversion on the king's fondness for Shakespeare is perfectly unblameable: the gust of all that he says is merely to convey the remark, that pious and clement sentiments have often been put into the mouths of tyrants, and by no poet more than by Shakespeare, with whom Charles I. was so well acquainted.

On being appointed to the office of Latin secretary, Milton removed first to a lodging at Charing Cross, and afterwards to apartments in Scotland Yard. In this last residence his wife had her third child, a son, who died in his infancy, on the 16th of March, 1650. In 1652, he changed his abode to Petty France, where he occupied, till the Restoration, a handsome house opening into St. James's Park.

He had no sooner finished his *Iconoclastes*, than he entered into his controversy with Salmasius. This learned Frenchman, (Saumaise, or Salmasius.) an honorary professor of Leyden, was employed by Charles II. to write the *Defensio Regia*, or an appeal to the world in behalf of the cause of royalty, prelacy, and the house of Stuart. Milton was employed to answer it, and he performed his task in 1651, by his celebrated *Defensio pro Populo Anglicano*. He was present when the council of England enjoined him the task. Milton, when he undertook it, was weak of body and dim of

* When a copy of the *Eikon* was sold among the books of the first Earl of Anglesea, a memorandum was found in it, in that nobleman's handwriting, attesting that Charles II. and the Duke of York had disavowed the *Eikon* as the work of their father.

sight, and his physicians predicted that it would cost him the loss of his eyes; but he persevered, and finished a work, the eloquence and intellectual power of which is only slightly disfigured by some sportive sallies of wit, and some harsh personalities. The work was applauded by all Europe. Foreigners of the highest talent and erudition, and the ambassadors of crowned heads, waited upon him, or wrote to him to express their congratulations. The council of state made him a pecuniary reward of a thousand pounds.

On the 2d of May, 1652, his family was increased by the birth of another daughter, Deborah, of whom his wife died in child-bed. Meanwhile his sight was impaired by incessant study, so as to leave him probably as early as this same year nearly blind, at least one of his adversaries about that time charitably upbraids him with the calamity as a punishment from heaven, and denominates him as a "*monstrum horrendum cui lumen ademptum.*" His fortitude under the event is admirably expressed in his sonnet to Cyriac Skinner.

The precise date of his second marriage, is not much better ascertained than that of his confirmed blindness, though probably both events took place about 1654. His second matrimonial choice was Catherine, the daughter of a Captain Woodcock of Hackney. She was the object of his fondest affection; but died within a year after their marriage, like her predecessor, in child-birth, and the daughter whom she bore to him soon followed her to the tomb. His sonnet to her memory must be in every one's remembrance. During this period his powers were again employed in controversy.—De Moulin's "*Cry of the Royal Blood to Heaven*," published in 1652, poured forth the most violent abuse against the English as a nation, and Milton as an individual. De Moulin, the son of an obscure French satirist at Sedan, was the real author of this work; but Alexander More, a man of Scotch parentage, and a preacher of considerable celebrity, settled in France, and Principal of the Protestant College of Castres, wrote a dedication of the *Clamor Regii Sanguinis* to Charles II. and committed it to the Press; on him, therefore, Milton retaliated with a vengeance which sufficiently exposed the impeachable part of More's character. With his *Second Defence of the People of England*, Milton closed for the present his controversial labours; and probably endeavoured among his studies to retire from the mortification and disappointment which he felt from the exhibition of despotic principles and conduct in the Protector. There is reason to believe that he felt this mortification. Like Blake and Sir Matthew Hale, he might plead the employment of his country as lawful even under a tyrant, and he might think a temporary usurpation, on the whole, preferable to the return of the unprincipled royal exiles. But it would have been agreeable to have had a more distinct declaration of his motives from his own pen. He was engaged in 1653 in continuing the History of England, and a Latin dictionary, and had begun to frame his immortal epic poem. The historical work, which is only a great fragment, appeared in 1670, mutilated by the licenser of some of its finest passages. The materials of his Latin Thesaurus were left imperfectly digested, but are said to have been usefully employed by the compilers of the Cambridge Dictionary, to whom they were probably given by his nephew Phillips. In the same year he published a MS. of Sir Walter Raleigh's, consisting of aphorisms on the art of government, and composed in a strain of peculiar elegance the manifesto issued by the Protector in justification of his war with Spain. In the following year Cromwell finished his splendid but criminal career, and his son Richard descended with magnanimous innocence to the safe level of a private station. When the fluctuations of government threatened general anarchy, Milton was induced to give his advice on civil and ecclesiastical topics, in some short publications; one of which was, a ready and easy way to establish a free commonwealth; the excellencies thereof compared with the inconveniences and dangers of re-admitting monarchy. This appeared but a short time before the restoration, so zealous and sanguine was he to the very last with respect to his political system. It was in vain, however, to contend with pamplets against the national inclination. The king returned in triumph; and Milton, discharged from office, left his house in Petty France, and was secreted under the roof of a friend in St Bartholomew's close, near to West Smithfield, till the act of oblivion, in the exceptions to which he was not included, ascertained his safety and reinstated him in society.

All parties have agreed in paying this compliment to Charles II. that it was owing to no weakness or oversight of his, if Milton escaped. It is supposed that his friend Andrew Marvell, the member for Hull, made some interest for him in the House of Commons; and we are told that Sir Thomas Clayes, and Secretary Morris, made exertions for his preservation. But the most earnest and grateful interposition seems to have been that of Sir William Davenant, who had been saved on a former occasion by the mediation of Milton. But though his person was spared, his *Iconoclastes, and the Defence of the People of England*, were condemned to be burnt by the hands of the hangman. Milton might well smile at this vindictive show of triumph. No sentence, no hangman, no flames could destroy the fame of the *Defence of the people of England.* He might also console himself by reflecting, that those who sentenced his book to be burnt, were the same who dug up the body of Blake to be hung on a gibbet, and who brought back the punishment of embowelling on the scaffold, ere they were yet dead, the expiring victims for treason; a relic of barbarism which had been abolished during the republic. Milton was for some time in the custody of the Serjeant-at-Arms, but was discharged, and attention was even paid to his complaint of the demand of excessive fees. This attention, however, was paid to him by the parliament, and not the crown.

Being now in reduced circumstances, and under the discountenance of power, he removed to a private habitation in the city, and, in order to alleviate his forlorn condition, he desired his friend Dr. Paget to look out for a third wife for him. He recommended a relative of his own, Elizabeth Minshull, of a good family in Cheshire, and the union took place in Milton's fifty-third or fifty-fourth year. About the time of his marriage, or probably a little before it, he published a short treatise, entitled *Accidence Commenced Grammar*, intended to facilitate the first weak step of the juvenile student, and remarkable only for its exhibition of a mighty mind stooping in dignified condescension to utility. In 1655, he gave to the public another MS. of Sir Walter Raleigh's, containing aphorisms of State, with the title of the "*Cabinet Council.*" That he was offered from the court, and refused the post which he had held under the former government, has been asserted, but with little probability, since his manners were by no means accommodated to the new reign, and he had offended too deeply to be more than forgiven.

He had now to resume the character of a poet, which for many years had been sunk in that of a politician and controversialist, for his few compositions in verse during this period, though exquisitely beautiful, were not sufficiently attended to, to add to his poetical reputation. When he first formed the resolution of writing an epic poem, he thought of some subject in the heroic times of English history. Religion and the study of the Hebrew Scriptures decided him in favour of a religious subject. His mind, now concentrated and undisturbed, fulfilled the great conceptions which he had designed of *Paradise Lost*. The exact time employed in the composition of this poem is not ascertained, but it probably occupied his thoughts with no considerable interruptions of any other literary subject for eleven years, from 1654 to 1665, at which period Elwood the quaker says it was finished; a time when Milton, to avoid the contagion of the plague in London, made a retreat to Chalfont in Buckinghamshire. Paradise Lost was first printed in 1667, in small quarto, and divided into ten books; and his biographers have been very minute in recording the trifling sum which he received for the copy-right of it. Much discussion has also taken place respecting the original conception of this grand performance. Voltaire first suggested, that the hint had been given by the Adamo, a poor drama, full of allegory, conceit, and bombast, written by one Andreini, a strolling player of Italy. Dr. Johnson rejected the hypothesis with contempt, but from the circumstance distinctly proved, of Milton's poem being first projected by him in a dramatic shape, and from the similarity of the allegorical beings first sketched by Milton with those of Andreini, it seems by no means improbable, that the supposition suggested by Voltaire, and illustrated by Mr. Hayley, is correct.

In the second edition of the *Paradise Lost*, which was published in 1674, the author divided the seventh and tenth books, for the purpose of breaking the length of their narrative, each into two, and thus changed the original distribution of his work, from ten to twelve books. On this new arrangement the addition of a few lines became necessary to form a regular opening to the eighth and the eleventh books; and these nine verses, with six others, inserted partly in the fifth and partly in the eleventh, constituted all the alterations for this mighty production, on which his own and the epic fame of his country was to rest.

Paradise Regained, written upon a suggestion of Elwood's, and apparently regarded by the author as the theological completion of this plan, followed in 1670. He is said to have viewed this production with the partial fondness of a parent for his latest offspring. He could not bear the disparaging comparison of it with his great work, which was generally made. The general opinion of this poem certainly places it at an humble distance from *Paradise Lost*. The extreme narrowness of its plan, the small proportion of it which is assigned to action, and the larger portion which is given to disputations and didactic dialogue, its paucity of characters and poetical imagery, and its general deficiency in the charm of numbers, exclude it from a wide range of popularity. It is embellished, however, with several exquisite passages, which discover the still existing author of the *Paradise Lost*. *Sampson Agonistes* was published at the same time, a manly, noble, and pathetic drama; though it cannot be asserted that its action is undefective, or that all its scenes tend harmoniously to the developement of the fable. The unlimited and capricious wanderings of the choral measures are also such as would be likely to offend us, if we were not prejudiced by the consciousness of reading Milton.

The poet, in this respect, imitated the Greek drama, which unites in its choruses verses of all descriptions, without any rule which modern scholarship can ascertain. But the vocal structure of the Greek language might admit of harmony with great irregularity of measures; and Athenian ears might learn by habit to delight in such anomalous harmony (if it was anomalous.) whilst our more obdurate tongue requires the precincts of verse to be distinct and definite; and we are habituated to delight chiefly in the flow of measure which the ear competently understands, and which it in some degree anticipates.

With this piece the history of Milton's poetry closes; but writing was become so much a habit with him, that he was continually making additions to his works in prose. In 1672, he published a system of logic, after the method of Ramus, and in the following year he again ventured into the field of polemics, with a treatise *Of True Religion, Heresy, Schism, and Toleration, and the best means to Prevent the Growth of Popery.* So imperfectly was toleration then understood, that Milton persuaded himself he was consistent in denying it to Papists, although he declares that he would not even towards them exercise any personal severity.

In 1674 he published his familiar letters, and some of his university exercises; the former with the title of *Epistolarum Familiarum Liber unus*, and the latter with that of *Prolusiones quaedam Oratoriae in Collegio Christi habitae.* It has been commonly affirmed that he translated into English the declaration of *the Poles on their elevating the heroic John Sobiesko to their elective throne*; but Dr. Symmons throws some doubt upon the fact, as the Latin document could have arrived in England only a very short time before his death; and as the translation bears no resemblance to his character of composition. It is more certain that in some part of the same year, the last of his life, he wrote a brief history of Muscovy, which was published about eight years posterior to his death.

With this work terminated his literary labours; the gout, which had for several years afflicted him, in spite of his extreme temperance, seems to have brought on rather premature senility and exhausted his vital powers. In his sixty-sixth year, and on the 8th of November 1764, he expired, so quietly that those who waited in his chamber were not conscious of his death. His funeral was attended by many great and learned individuals, and not without a friendly concourse of the vulgar; his remains were deposited by the side of his father's, in the upper part of the chancel of St. Giles's, Cripplegate. In consequence of an alteration made in that part of the church, the stone originally inscribed with his name was removed at the end of a few years, and was never replaced. But this unintended injury was in later days compensated by the erection of his bust, (the work of Bacon) at the expence of the elder Mr. Whitbread. Mr. Benson, one of the auditors of the impost, had, in 1737, introduced a similar memorial of

Milton into Westminster Abbey. By his will he left nearly £2000, besides £1000, his first wife's portion, which remained in the hands of the Powells, and which ought to have been paid, if it was not, to his daughters. He had lost £2000, the emoluments of his office, which he had placed on government security.

Milton was distinguished in his youth for personal beauty, and continued to be a well-looking man to the last.* He was a skilful swordsman, vigorous and active in his exercises, manly and erect in his deportment. He was also, like his father, accomplished in music, though not a composer. His learning embraced the Hebrew, Greek, Latin, and Spanish, and, if not absolutely versed in the sciences, he had penetrated more than their surface. Though from parts of his controversial writings, we might presume his temper to have been harsh, he indulged in no enmities except on public grounds, and in private he was mild and courteous. This we have on the authority of F. Junius, the author of De Pictura Veterum, and H. Heinsius mentions the general report of the amenity of his manners—"Virum esse miti comique ingenio aiunt."

His prose compositions vary in merit. The earliest of them possess a more crude and unwieldy character of strength. As he continued to write prose, there is a visible, though not equally progressive improvement. In a general view of them, there is a strength and spirit of genius rising often to grandeur, but a deficiency of taste to purify, and harmonize, and perfect, the powers of expression. The picturesque is often redundant and out of keeping, and the structure of his sentences laboriously scholastic.

The homage paid to his poetical genius is so universal, that we shall not distend our article with a critical dissertation on them. Addison made his own generation sensibly alive to the beauties of Paradise Lost, though there is reason to believe, that, even before the time of Addison, the great Epic was not so much neglected as has been often alleged. Since the middle of the last century, the public attention has been more and more drawn to his minor poems, till it may be said to be now rivetted on them with almost unqualified extacy. Of Paradise Lost it has been justly remarked, that, in forming our estimate of the powers of mind possessed by different races of men, it raises our opinion of the strength and magnificence of the English imagination. It is a sublime work, that adorns our country more than "cloud-capt towers or gorgeous palaces." Even its imperfections seem to be unavoidable, and to have arisen out of its theological subject in a way, in which, with few exceptions, it is difficult to conceive how the author could have well avoided them. But taking the subject all in all, (we quote Mr. Campbell's Essay on English Poetry.) his powers could no where else have enjoyed the same scope. It was only from the height of this great argument that he could look back upon eternity past, and forward upon eternity to come, that he could survey the abyss of infernal darkness, open visions of Paradise, ascend to heaven, "and breathe empyreal air." On the style of Milton, and on the most sublime trait of excellency in his poem, namely, his delineation of the celestial and infernal angels, we beg to conclude with a quotation from the critical work already mentioned. "If we call diction the garb of thought, Milton in his style may be said to wear the costume of sovereignty. The idioms of other languages contributed to adorn it. He was the most learned of poets, yet his learning interferes not with his substantial English purity. In delineating the blessed spirits, he has exhausted all the conceivable variety that could be given to pictures of unshaded sanctity; so that his excellence above every thing, ancient or modern, is conspicuous. Tasso had indeed pourtrayed an infernal council, and had given the hint to our poet of ascribing the origin of Pagan worship to those reprobate spirits. But how poor and squalid in comparison of the Miltonic pandemonium are the Scyllas, the Cyclopses, and the chimeras of the infernal council of the Jerusalem. Tasso's conclave of fiends is a den of ugly incongruous monsters:

> "*O come strane o come orribile forme,*" &c. &c.
>
> La Gerusalemme, Canto iv.

The powers of Milton's hell are godlike shapes and forms. Their appearance dwarfs every poetical conception, when we turn our dilated eyes from contemplating them. It is not their external attributes alone which expand the imagination, but their souls, which are as colossal as their stature—their thoughts that wander through eternity—the pride that burns amidst the ruins of their divine natures—and their genius, which feels with the ardour, and debates with the eloquence of heaven.

The subject of "Paradise Lost" was the origin of evil—an era in existence—an event more than all others dividing past from future time—an isthmus in the ocean of eternity—the theme was in its nature connected with every thing important in the circumstances of human existence, and, amidst these circumstances, Milton saw that the fables of Paganism were too important and poetical to be omitted. As a Christian he was entitled wholly to neglect them, but as a poet he chose to treat them not as the dreams of the human mind, but as the delusions of infernal existences. Thus anticipating a beautiful propriety for all classical allusions, thus connecting and reconciling the co-existence of fable and of truth, and thus identifying the fallen angels with the deities of "gay religions full of pomp and gold," he yoked the heathen mythology in triumph to his subject, and clothed himself in the spoils of superstition." (*n*)

MINDANA. See Magindanao.

MINDEN, or Munden, a city in the kingdom of Hanover, and principality of Calenburg, is situated on the Weser, which is crossed by a bridge 600 feet long. It is about two miles in circuit, and encircled with walls and ramparts. The principal public buildings are, the Hotel de Ville, the cathedral, which is a fine edifice, the church of St. John, the Gymnasium, and the Orphan's

* The venerable figure of Milton is described by Richardson as he was sitting (according to custom) before his door, in a great coat of coarse cloth in warm weather to enjoy the fresh air, and thus receiving visits of persons eminent for talents or consideration. Richardson proceeds to say, "Very lately I had the good fortune to have another picture of him from an ancient clergyman in Dorsetshire, Dr. Wright He found him in a small house, he thinks but one room on a floor; in that, up one pair of stairs, which was hung with rusty green, he found John Milton sitting in an elbow chair, black clothes, and neat enough; pale, but not cadaverous; his hands and fingers gouty and with chalk stones. Among other discourse, he expressed himself to this purpose, that was he free from the pain this gave him, his blindness would be tolerable.

House, where there is a manufactory of stockings. It has three Lutheran, one Calvinist, and two Catholic churches. The principal manufactures in this place are those of wax candles, hats, leather, and soap. There are also refineries of sugar and bleach-fields. The white beer of Minden has been long celebrated. An account of the battle of Minden, fought here in 1759, will be found in our article BRITAIN. Population, 7000. East long. 8° 53′ 26″. North lat. 52° 17′ 47″.

MINE,

An excavation made either in the rock, strata, or in the earth which generally covers the rock, of which there are three distinct kinds, viz.

1*st*, A mine employed in the art of war, particularly in sieges.

2*d*, A mine made for the working of veins, containing the ores of metals; which veins are generally in a position nearly vertical.

3*d*, A mine for the working of such minerals as generally lie in beds, having a moderate angle of inclination with the horizon, such as a *coal-mine*, an *ironstone-mine*, or *limestone mine*,

The first kind of mine will be found described in the article FORTIFICATION.

The second kind will be described under the article VEIN.

The third kind, in particular the *working of coal-mines*, will be now described.

Although mineral coal is found abundantly in various quarters of the globe, as noticed under the article COAL, it is admitted that the most valuable fields of it are found in Great Britain, and have been wrought to a much greater extent there than in any other part of the world.

As nothing but pit-coal is used as fuel for domestic purposes in Great Britain, excepting in a few of the inland districts, where a small quantity of wood and turf are substituted; and as all the numerous and extensive iron-works, with the innumerable steam-engines and manufactories, depend entirely upon a regular supply of coal, at a moderate price, the working of the coal-fields, in a systematic and economical manner, has been much studied, and brought to greater perfection in Britain than in any other country.

Coal, as an inflammable substance, appears to have been known to the ancients, and to the Britons, before the Romans visited this island, it being found so frequently in ravines and beds of rivers, of a colour and texture so decidedly different from the strata which in general accompany it; but as, at that period, and for centuries afterwards, the country was covered with immense forests, which supplied abundance of fuel for every purpose of life, there was no necessity for using coal as fuel.

The working of coal, therefore, only became an object of attention as population and civilization advanced, when agriculture began to be studied, the woods cleared away, and the arts of civil life cultivated; accordingly we find, that the working of coal in Britain, as an article of commerce, is comparatively of modern date, and appears to have commenced about the end of the 12th century. The first charter, giving liberty to the town of Newcastle-upon-Tyne to dig coal, was granted by Henry III. anno 1239; it was then denominated *Sea-coal*, on account of its being shipped for places at a distance. In the year 1281, the Newcastle coal-trade had become so extensive and important that laws were enacted for its regulation.

In Scotland, coals began to be wrought much about the same time; and a charter was granted in the year 1291, in favour of the abbot and convent of Dunfermline in the county of Fife, giving the right of digging coals in the lands of Pittencrief, adjoining the convent. From this period the working of coal gradually increased, though on a very limited scale, until the beginning of the last century, when the steam-engine was brought forward by Newcomen in the year 1705, and was applied to collieries in the vicinity of Newcastle about the year 1715. This machine produced a new era in the mining concerns of Great Britain, and, as it were in an instant, put every coal-field within the grasp of its owner. Collieries were opened in every quarter; and the coal trade rapidly extended to an astonishing scale. This extension of the trade was greatly aided by the genius of the late James Watt, Esq. of Glasgow, whose philosophic mind made the most brilliant discoveries, and so very much improved the principles and power of the steam-engine, as to render it one of the most complete and must useful pieces of mechanism. To Newcomen and Watt the mining interest of Great Britain is highly indebted; to the latter, the empire owes its great rise and improvement as a manufacturing country.

The collieries of Great Britain are now upon the most extensive scale, and are of the first importance to the kingdom; both as regarding its political and commercial interests; so much so, that it is evident, without cheap coal, the manufactories of Great Britain could not be brought forward in competition with those of the other nations of the world, where manual labour is comparatively very low; in short, the coal-mines of Great Britain form a physical and prominent point in the political state of the empire. The capitals employed in the collieries, and in the shipping connected with them, are immense, amounting to many millions. A very considerable proportion of the population of the kingdom is employed in the mines and coal trade, while the ships which carry coals coastwise, are a nursery for thousands of the most intrepid seamen which are to be found in the world.

It cannot easily be estimated what is the total produce of coals in Britain, but it must extend to many millions of tons; for it is known that the output of coal upon the rivers Tyne and Wear, in the counties of Northumberland and Durham, amounts to three millions of tons annually, of which only a small quantity is used in the district, the greater part being shipped coastwise. In these two districts alone, it is estimated that 70,000 people are employed in the coal trade, and that the capital invested in the collieries and shipping is above two millions and a half of money.

With regard to the formation of coal, many theories have been brought forward; but although these display no common share of genius and patient investigation, they have hitherto led to nothing conclusive or satisfactory on the subject. The object in this treatise is, to give a distinct view of the geological situation of coal fields, their absolute forms, the dislocations and troubles which occur in them, and the method of working coal mines.

The great coal-field of Britain, which is composed of numerous subordinate coal-fields, crosses the island in a diagonal direction, the south boundary line extending from near the mouth of the river Humber, upon the east coast of England, to the south part of the Bristol channel on the west coast; and the north boundary line extending from the south side of the river Tay in Scotland, westward, by the south side of the Ochil mountains, to near Dumbarton, upon the river Clyde; within these boundary lines North and South Wales are included. This area is about 260 miles in length, and, on an average, about 150 miles in breadth. Within these bounds all the chief coal-fields are found upon which collieries have been established in Britain; and no coal-field of any consequence has been found, either to the north or south of the lines above mentioned, excepting some small patches of thin coals of inferior quality, and the coal field of Brora in Sutherlandshire, Scotland, which is far disjoined from any other coal-field.

When we take a cursory view of this globe of earth, composed of high, wild, and rocky mountains, its numerous valleys, rivers, and undulated surface, together with the vast expanse of ocean, we are apt to consider the mountains and rocks as forming a kind of chaos, without regularity or order; but the laborious and patient investigations of mineralogists have shown, that there is in the arrangement of the various rocks, an order and regularity beyond what was, or is, commonly imagined,—a regularity, perfectly consistent with that Infinite wisdom and Almighty power which formed the vast, the unbounded system of the universe. It is this regularity in the succession and arrangement of the various rocks, from the Alpine heights to the valleys and level of the sea, which guides the mineralogist in his investigations, when searching for those minerals which are so beneficial to man in his state of civilized society.

Mineralogists have divided the rocks which compose the globe into four classes, viz.

1. Primitive Rocks.
2. Secondary, or Transition Rocks.
3. Floetz, or Newer Secondary Rocks.
4. Newest Floetz Trap Rocks.

In the primitive class of rocks, granite, which generally forms the highest parts of mountain ranges, is reckoned by mineralogists to be the lowest series of rocks, and upon which all the other rocks rest.

It is worthy of particular remark, that the four classes of rocks before mentioned, lie in regular succession, the primitive rocks being the lower series, and the newest floetz trap rocks being the last in succession; and although the rocks composing each of the four classes may alternate variously with each other, yet the order of the four classes has never been found inverted; that is, the primitive and secondary rocks have never been found overlaying the other two classes of what are termed newer floetz rocks.

Beds of coal have not hitherto been found in the primitive or transition class of rocks, but they are found in great abundance in the third class, termed the floetz or newer secondary rocks. Coals are also found in the newest floetz trap formation; but the coal-fields are not extensive, though they are sometimes of uncommon thickness.

One striking and discriminating mark in these rocks is, that in the primitive class not a vestige of organic remains is to be found, and very few in the secondary rocks, whereas the strata which compose the coal-fields abound with innumerable impressions and forms, both of animals and vegetables: The whole arrangement of the strata of the coal-fields exhibits a structure and form most distinctly differing from the other classes of rocks, and, therefore, has been with much propriety termed by the celebrated Werner, *The Independent Coal Formation.*

The strata or rocks which accompany coal are chiefly as follows:

1. Sandstone of various hardness and colour, viz. shades of white, grey, and light red.
2. Slate-Clay.
3. Bituminous shale.
4. Indurated argillaceous earth or fire-clay.
5. Argillaceous ironstone.
6. Greenstone.

Although the independent coal-formation occupies a great area of Britain, as before mentioned, its continuity is frequently interrupted by mountain ranges and rock formations of very considerable extent, where no coal is to be found; and even in those districts where there are valuable fields of coal found, the beds of coal do not in general extend over a great district of country, without being interrupted by what is commonly termed troubles, or more properly dikes and slips; hence the difficulties which occur in working coals, and the caution requisite in searching a district for them.

The beds which compose the first and second class of rocks generally lie in a situation forming a great angle with the horizon, being in many cases nearly vertical, whereas the strata composing the coal-formation are commonly found forming a small angle of elevation with the horizon, although there are instances of their being absolutely vertical.

In some coal fields there is only found one bed of coal, and in others a very great number, varying in thickness from an inch to many feet; it must, however, be remarked, that those beds of coal which are very thick, have generally thin beds of stone running through them in a horizontal position, forming a number of snbordinate beds of coal, lying very close to one another, having, however, the appearance of one thick bed of coal.

In order to exhibit in a clear and distinct view, the various strata connected with beds of coal, the thickness of the coals, and alternations of the strata betwixt them, the following sections are examples, taken from the chief coal-fields in England and Scotland.

		170	1	6

The preceding section contains sixteen beds of coal, of various thickness, amount'ng to thirty feet two inches, many of which are unworkable. The quality is of the rich caking kind, such as the Newcastle coals in general are; they are soft in their texture, break into very small pieces, and abound much with inflammable air.

In the sections which have been formerly made of the Newcastle coal-field, the term *Whin* is applied to many of the strata; these strata, so named, are, however, not *Whin*, but are sandstones of the hardest kind. This misapplication of the name *Whin*, (or Greenstone) has led mineralogists to wrong conclusions as to the coal formation of that district.

		107	0	0

The preceding section contains thirteen beds of coal, of various thickness, amounting to 69 feet 3 inches. The first four coals constitute a thickness of 33 feet; these are wrought as one bed, under the name of the ten yard coal; they are of open burning quality, break into large quadrangular pieces, abound with inflammable air, and are very liable to spontaneous ignition.

Indurated and fire clay predominate in the stratification; but the precise systematic names are not easily applied from the descriptions received. The names given to the coal strata in Staffordshire are very uncommon, and altogether local. These provincial terms are so various, that they present a great difficulty in comparing the strata of one district with another.

In the preceding section there are 24 beds of coal, of various thickness, amounting to 59 feet 4 inches, but many of them are unworkable; all of them are of open burning quality, and break into large quadrangular pieces. They contain no inflammable air, but the carbonic acid gas is very abundant. It will be seen from inspecting the section, that sandstone abounds in the stratification, and that there are several considerable beds of red sandstone. It is necessary to remark, that the red sandstone of the coal-fields is altogether different from what is termed the *Old red sandstone*, in which no coals are supposed to exist. The red sandstone of the coal-fields is of a bluish colour, whereas the other sandstone is of a deep red, and much closer in the grain.

The above is a very interesting section of a coal-field, which according to *Werner* belongs to the *Newest Floetz trap formation.* The striking peculiarities are,

1*st*, The great body of greenstone of the common crystalized texture, known in Scotland by the name of blue whinstone, found at the surface, and lying above the common coal strata, which are comparatively soft and have little coherence.

2*d*, The vast body of coal lying together, consisting of 10 beds. There are only 7 beds in the section, but the fourth coal is commonly reckoned three beds, and the lower coal two beds, there being a difference in the quality, with thin divisions in some places betwixt them. The whole thickness is 90 feet 2 inches. Some of the coal is of the open burning kind, but the great part is of the close burning quality, similar to the Newcastle coal, and breaks into small pieces. The coal abounds with inflammable air, and is liable to spontaneous ignition. In a great part of this coal-field the coals amount to only one-half of the thickness represented in the section; but in the place where the section is taken, the coals lie as if they had been cut through, and one-half slid over the top of the other. This singular coal-field is very limited in point of extent.

From an inspection of the four preceding sections it will be seen, that although the alternations of the strata are various, they may be referred to two kinds; viz. *sandstone* and *clay* variously modified; the only exception is the *greenstone*. There is no bed of limestone in any of them; this is however one of the strata found in coal-fields, and sometimes forms the roof of a coal. Beds of limestone are generally found in the lowest series of the coal strata of a district.

With regard to coals termed workable or unworkable, this does not depend upon the thickness of a bed of coal, but upon the price obtained for it: so that a coal which is unworkable in one district, on account of its thinness, would be workable to advantage in another.

The greatest depth to which coal strata have been ascertained is 500 fathoms. This has been done in the Newcastle district, but it is not supposed that they go down to an indefinite depth, from the bason shape of coal-fields. It is with reason supposed, that the rocks upon which the Northumberland coal-field rests are a continuation of the metalliferous beds which form mountains towards the county of Cumberland.

No coal-fields of any extent are found to be absolutely flat, although small portions of them may be so; they generally lie with an angle of inclination to the horizon; they are, however, found at every various angle of inclination; viz. from the horizontal to the perpendicular line; but the most common range of inclination is betwixt 3 and 11½ degrees; that is, from a rise of one foot perpendicular in twenty feet horizontal, to one foot perpendicular in five feet horizontal. In coal mining the angle of inclination is seldom mentioned, the common term for the inclination, or dip, being stated as one in five, one in ten, or one in twenty, according to the circumstances of the case. A coal is reckoned very flat, which lies at an inclination of about one in twenty; and a coal is reckoned to have rather a great inclination, or what is termed a quick dip, when it lies at an inclination of about one in four. Coals having an inclination of from one in three, to one in one, are termed half edge coals; and those which have a greater inclination than one in one are denominated edge coals.

As coals with their concomitant strata lie in a conforming situation, and parallel to each other, similar to the leaves of a book, and at an inclination with the horizon, having a cover of earthy alluvial matter in general over them of considerable thickness, each of the strata meets the alluvial cover in the manner as represented, Plate CCCLXXXVIII. Fig. 1. where A is the surface line, B the under part of the alluvial cover C, and *a*, *a*, *a*, coals with their accompanying strata. This alluvial cover is found to be of various thickness, from a few inches to many fathoms; and it is this covering which creates the greatest difficulty in searching for coal and other minerals. It is in mineralogy to the strata which are underneath, what the flesh is to the bones in anatomy, when the covering is removed, the absolute structure is at once seen.

In describing the absolute forms or shapes of coal-fields, it is necessary that the cover of earth above the strata be considered as removed, that every point may be more easily comprehended; and, to render the subject less intricate at first, we shall consider the coal fields as being of a regular shape, and without dislocations.

In general, coal-fields have either the form of a circular or long elliptical bason, or are segments of these figures; so that no extensive field of coal lies as to itself in the same plane, though a small portion of it may appear to be so. There are but few instances of the entire bason form, but this form we shall first explain, in order to lead on to the more intricate varieties which occur. Plate CCCLXXXVIII. Fig. 2. represents the horizontal section of an elliptical coal-field, with the coals A and B rising to the surface in every direction, with their accompanying strata, and dipping to the centre of the bason C. Fig. S. is a section of the bason in the line DE. It is evident from an inspection of the figures that the strata in the line FG (Fig. 2) have a greater dip than the strata in the line DE, because they reach the centre of the bason in a shorter horizontal distance; hence, if the bason were forty times longer than it is broad, the dip of the strata from D to C, and from E to C, would be very flat when compared with the dip from F to C, and from G to C, which would be comparatively great. Here we conceive the bason to be of a regular elliptic form, but we find in general that the transverse line DE does not divide the bason equally, but unequally, as represented in Fig. 4. where it is evident that the dip of the strata from H to C is much greater than the dip from I to C, so that while the coals from C to I are flat, having a moderate rise, the coals from C to H have a great rise, and are frequently of the class of edge coals. A right understanding of these plans and sections will make the other figures of a coal-field and segments of the bason more easily comprehended.

The next form or shape of a coal-field is that which is semi-elliptical, as represented by the horizontal section (Plate CCCLXXXVIII. Fig. 5) where A and B are coals with their accompanying strata, having their line of bearing in the direction C. D, and the line of dip from E to F, these coals are cut off in the line of dip by a natural fissure in the strata C. D; hence, in prosecuting the working of the coals to the dip, they are lost, and in place of coal, nothing but stone, or the strata accompanying coal, are to be found: the nature of this fissure or obstruction will be explained afterwards.

These forms of coal-fields now described, or modifications of these forms, are what we find the most common. There are, however, instances of the inverted bason form, and of inverted segments of it; but these are very rare in comparison with the other. Fig. 6. is the vertical section of this form, A, B, C, represents the coals dipping in every direction to F and G.

The cover of earth which lies above the strata is of two distinct kinds, both of which are alluvial, the one older than the other, viz.

1. The recent alluvial cover.
2. The old alluvial cover.

The recent alluvial cover is found by the sides of rivers and arms of the sea, in general very little elevated above the surface of the waters which evidently formed them.

The old alluvial cover succeeds the recent alluvial cover, is in general more elevated, and extends to the tops of the mountains; there, however, it is found very thin. It is in the intermediate moderately rising ground where it is found of the greatest depth.

The recent alluvial cover we have found to be in some instances nearly 100 feet, and the old alluvial 180 feet in depth, above the rock.

The recent alluvial cover is generally composed of soil, clay, wet sandy loam, sludge, and sometimes beds of peat earth, also beds of gravel; and in digging through it, trunks of large trees and brushwood are frequently found, with beds of sand containing great varieties of sea shells; adjoining the arms of the sea, the remains of marine animals from the largest to the smallest size are also occasionally found. In the alluvial cover, by the sides of quick running rivers in coal districts, pieces of coal and of the accompanying strata abound, but adjoining slow running rivers and arms of the sea, these fragments are seldom to be found, excepting when brought there accidentally.

The old alluvial cover is commonly composed of clay intimately mixed with sand, small rounded stones, and frequently with boulder stones, from a few pounds to several tons in weight; it is quite impervious to water, and is termed *till* by agriculturists. In examining this cover when broken up, it is found to contain fragments of almost all the strata of the adjoining coal-field, such as sandstones, slate-clay, ironstones, and coal, the largest only a few inches in size, the angles sharp, which show they had not suffered by attrition. It is remarkable that no remains of trees or plants are to be found in this earth, nor any remains of marine animals or shells, though immediately adjoining the recent alluvial soil, where they are so abundant. This cover has sometimes beds of sand in it, and at the foot of mountains is mixed with many fragments of the mountain rocks.

As to the general situation of coal-fields with their accompanying strata, they are found,

1. Under the level of the sea.
2. Above the level of the sea, moderately elevated.
3. Considerably elevated above the level of the sea.

Having considered the shape or form of coal-fields as uniform and entire, we have now to describe the dislocations and ruptures of the strata, for it is found in practice, that in place of a regular figure, the bason form is broken, dislocated, and deranged, forming segments of every various form, the dislocations, extending from a quarter of an inch to upwards of 600 feet, in a perpendicular or sloping direction, or separated horizontally from the breadth of an inch to upwards of 100 feet: It is these dislocations, which render the searching for coal, and the operations connected with the working of it, so difficult and intricate, while at the same time they are frequently of the greatest benefit.

The dislocations and obstructions which are found in coal-fields, are known by the names of

1. Dikes.
2. Slips.
3. Hitches.
4. Troubles.

The three first relate to the dislocation of the strata, the fourth, or what is termed troubles, relates to the changes which take place in the bed of coal.

A dike is like a wall of extraneous matter, which divides all the beds of coal found in a coal-field. It varies from a few inches to many fathoms in thickness, and penetrates through the strata to the greatest depth the miner's operations have yet reached; they are composed of,

1. Sandstone.
2 Greenstone.
3. Basalt.
4. Porphyritic clay mixed with white calcareous spar.
5. Heterogeneous mixture of the coal strata.
6 Water gravel.
7. Quicksand.
8. Old alluvial clay.
9. Recent alluvial clay.

The first five in the order may more properly be named dikes. The four last are more commonly known by the name of gaws, gashes, or chasms.

A slip is a fissure in the strata, from the tenth of an inch to two or three feet in width; which fissure is filled with rubbish and fragments of all the strata found in the coal-field. The strata, on one side, are slipped past those on the other side of the fissure, and this dislocation receives the name of a slip, where the coal has slipped off its parallelism fully its own height. These slips are found from the extent of a few feet, to upwards of 600 feet perpendicular.

A nitch is a smaller kind of slip, where the dislocation is from an inch to the extent of the thickness of the coal. In some mining districts, slips and hitches are known by the very appropriate name of steps.

Troubles affect the stratum, or bed of coal, not only as rendering it very difficult to work, but very inferior in quality, and frequently altogether useless as an article of commerce. These troubles are not found in the chief extent of a coal-field, they only affect it partially, and may be classed under the following heads :

1. Stone in irregular beds.
2. Nips.
3. Shaken coal.
4. Foul coal.
5. Pyritaceous, or brassy coal.
6. Sparry coal.
7. Stoney coal.
8. Black coal.
9. Sooty coal.
10. Dike coal ; named,
    a, Burnt coal.
    b, Dander coal.
    c, Humphed backs.
11. Glazed backs.
12. Troubles in the roof and pavement.

The position and effect of these dislocations and troubles have now to be described.

Dikes, as to their longitudinal direction, are found not only stretching in the line of bearing through the coal-field, but in every direction, sometimes for many miles nearly in the same straight line, while other dikes havh irregular deflections, but without sharp angular turns. It seldom occurs that great dikes are numerous in a coal district, but the contrary is frequently the case with dikes of a small size ; they can only be seen in the beds of rivers, or on the sea-shore, but those of greenstone and basalt, from their superior hardness, frequently rise above all the other strata, like a crest or projecting ridge.

Dikes of greenstone, of a few feet to three or four fathoms in thickness, are found sometimes very numerous, even in a very limited extent of coal field, not exceeding the area of 200 acres, lying in various directions, and crossing one another. Fig. 7. Plate CCCLXXXVIII. represents the horizontal section of a coal-field, intersected with greenstone dikes. AB and CD are two dikes lying parallel to each other, EF and GH are cross or oblique dikes, which not only divide the coal strata, but divide and separate the dikes AB and CD. In looking at a horizontal section of a coal-field, the dikes, which intersect it, appear to affect the strata no more than the dividing and separating of them, excepting when greenstone dikes occur, in which case, a change of the coal adjoining them is very evident, as will be noticed afterwards, when the effects of dikes upon the strata in the verticlal section are treated of. But before entering on this subject, the longitudinal direction of slips will be considered.

Slips run in a longitudinal direction through the strata of a coal-field, and in every obliquity to one another. Fig. 8. Plate CCCLXXXVIII. represents a horizontal section of a coal-field, with two slips, AB and CD, in the line of bearing, which throw the strata down to the crop ; this is the simplest form of slips. Fig. 9. represents part of a coal-field intersected with slips somewhat similar to a broken sheet of ice. In this Figure, AB is a dike ; all the other lines and ramifications in the figure are slips of every variety and kind, producing dislocations from the least measurable distance to many fathoms ; the slips at the points marked *a*, *a*, *a*, disappear ; the lines at C represent four slips of a small size, known by the name of hitches.

There does not appear any general law as to the line of direction of these slips, only the ramifications are generally more in a dip and rise direction, than in the line of bearing of the coal-fields.

The effects of dikes and of slips upon the coal strata, when viewed in a vertical section, are more evident than in the horizontal section, where they only appear like walls, veins, and lines of simple separation. Fig. 10. Plate CCCLXXXVIII. is a vertical section of a coal-field from dip to rise, with three strata or beds of coal, *a*, *b*, *c*. AB is a dike at right angles to the plane of the coal strata. This rectangular dike has only the effect of dividing and separating the coals, and all the accompanying strata, but produces no alteration in the line of rise ; but further to the rise, the oblique dike CD interrupts the coals *a*, *b*, *c*, and not only divides and separates them, but throws them and all their accompanying strata greatly lower down ; but though thrown down, as represented in the figure, the coals and strata still keep the same parallelism and direction of rise. Still further to the rise, the oblique dike EF interrupts the coals *a*, *b*, *c*, and not only divides and separates them, but throws them, and all their accompanying strata, greatly up, and produces a much quicker dip and rise, as represented in the figure. Sometimes the coals in the division H, betwixt the dikes C and E, are found nearly horizontal, and the effect of the dike EF is sometimes such as to throw out the coals altogether, so that no vestige of them can be found in the division K. Such are the most prominent changes in the strata, as to their line of direction produced by dikes ; but of these changes there are various modifications.

The effect of slips on the strata is represented in the vertical section, Fig. 11, where *a*, *b*, *c*, are coals with their accompanying strata. AB is a slip which intersects the strata, and throws all the coals of the first compartment very much lower, as represented in the compartment No. 2.; and, from the magnitude of the slip in this instance, it throws in other coals, marked 1, 2, 3, which were not found in the compartment No. 1. CD represents a slip having the same effect, but not to the same extent. EF represents a slip intersecting the strata, but contrary to the former in its position ; the effect of this is, that the coals *a*, *b*, *c*, are thrown up, as represented in the compartment No. 4. Sometimes this slip brings into view coals situated under these marked *a*, *b*, *c*, such as the coals 4, 5 6 ; and when it happens, as we have freequently seen, that a coal marked 4 is directly opposite a well known coal, as *e* in the compartment No 3, the case is difficult and bewildering to the miner. Besides these varieties, we find a number of slips or hitches often very near to one another, as in the compartment No. 5, where the dislocation of each slip is not great, but the amount of the whole forms a considerable slip as to the coals in the compartment No. 6. These are the general effects of dikes and slips in a vertical section of the strata from the dip to the rise; whether these dislocations lie in the line of bearing, or with a moderate angle of obliquity to it, that is under 45 degrees. The effects of dikes and slips, in pursuing a dead level course direction, are exemplified in Fig. 12. Plate CCCLXXXVIII. Where the coals and accompanying strata are of course horizontal, and the dikes and slips, lying at a greater angle than 45° to the line of bearing, they are termed dip and rise dikes, or slips, as AB, CD, EF.

From what has been stated regarding the effects of dikes and slips, as to the dislocation of the strata, independently of any changes produced in the coal and strata adjoining, to be noticed afterwards, those who are employed in conducting the operations of collieries, consider that these dislocations follow a general law, which is this: Let Fig. 1, Plate CCCLXXXIX. represent a stratum, or bed of coal, with the accompanying strata; A, the pavement of the coal, and B the roof; if, in prosecuting the mine, as at C, a dike, D, is met with, which forms with the pavement a right angle, viz. of 90°, it is concluded that the dike only has divided and separated the strata its own thickness, so that when a mine is driven through it, the coal is found directly opposite; but, in the further prosecuting of the mine, if a dike, F, is met with as at E, which forms an obtuse angle with the pavement, that is, an angle greater than 90°, it is concluded that the dike has not only divided and separated the strata its own thickness, but has thrown up the coal and accompanying strata, which, on running a mine through the dike, is found to be the case as at G. Lastly, if a dike H is met with at I, forming an acute angle with the pavement, as in the figure, that is, an angle less than 90 degrees, it is concluded that the dike has not only divided and separated the strata its own thickness, but has thrown down the coal and accompanying strata, which, on running a mine through the dike, is found to be the case, as at K.

The same very useful and important law holds as to slips, with this difference, that when the slip forms an angle of 90° with the pavement, there is a great uncertainty whether the strata on the other side are thrown up or down; and this can only be proved by mining and boring; only it must be remarked, that if, in perforating the slip, the coal is found neither thrown up or down, the occurrence is not a slip, but simply a fissure of the strata.

Dikes and slips are denominated upthrow or downthrow, according to the position in which they are met in working the mine. Thus, in Fig. 10. Plate CCCLXXXVIII. if the miner is advancing to the rise, the dike AB neither throws up nor down. CD is a downthrow dike to the rise of a certain number of fathoms, and EF is an upthrow dike also to the rise. On the contrary, if the dikes are met with in working from the rise to the dip, the names of the dikes, as to being upthrow and downthrow, are exactly reversed; viz. what was an upthrow in the first instance, is a downthrow in the second; and, in meeting the dikes or slips this reverse way, the same law of course holds as to the angle formed by the pavement, and the intersecting line of the dike or slip.

In the same manner, dikes and slips, which run from the dip to the rise direction, are denominated upthrows or downthrows, to the east, to the west, to the south, or to the north, according to the line of bearing of the coal-field, and the direction in which the dikes or slips are met with in the mine; so that a dike or slip which is an upthrow to the east, when pursuing the coal mine eastward, is a downthrow dike or slip, when pursuing the coal mine westward.

Hitches are slips of the strata of a small size, and are so denominated when the slip or dislocation does not exceed the height of the coal; they are frequently very small, even the least part of an inch, yet though of the smallest size, their effects are distinctly visible affecting the coal. Hitches are frequently denominated, very appropriately, *steps* by the miner. Plate CCCLXXXIX. Fig. 2. shews the effect of hitches upon the strata, where the hitches A, B. C, D. E, F, G, H, dislocate the coal and accompanying strata. At A the hitch is the height of the coal, at B it is half the height up, at C and D the effect is less, at E it is nearly the height of the coal, at F the effect is scarcely visible, at G it is down, and at H the coal is again thrown up to the extent of its height. Hitches do not extend generally very far, either in a longitudinal or in a perpendicular direction; for though they may be found in one or two coals in a coal-field, they may not be seen in the the upper or under coals, so that their effects in the coal-field are commonly very limited, when compared with the effects of dikes or of slips.

Troubles.—These affect the stratum or bed of coal, and are of various kinds, as before mentioned, viz.

1st, *Some in irregular beds*.—This trouble sometimes begins as a horizontal division in the coal scarcely visible, gradually increasing in thickness, and that frequently to such a degree as to render the coal altogether unworkable; in a thick bed of coal, a stone of this kind sometimes increases from a line even to several fathoms in thickness, in which case one or other of the portions of the coal thus divided, is either abandoned as unworkable, or each of the two divisions is wrought as a separate and distinct coal. It is to be remarked, that the two portions of coal are together generally equal in thickness to the bed of coal before the stone made its appearance; if however bands of stone or of argillaceous clay are found lying regularly through coals in a coal-field, these are not reckoned troubles.

2d. *Nips*.—This is a very remarkable trouble in coal, and is not very common; it is produced by the roof and pavement of the coal gradually approaching each other, until not a vestage of coal is to be seen. The extent of this trouble is from an area of a few feet to that of many acres. The horizontal form of a nip is very irregular, and when found, no idea can be formed of its extent; it is frequently the case, that if the coal has an argillaceous roof and pavement, these disappear with the coal, and the upper and under harder strata of sandstone are in contact, divided only by a very thin sooty line. Plate CCCLXXXIX. Fig. 3. represents the vertical, and Fig. 4. the horizontal section of a nip.

3d. *Shaken Coal*.—By this trouble the texture of the coal is not only destroyed entirely, but the whole of the coal from roof to pavement is of no use whatever; the roof and pavement generally keep their common parallelism, and no convulsion is to be observed in the adjoining strata. The shaken coal has the appearance of the rubbish of an old coal waste, being a heterogeneous mass of dusty coal, mixed with small cubical pieces of good coal. This shaken coal is so soft, that frequently it can be dug with a spade.

4. *Foul Coal*.—This denomination of trouble is ap-

plied to no specific kind of coal, every coal which is deteriorated in quality, or so mixed with heterogeneous matter as to be useless, or the greater part so, is denominated foul coal.

5. *Pyritaceous Coal*, or the *Brassy Coal* of the miners.—This trouble arises from the coal being so mixed and entwisted with pyrites as to be of no use as coal. It may be remarked, however, that the term pyritaceous coal is not applicable to those coals which have pyrites in them of a lenticular form, and which can with ease be separated from the coals, for these do not deteriorate the quality of the coal as they are picked out.

6. *Sparry Coal.*—This trouble arises from the coal having an increased number of fissures together, and filled with a hard white sparry substance, the sulphate of lime, so that the coal is rendered useless and very difficult to work.

7. *Stoney Coal.*—This trouble arises from the coal becoming very much mixed with stone in an irregular manner. These stones do not lie in regular beds; and they are so intimately joined or connected with the coal, that they cannot be taken out without destroying and breaking to small pieces a great proportion of the coal to which they are attached; on which account such stoney coals have frequently to be sent to market with the stone in them, which is greatly against their sale. Coals having regular bands of stone in them, and which are easily separated, do not come under the denomination of stoney coals.

8. *Black Coal.*—This is a trouble which rather affects the appearance than the absolute quality of the coal; it generally occurs suddenly, that is, while in one part of the coal-field the coals have the common bright fracture, a slip or hitch of very trifling magnitude will produce on the other side coals termed black coal. The appearance is dull, without the least lustre. It is equally compact in texture as the other coals of the field, and burns well. This trouble, however, greatly reduces the value of the coal at market, its appearance being so very much against it.

9. *Sooty Coal.*—This trouble renders the coal of a dead, sooty, friable appearance, and of no use, is never of great extent, nor does it appear to have arisen from any convulsion of the immediately adjoining strata, as the roof and pavement where it occurs keep their parallelism with each other. This trouble is, however, generally found when approaching some considerable dislocation of the strata, such as a slip or dike.

10. *Dike Coal*, named also *Burnt Coal*, *Dander Coal*, or *Humphed Coal*, are all names applied to the same kind of trouble in the bed of coal. The particular names above mentioned are applied by the common workmen and miners, the name dander signifying *scoria*. The appellation humphed is a provincial term, and only used amongst miners, signifying the same thing as burnt or dander coal. This kind of trouble is in general found to exist on both sides of dikes composed of greenstone, basalt, or prophyretic clay; the trouble beginning at a distance from the dike on both sides, the coal at first by degrees losing its bright fracture and becoming *black coal*, then burnt or dander coal, which next the dike appears run into a tortuous mass, with irregular cellular cavities, and is more of the nature of a dull, black, stoney matter, than any thing connected with coal. Coal found in this kind of trouble has none of the qualities of glance coal, the blind coal of Scotland, or the stone coal of Wales; for, although placed in a heap, they will not kindle though fire is applied, they will grow red hot, but instantly cool, as stones would do when heated and the fire withdrawn. Some pieces are found occasionally of the purest kind of glance coal, with a very bright metallic lustre, and so hard as to be with difficulty scratched with a knife; such coal is divided by numerous small veins of a white sparry substance. This kind of trouble, besides being found adjoining dikes of the above description, is found occupying considerable districts of a coal-field; and though no change is observed in either the roof or pavement, the coal is completely useless, and will not burn though fire is applied to it. It is, however, in general different in appearance from the coal found adjoining dikes as before mentioned, in as much as more of the stratified texture remains, and is not run into a tortuous mass with irregular cavities. It has been asserted by some miners, that this change is occasioned by greenstone or basalt being near the coal, either above or below it. This we presume remains to be proved.

The term burnt coal is not known amongst mineralogists, or rather is not admitted; the name is applied by the unlettered miner, from the simple ideas rising in his own mind, being altogether a stranger to those theories which so warmly interest and so much divide the philosophic world. It must be particularly remarked here, that when a coal-field is working of the common coal, it is sometimes gradually changed into a species of glance-coal, which burns of itself, when ignited, and is used for economical purposes, has no smoke, and only a blue flame, with intense heat. This is not reckoned one of the species of the burnt coal of the miner, but is simply one of those changes in quality incident to coal.

11. *Glazed Backs*, *Lips*, or *Leips.*—This is a trouble in the coal more generally found in an oblique direction as to roof and pavement, seldom perpendicular; they are also more frequently found lying in the line of bearing, than in a crop and dip direction, and are distinctly different from the natural divisions found in coal. Although there can scarcely be perceived any slip in the roof, it is evidently a slip of the very least degree which occasions this trouble. Both sides of the fissure are smooth and glossy, and the coals thus divided have no tenacity, which renders this trouble dangerous to the miner by the coal falling suddenly forward without warning. A single fissure of this kind can scarcely be called a trouble, but when many of these are near to one another, the coal is injured, and the roof rendered very dangerous.

12. *Troubles in the roof and pavement of the Coal.*—These troubles are more generally found when approaching a dislocation of the strata, though they are occasionally found in other parts of the coal-field. They affect the roof with narrow pendent ridges of stone or protuberances, at times very close together, in other instances like long inverted waves. The troubles in the pavement are generally sudden wave-like swellings. These troubles frequently affect the coal very much, rendering it sometimes not only firmer in the texture, but uncommonly hard; at other times the coal adjoining them is soft, and so deteriorated as to be altogether useless.

Besides these troubles, there is frequently another kind found in the roof, of a very singular form, known by the name of a *pot bottom*, or *cauldron bottom*; they are from the size of a few inches to five feet in diameter. One of these is represented in Plate CCCLXXXIX. Fig. 5. In working the coal, the miner generally knows that he is approaching one of these by the coal becoming harder and more twisted in its texture, and this continues till the trouble in the roof is passed. The general form is similar to that represented in Fig. 5. *a* is the bed of coal, *b* the pot bottom, having an irregular and rough inverted mouth of stone, *d* is coal generally from half an inch to an inch thick, altogether different in texture and appearance from the bed of coal, with which it is connected, being of a bright pitchy lustre, and breaks into very small pieces; sometimes it is of the nature of glance coal. The stone *b* which fills the inverted pot is frequently of the same kind of stone which composes the roof, but more frequently is an argillaceous stone, of the nature of good fire-clay. The sides of the pot bottom at *d* are generally as smooth as glass and furrowed in the vertical direction, so that there is no tenacity where the sides of the pot bottom join the roof; this circumstance renders these troubles very dangerous, particularly when of a large size. The peculiar singularity attending this trouble, is the uniform twisted texture and alteration which are found in the coal immediately under it, without any mixture of the stone which composes the pot bottom.

The Roofs of coal are formed of all varieties of the coal strata, as may be seen from the examples of stratification in the preceding part of this treatise. As roofs they are of various quality, from good to very bad; a roof is reckoned good which keeps entire, not only while the coal is working, but for a considerable time after. Sometimes a stratum of roof stone next the coal comes down along with the coal while working, named a *following*, leaving a firm roof-stone above; at other times a stratum or two of the roof-stone have to be taken down shortly after the coal is wrought: this is also termed a *following*; and while the miner works under it, he supports it by prop-wood for his own safety; but these are not reckoned dangerous roofs.

A bad roof is that, which, having little tenacity in itself, cannot be kept up either in boards, rooms, or in narrow mines, even by the aid of prop-wood; it has, therefore, to fall in the waste, care being taken to keep it up along the wall-faces; and the iron rail-roads are in some bad roofs laid upon the top of the fallen strata. The roofs which are most dangerous to the workman are those where the roof stratum is thick, with many open cutters in it, or where there are irregular beds, thick in the middle and wedge-shaped towards the edges. These roofs give no warning before they fall, by which the danger is much increased. The ordinary way in which a miner tries the roof to be safe or not, is to strike it gently with the side of his pick; if the sound produced is sharp and clear, he concludes that the roof is good, but if the sound is obtuse and hollow, he is certain that the roof is bad and dangerous. He may, however, be deceived in trying a roof composed of a thick stratum, as it will produce a clear sound, though ready to fall, owing to the cutters with which it is intersected.

Having stated the effects of dykes, slips, and hitches, as to the dislocation of the strata, the changes produced by them upon the coals and strata adjoining have now to be noticed.

When coals approach dykes composed of sand-stone, heterogeneous mixture of stones, water, gravel, quick-sand, or clay, we seldom find any great change in the composition of the coal, excepting that it is either rendered a little softer or harder, with the natural fissures occasionally very open, and filled with sulphate of lime and pyrites, or with sand or clay when close to dikes of this composition. The strata adjoining are in some cases rendered flatter than in the general coal-field; in other cases the dip and rise are greatly increased, and the line of level frequently altered. We have, however, to notice a very remarkable and decided change in the stratum or bed of coal, as it approaches dikes composed of greenstone, basalt, or porphyritic clay, dikes of greenstone or of basaltic rock, (the common blue whinstone of Scotland,) are much more common in the coal-field of Scotland than the porphyry dikes; and their effects are well known, as they are frequently met with in several of the mining districts. The first indication perceived in approaching one of these dikes, is, that the coal begins to lose its common brightness in the fracture, and assumes a dull black appearance, but still retains its common qualities of good burning coal, with very little difference; but every foot of advance towards the dike the coal becomes worse, loses every appearance of common coal and all its qualities; the texture of the coal is lost, and the whole stratum of it becomes a mass of black stoney matter, as before described, when treating of troubles appertaining the bed of coal, under head No. 10. *Dike Coal.* Adjoining to the dike, the cavities of this coal are sometimes filled with a soft yellowish clay, having an unctuous feel; this clay is also sometimes found in the fissure betwixt the coal and the face of the dike, when the dike is cut through. The coal on the other side is found exactly changed as in the approach to the dike before mentioned, viz. hard, stoney, and cellular next the dyke, and these qualities gradually disappearing till the coal assumes its common lustre, with all the qualities of good coal, as found before the deteriorating symptoms appeared on approaching the dike.

When coals approach slips, a variety of changes are found, and they are very seldom met without symptoms appearing of their approach, particularly if they are of considerable magnitude. The most common symptoms of their approach are, numerous hitches, swellings in the roof, sudden risings or wavings of the pavement, the coal much stronger in its texture than common, and more difficult to work; at other times much softer than usual, and this softness at times increases to such a degree as to lose all firmness of texture. In this state it is sometimes like coal dust mixed with small cubical pieces of good coal; at other times it is found uncommonly friable, somewhat like soot. The occurrence of iron pyrites is very common, in some instances filling fissures and cavities, having a beautiful golden lustre, and crystallized, some of the crystals forming cubes of more than half an inch in size, and finely laminated; in other instances, the pyrites are so run into and entwisted with the coal as to form a very heavy mass of singular texture. We also find the sulphate of lime very abundant near to slips, filling up the numerous fissures of the coal, and entwisted with it coals of the soft and of the sooty quality above mentioned; where the pyrites and sulphate of lime abound, the coals are of no use as fuel. An increase of water from the fissures, as a dike or slip is approached, is also common; and when the slip is found, very great feeders of water sometimes occur. If the coal is dry, inflammable air (if found generally in the coal field) comes off in great quantity; and there are instances of inflammable air being found at a dike or slip, though never seen before in the district.

Sand-dikes, or gashes containing quick sand, are dangerous from the quantity of water they contain, which is found in some instances so great as to drown and destroy the colliery, if not prevented by powerful means.

We have now to describe the general effect produced upon the coals and accompanying strata by dikes and slips, in order to shew how coals wave, or are spread over a great district of country; and this is essentially necessary before attempting to describe the modes which have been adopted in searching and boring for coal.

Although, as before mentioned, there are instances of coal-fields of a circular bason form, and more commonly of a long elliptical shape, yet there are few instances, comparatively, of this entire form, either in the right or inverted position; yet we reckon that the entire bason form is the true and complete form of a coal-field, and that the general form of coal-fields are portions of this bason shape, produced by the natural effects of dikes and slips, of which the following detail, with the corresponding figures, Plate CCCLXXXIX. will elucidate. Fig. 6. represents a horizontal section or plan of a coal-field, as found immediately under the alluvial cover. Only two beds of coal are represented in this example, that the subject may be rendered as little complex as possible, and, therefore, whatever changes in position, and whatever dislocations take place in the coals, take place also in all the accompanying strata, at least this may be admitted in a general point of view. The area in the figure is supposed to contain a space of 64 square miles, viz. a square of 8 miles on the side. The coal district is bounded by transition rocks on the north, more elevated than the coal district. A, is an elliptical bason-shaped coal-field, where the coals *a*, *b*, dip inwardly, as represented by the points of the arrows, but they dip much quicker next the transition rocks, as they then conform with the dip of these; and though the coals are the same distance from each other in every part of the bason, when measured at right angles to the pavement, they appear in the horizontal section much closer upon the north than on the south side of the bason. This apparent difference depends entirely upon the angle of inclination which the coals make in particular positions with the horizon, as will be shewn distinctly in the vertical section. Upon the south of the coal-field A, the slip B is found dislocating the strata, throwing the coals down from the surface 140 yards to the south, and forming the coal-field C, where the same coals of the coal-field A are found again, having the same parallelism of dip. The slip D is found upon the south of the coal-field C, dislocating the strata, and throwing the coals down from the surface 100 yards to the south, and forming the coal-field E, where the coals of the coal-field C are also found. The slip F is found dislocating the strata, and throws the coals down 210 yards, and forms the coal-field G in the same manner as the former coal-fields, as represented by the coals *a*, *b*. The coal-field G, in place of a slip to the south of it, takes, as it is termed, a counter dip, occasioned by a ridge in the strata of a saddle shape, beyond which ridge the same coals form with a contrary dip, as represented by the arrows, and form the coal-field H. In this manner coal-fields are found stretching over a district of country in a crop and dip direction, somewhat similar to what is represented in the Figure, but with many varieties arising from the obliquity of the slips to each other. This spreading out of the coal-fields in the crop and dip direction is produced by slips generally lying, not parallel, but somewhat in the direction of the line of bearing, and by ridges and counter dips lying in the same direction. Besides the coals *a*, *b*, inserted in the Figure, as an example, all the coals, above and below these, with their accompanying strata, suffer the same alteration as before mentioned.

While these slips and dislocations lying nearly in the line of the bearing of the coal have the effect of throwing the coals over a district of country in the line of dip and rise, the dikes, slips, and dislocations which lie in an oblique direction to the former, such as the slips marked K in the Figure, have the effect of stretching or extending the coal-field over the country in the line of bearing. The lines marked L, are dikes which only separate the strata the thickness of the dike, without throwing the coals and the accompanying strata either up or down. It will be seen from the Figure that the oblique dislocations, when they throw the strata down, and the same parallelism of dip remains unaltered, that the crops extend to a greater distance before they meet the alluvial cover; and, on the contrary, when the slip is an upthrow, the crops of the coals and accompanying strata are diminished in breadth by coming sooner in contact with the alluvial cover. K *c*, is a slip down to the east, forming the coal-field M. K *d* is a slip down to the west, forming the coal-field N. K *e* is a slip up to the west, which cuts off the coal-field N in that direction. K *f* is an upthrow slip to the east, which has the effect of throwing back the crops of the strata. K *g* is a downthrow slip to the west, which has the effect of throwing forward the crops of the coals and strata. K *h* and K *i* being downthrow slips to the west, have the same effect as in the last instance. K *k* being an upthrow slip to the west, has the effect of throwing back the coals and accompanying strata. In this manner coal-fields are extended over a district of country in the line of bearing, in every variety of change, according to the line of obliquity in which the slips occur with regard to the line of bearing, and the extent of the dislocation, as to the magnitude of the slip. These of course frequently change the direction of the line of level at times to the extent of 90°, as must be obvious from inspecting the Figures; because, generally, the line of level is a line parallel to the crop, that is, parallel to the line of the coals where they intersect the plane of the alluvial cover, which will be more particularly exemplified when the working of coal is treated of.

The next point of consideration is the vertical section of the coal-fields before exemplified. Such sections are generally made in the line of dip and rise, on which account the section, Fig. 7. is in the direction of the dotted line OP, Fig. 6. and the coal-fields, beds of coal, slips, counter dips, and crops, are marked with the same letters as in the horizontal section, which exemplifies the positions noticed in the horizontal section. These sections are to be considered only as diagrams, shewing within a very limited space the phenomena connected with coal-fields, it being impossible to shew the several parts in equal proportions to one another, as the sections represent miles in extent, whereas coals are only a few feet in thickness, and the distance between them a few fathoms. In order, however, to shew the effect of a great slip upon a scale of proportion, Fig. 8. represents three coals *a*, *b*, *c*, rising southward 1 in 5; the coal *b* is

15 fathoms distant from the coal c, and the coal a is 10 fathoms distant from the coal b; the coals a and b crop out at the line of junction with the alluvial cover, but the coal c is cut off by the slip AB down to the south, forming the south coal-field, where the coals a, b, c, are found dislocated and slipped down. The magnitude of this dislocation is measured by the taking the distance betwixt the pavements of any of the coals in the north and south fields, measured along the face of the slip, which in this instance is 50 fathoms. It will also be observed, from this figure, that though the distance betwixt the coals a and b is only 10 fathoms perpendicular, yet their distance, when they crop out, is 50 fathoms in a horizontal line; and the distance betwixt the coals b and c being 15 fathoms, their distance, when they crop out, is 75 fathoms. It follows of course, that those coals which have a great dip, or make a great angle with the horizon, have the less difference betwixt their perpendicular distance from each other, and their distance from the one crop to the other, where they meet the alluvial cover, whereas those coals which lie comparatively very flat, or at a small angle with the horizon, have a very great difference betwixt their perpendicular distance from each other, and their distance where they crop out or meet the alluvial cover, as may be seen by inspecting the figure. The proportion betwixt these is found by multiplying the perpendicular distance by what is termed the rise: thus, if the distance betwixt two coals is ten fathoms, and the dip 1 in 5, then 10×5 gives 50 fathoms for the distance in the horizontal section at the crop, or if the horizontal distance and dip are known, then the horizontal distance divided by the dip gives the perpendicular distance betwixt the two coals, viz 50 divided by 5 gives ten fathoms perpendicular distance as above.

Having thus endeavoured to show, that when coal-fields are not viewed upon a limited, but an extended scale, that they form either circular, or more generally, long elliptical basons, or portions of this figure, though sometimes in an inverted position, it must from this circumstance appear evident, that every coal and its accompanying strata will crop out and meet the alluvial cover, excepting when they are cut off and prevented from doing so by slips, or where they form portions of an inverted bason, or take a counter dip, as may be seen by inspecting the preceding figures relative to the shape of coal-fields. In the foregoing examples, the coals and accompanying strata are considered as keeping nearly the same distance from one another in each coal-field, and that they keep nearly the same parallelism as to the angle of dip and rise, with the quality of the coal unaltered in the several coal-fields produced by the slips and dislocations of the strata. In many instances we find this to be the case; but many changes are found to be produced, such as alterations in the angle of dip and rise of the strata before coming to slips or dislocations, a general change in the angle of dip and rise in the coal-field formed beyond them, some of the coals varying in thickness in the different coal-fields separated by these slips, and sometimes the thickness of the strata betwixt two beds of coal is doubled; at other times the distance betwixt them is rendered so little in some instances, as to be no longer visible; by which means, two seams of coal which were wrought as distinct beds of coal, are joined together, form one bed of coal, and wrought as such. Instances are also found of beds of coal composing a coal-field on one side of a slip disappearing on the other side; but this does not take place with the chief or main beds of coal. Differences, in point of quality, are occasionally found in the coals divided by slips and dislocations, though it is clearly evident that it is the same formation of coal-field on each side.

Although coal-fields are of the form as before described, it must be remembered that the extent of a single coal-field, in the line of bearing, is found to be several miles in length, suppose six miles; that is, they are sometimes found of this extent, without any great dislocations, as to have the effect of forming new coal-fields; and they are found in the line of dip and rise to extend above two miles. Other coal-fields are very small, not extending to half a mile in the line of bearing; yet, from the extent of the coal-basons, we must remark, that, in considering the shape of a small portion of a coal field, and the operations connected with the working of it, the idea of the bason-shape is abandoned, and the coal field and beds of coal are considered as a regular lying inclined plane. This, upon a limited scale, is not far from the truth, considering the great extent of the basons; but this idea will evidently be found very erroneous the instant a coal-field is viewed upon an extended scale, and extensive operations pursued in it.

The next point to be described, is the methods commonly pursued by mineralogists and miners in searching for coals, premising, however, that a clear idea has been formed of the facts before stated, as to the general natural phenomena connected with coal-fields. In making a survey in search of coals, there are two distinct points of survey to be attended to.

1*st*, The searching for coal in a district of country where no coals are known to exist.

2*d*, The searching for coal in a district of country where the coal formation is known to be, or where coals are working at no great distance from it.

In searching for coals in a district of country where no coals are known to exist, the first point for consideration is the general aspect and outline of the country under survey. Although, from taking this general view, we cannot determine whether it contains coal fields or not, yet, if the country is composed of hills or mountains, with steep acclivities, precipitous rocks, and sharp and rugged summits, with narrow valleys betwixt the mountains, we have no reason to expect that strata will be found there containing coal; and excepting this very obvious and plain feature, as to aspect, we do not know any other upon which we can conclude with any degree of certainty, whether coals will be found in a district of country or not.

It must, however, be remarked, that, in the second coal formation of Werner, as noticed in the geological view of the situation of coal fields, that though the great beds or masses of greenstone overlying a coal-field do not rise into what may be denominated mountains, they form, in this singular variety of the coal-field, hills, several hundred feet above the level of the sea, with rugged precipices, rudely columnar, in some instances nearly 200 feet high, under which coal is not only found occasionally, but in amazing thickness, though not of great extent. This is therefore a rugged aspect, formed by a peculiar kind of rock, under which coal is occasionally found.

This, we apprehend, is all that can be said regarding the general aspect of a country, as to whether it contains the coal formation or not; for when it is known that coals are found not only at great depths under the sea, but at very considerable heights above it, even so high as to form with their concomitant strata considerable hills, we may, from these circumstances, infer, that coals are found under every variation of surface, such as the ocean's sandy shores, the recent and old alluvial covers, and also under every kind of varied hill and dale. But we must observe, that there are also vast districts of country with all these varieties of surface, and exactly similar in aspect, under which no coals are to be found. This shews how limited our conclusions are from the aspect of a country, whether it contains the coal formation or not.

It thus appears that no conclusions can be drawn, with any degree of certainty, from the aspect of the country, as to whether coals are to be found in it or not. But mineralogists, who have surveyed many countries, and who have had an opportunity of examining the peculiar character, outline, and forms of mountains and hills, arising from the nature or kind of rocks constituting their mass, conclude, from the aspect in general, very correctly, of what rocks they are formed; but this discrimination is not applicable to coal-fields, as the rocks which compose the various beds, alternating with the coal, are, in general, much softer than the mountain rocks, and form few or no precipices. Where the coal formation forms a group of hills, they have the appearance of some of the transition class, with the exception of being softer in their contour and outlines; but this does not afford a distinction of character sufficiently precise, as the long running ridges of hills of moderate elevation, forming the hill and dale country which contains coals, present, like other ridges, a line of horizon nearly level, with few or no indentations, and no abrupt precipices, excepting when greenstone or basalt occurs, either overlying the strata, or forming a dike in the coal-field, and rising above the other softer strata. This situation of the greenstone is altogether different from that of the greenstone in the second coal formation of Werner. The long ridges containing coal, and forming what is termed a tame horizon, are very similar to the hills composed of chalk. It is to be remarked, that the line of bearing of the hills and dales is somewhat in the direction of the large rivers, or main trunks of rivers, which drain the district of water.

Since so very little can be depended upon, as to the conclusions to be drawn from the aspect of a country regarding coals being found in it, the next step is to examine the surface, or alluvial cover, which, in most cases, hides the strata underneath from view. Were it not for this cover, the searching for coals and other minerals would be a very plain and simple process; and, as this cover is frequently many fathoms in thickness, and sometimes of very heterogeneous composition, the pitting or boring through it is often attended with considerable difficulty.

If the district under survey for coal is composed of the bleak and sandy shores upon the margin of the ocean, or of the recent alluvial land at the mouth, and along the course of large rivers, whose waters move with a slow current, it very seldom happens that any symptoms of the kind of strata underneath can be discovered, even although these covers be examined to a considerable depth, as it is not common to find any fragments of the adjoining rocks mixed with them. We have seen these covers passed through to the depth of ninety feet without finding even the smallest fragments of stone, nothing being found larger than grains of sand. As these sandy and earthy deposites, which cover the rocks upon the margin of the ocean, and by the sides of slow running rivers, are very flat, and rise inland with an imperceptible angle of elevation, it seldom happens that any discovery of the rocks can be made, either in the beds or sides of the rivers and brooks which flow through them; therefore, in all such cases, recourse must be had to pitting and boring, in order to ascertain the kind of rocks underneath, and whether they belong to the coal formation or not. The plans commonly adopted for passing through the alluvial covers will be afterwards described, when treating of boring.

As we proceed inland, the recent alluvial cover becomes thinner, and disappears at its line of junction with the old alluvial cover, which line is, in most cases, very distinct. This kind of cover forms frequently a hill and dale country, considerably elevated above the level of the sea. The rivers and brooks which intersect it often expose the rocks to view, so that it can be determined, from inspection, to what class they belong. Therefore, in such a country, the first step to be taken in the survey in search of coal, is to investigate the beds and sides of every river and brook, noting the kinds of rock which appear, and also their dip and line of bearing. Every piece of broken ground and quarry must be examined in the same manner.

Springs of water require also to be examined; and although those which have an ochery deposit, are not to be supposed as affording unequivocal symptoms of coal, yet they are sometimes indicative of coal, or of ironstone accompanying coal. At the same time, it must be remarked, that these ochery deposites are found in waters which drain through common clay; and often very abundant from peat earth.

If, after heavy rains, which cause springs to flow copiously, small bits and grains of coal are found thrown out by the water, we have reason to conclude that coal is to be found at no great distance; and the searching for it must be proceeded in accordingly.

If, in the sides of rivers, brooks, or broken ground, a black sooty appearance is seen, this is frequently found to be the crop or outburst of a coal, and ought to be followed in the line of dip, by throwing an open trench. If it is the crop of a coal, the sooty appearance will become more compact as the operation proceeds to the dip. Small shining angular pieces of coal will be found mixed with it; and at last coal, apparently solid, but still very friable, will succeed, resting upon the pavement of the coal. The trial must proceed until the roof is found firm, regular, and parallel with the pavement. It frequentlly happens that all the natural cracks and fissures of the coal near the crop are filled with clay, which gives the coal a very unpromising appearance; yet this disappears after proceeding a few fathoms more to the dip. When a coal is found regular as a stratum betwixt the pavement and roof, we conclude that the full thickness of that particular bed of coal is found, providing we see no appearance of any of the dislocations or troubles before described, which must be kept in view when drawing conclusions from the appearance of coals, when thus found. After a bed of coal is found regularly formed, as before described, if its absolute situation and thickness farther a dipping is required to be known; or, if the strata lying either above or below it are to be investigated in search of other beds of coal, these points must be ascertained by pitting and boring.

In the face of steep banks of earth, even when the ground is not broken, the crops of coals are frequently observed by a black colour given to the soil; which appearance is also observed in lands which have been recently ploughed. When this appearance is seen in the face of a steep bank, the search for a bed of coal should proceed to the rise, or a little higher up the bank than where the black colour appears. But when this appearance is found in flat ground, a trench must be cut at right angles across it, so as to ascertain the line of dip; and, when this is found, the investigation will go forward in the line of dip, as before directed.

If, by the sides of rivers or brooks, pieces of coal are found much rounded in the angles, it is to be inferred that the bed of coal from which the fragments have been detached is at a considerable distance from the spot where they are found; but if the angles are sharp, it may be concluded that the bed of coal from which they come is at no great distance.

In digging through the old alluvial cover which rests upon a coal-field, numerous fragments of coal, and of all the accompanying coal strata are found, as well as small rounded gravel of the mountain rocks, and large boulder stones. It is remarkable that the fragments of coal, and of the coal strata, are, in general, not worn by attrition, but are sharp and angular; which show, that the formation of this old alluvial cover was by water, in a very different state from that by which the recent alluvial cover has been formed, and is daily forming. Yet though these appearances give evidence that the district contains the coal formation, they do not point out in what direction the crops of the coals from which they have been detached are to be found. It is proper to remark, in this place, that though unequivocal symptoms of coal are found, and that it may be inferred that we are within a coal formation district, yet we can conclude nothing satisfactory, as to the thickness of the beds of coal, until proper trials are made.

Lime stone, which abounds with organic remains, particularly if it is of some considerable thickness, is, in many cases, an index to a coal-field; as it is much harder than the common strata of a coal-field, it crops frequently out to day, that is, it is distinctly seen at the surface. We find also, that these thick beds of limestone are commonly found in the lower series of the strata of the coal formation, for which reason, whereever a bed of this kind of limestone is found, the dip should be first ascertained, and then the coals searched for in the line of dip; for although coals, and their accompanying strata, exist to a great depth under these beds of limestones, it seldom happens that any coals of good quality, or workable thickness, are found there.

If a district of country is to be surveyed, in which are mountains, or elevated ground abounding with rocks, these require in the first place to be surveyed. In most instances there is no great difficulty in determining to what class of rocks the mountain formation belongs, as some part of them is laid open by the streams of water with which they generally abound. If it is found they are composed of primitive or secondary rocks, as before enumerated, it is certain that no coals will be found under them; therefore the next point to be ascertained is, the dip of these rocks, because, in searching for a coal-field, it will be necessary to follow the primitive rocks in the line of dip, as the others follow in overlying succession. If the coal formation exists in that district, it will be found by tracing forward in that direction, and if found at the foot of primitive or secondary mountains, the strata of the coal-field will be found lying in a conforming situation with the face of the mountains, and forming a very great angle with the horizon. If the coal formation exists at the foot of such mountains, it will be in most cases easily discovered in the ravines and hollows formed by the mountain streams; and in many instances the coal and accompanying strata are seen so clear and distinct, that the operation of mining and working the coal may be immediately commenced without farther investigation; but as the edge coals are more difficult and expensive to work than the flat coals, it may be desirable to trace the coal-field farther onward. It has been found from experience, that when edge coals are thus found resting upon primitive or secondary rocks, that they form part of a great bason, and that after dipping to a considerable depth, they begin to deflect from their verticular line and form a hollow, or, what is termed by miners, a trough or bason, upon the opposite side of which the edge coals are found forming flat coals, rising in an opposite direction, as represented in Plate CCCLXXXIX Fig. 7, where I is the transition rocks, and *a*, *b*, the coals in the coal-field, A forming a trough or bason.

There are also instances of coal-fields where the edge coals have been wrought to a considerable depth without any symptom of their deflecting, and adjoining them flat coals are found cropping or rising towards the edge coals, as represented Fig 9. We are inclined to think that, in this instance, the edge coals, *a*, *b*, *c*, pass under the flat coals, *d*, *e*, *f*, at a great depth, and deflecting from the vertical line form the flat coals of the bason, *a*, *b*, *c*, on the opposite side; and that the great bason, formed by the edge coals thus deflecting, is filled up by a distinct set of flat coals and their accompanying strata, *d*, *e*, *f*. We are of opinion that the very interesting coal-field, south from Edinburgh, is of this kind of formation. All these varieties, now and formerly described, require to be kept in view, together with the various dislocations and troubles incident to coals. In prosecuting the search for coals beyond the edge coals, it generally happens that a short distance from the mountain foot or rising ground, the alluvial cover prevents the rocks or strata being any more seen; in this case, the whole district under survey must be minutely investigated, in particular all broken ground, beds of rivers, quarries, and new formed ditches, where it is probable, if the alluvial cover is not very thick, some vestiges of the strata will be seen, but if no vestiges of the strata can be discovered, the next step is to proceed with pitting and boring.

The foregoing rules are such as are at present adopted in surveying a district of country in which no coal is known to exist.

The next case is the searching for coal in a district of country where the coal formation is known to exist, or where coals are working at no great distance from it.

If it is only known that the coal formation exists in the district, without any particular account of the beds of coal, the dip, line of bearing, or form of the coal-field; the survey and investigations must be proceeded in according to the rules laid down, connected with the particular circumstances of the surface of the country under survey; and if coal cannot be discovered by minute investigation, the search must proceed by means of pitting and boring.

If coals have been wrought, or are working in the district of country under survey, particular inquiry must, in the first place, be made, as to the quality and thickness of the coals, their general dip, line of bearing, and shape of the coal-field, also if any dikes or slips are known to exist, and if they do, to learn their line of bearing, and extent of the dislocations of the strata produced. The form of the coal-field is important, as, without a knowledge of this, much difficulty and great mistakes may be the consequence. When numerous collieries are opened in a district of country, the subterranean geography of the strata is well known, the series or system of beds of coal composing the coal-field are ascertained, with their accompanying strata; and to an experienced miner they are as well known as the leaves of a book, excepting in cases where great derangement and dislocation of the strata have taken place. It is also of importance to know if the coals are liable to such troubles as alter their quality, render them thinner, or if they are separated occasionally by bands of stone, which in some instances separate the upper and lower parts of the bed of coal to such an extent as to form two coals.

The same general survey and investigation of the district must be followed according to the rules formerly laid down; and if no distinct view of the coals or strata can be seen, so as to draw accurate conclusions, the farther investigation must proceed by boring, care being taken not to overstep the coal-field, or beds of coals which are known to exist. This mistake will take place with the most cautious, if the form of the coal-field is not known and attended to.

The art of boring for coal is one of the chief points in mining, in order to ascertain the strata and beds of coal, before any great operation is commenced in winning or establishing a colliery, in which a great capital is frequently invested.

The rods commonly used are made of the best Swedish iron, about an inch and a quarter square; each rod is three feet in length, having a male screw at the one end, and a female screw at the other; these are what are named the common rods. The chissels for boring are eighteen inches in length, and are from two inches and a half to three inches and a quarter in breadth at the cutting edge, faced with the best steel; with these one short rod is connected, called the double box-rod, to which the chissel is screwed. It is also eighteen inches long, so that the chissel and box-rod together, form a three feet length equal to the common rods. There are also three short rods, named cut rods, of a foot, eighteen inches, and two feet in length, which are attached to the brace head, to render the height above the mouth of the bore suitable for the men to work the rods with effect; by this arrangement, the whole set of rods divides easily and accurately into yards and fathoms, for the more correctly keeping a journal of the strata passed through. What is termed the brace-head rod is eighteen inches long, having two large eyes at the top, set at right angles to each other, through which arms of wood are put, by which the men lift and turn the rods in boring. There are besides a number of other instruments connected with the boring rods, viz.

Wimbles, of various kinds.
Sludgers.
Rounders.

These are occasionally attached to the rods, as after described. There are also keys of different kinds for supporting the rods, and unscrewing them, when drawing them up, or letting them down into the bore hole; and when triangles are used so as only to unscrew four or five fathoms of rods at a time, topits, or top-pieces are used for each length of rods so cut, and an instrument, named the runner, is used for taking hold of the topits. Besides these, there are several instruments named beches, with contrivances for catching hold of the rods when they break down in the bore, which is not an unfrequent occurrence. When bores are only to be a few fathoms in depth, the whole operation is performed by manual strength; but when a deep bore of any consequence is to be made, a set of lofty triangles of wood is placed over the bore-hole, with a pulley at top, through which a rope is passed; one end is connected with a crane or windlass at the surface, to the other end, an oval iron ring, named a runner, is attached; by these means the rods are drawn up and lowered down with great facility.

In England, particularly in the Newcastle district, there are professional master-borers, who undertake to put down bores for coal, and give a precise journal of the strata passed through. The average price of boring in England and Scotland, where no uncommon difficulties occur, is six shillings for the first five fathoms, and an increase of six shillings each fathom for every additional five fathoms, viz.

1st 5 fathoms	6s.	£1	10	0
2d 5 do.	12s.	3	0	0
3d 5 do.	18s.	4	10	0
4th 5 do.	24s.	6	0	0
20 Fathoms.		£15	0	0

In this manner the price increases regularly with the depth; and in all common cases the master-borer finds and upholds the boring rods, but there are instances where the price is considerably higher than the above rate.

In Scotland, boring for coal is scarcely known as a profession, but there are master sinkers who occasionally bore, and who perform the operation with accuracy.

The boring tools are represented in Plate CCCXC. Fig. 1. in progressive numbers, viz.

No. 1. The brace head.
2. Common rod.
3. Double box-rod.
4. Common chissel.
5. Indented chissel.
6. Do.
7. Cross-mouthed chissel.
8. Wimble.
9. Sludger.
10. Rounder.
11. Key for supporting the rods at the mouth of the bore.
12. Key for screwing together and unscrewing the rods.
13. Topit.
14. Bechè.
15. Runner.
16. Tongued chissel.
17. Right-handed worm-screw.
18. Left handed do.
19. Finger grip.

The mode of conducting a series of bores in exploring the strata for coal, is next to be explained.

Plate CCCXC. Fig. 2. represents a district of country, in which, after a regular survey, coal strata, and the appearances of coal, have been found, having an evident dip to the south, as represented in the Figure. In this case, a convenient spot should be chosen upon the north part of the district to be explored, in order that the different bores may be carried southwards in the line of dip; the first bore is therefore put down at No. 1. suppose to the depth of sixty yards In this depth it is probable many varieties and alternations of the strata will be passed through, as exemplified in the sections of the strata; but for the sake of perspicuity, only a few strata are shewn in the figure, which strata are distinctly inserted in a journal as to their quality and thickness, and specimens of each carefully kept. The bore No. 1. passes through the strata *d*, *c*, *b*, *a*, without finding any coal. And as in proving a district with a regular series of bores, it is more economical to do so by means of bores of a moderate depth, than with very deep ones, which are attended with great expence, provided there be no particular difficulty in passing through the alluvial cover, which might render a number of bores very expensive. Suppose that, in the first instance, bores of sixty yards deep are resolved upon, as at No. 1 before mentioned, and that the dip of the strata is 1 in 10, the consideration then is, at what distance from No. 1. bore southward, will a second bore at the same depth strike the first stratum *d*, found at No. 1.? The rule is, multiply the depth of the bore by the dip, viz. 60 by 10 gives 600 yards, which is the distance required. In this manner the bores No. 2, 3, 4, and 5, are successively placed, with this particular exception, however, that the point of surface where the first bore is put down must be considered as the point of level to which the top of all the other bores relate. If therefore the top of No. 2. bore is 10 yards higher than the top of No. 1, that additional depth must be added to the bore ere it can be expected to reach the stratum *d*. On the other hand, if the top of any succeeding bore is under the level of the top of No. 1, bore, suppose 20 yards, that bore will reach the upper stratum of the former bore at a depth less, by 20 yards, than the depth calculated from a horizontal line from the top of No. 1. bore. Ravines frequently cut the strata in various directions, as at A, so as to lay the strata open to view; and if these are very deep, an advantage may be gained by boring there, and proving the strata to a considerable extent by a bore of moderate depth. In all instances where a series of bores are carried on, a correct and distinct profile of the surface ought to be made in the line of the bores. In No. 2. a coal is found near the surface, and another at the bottom of the bore, which last rests upon the first stratum *d*, found in the bore No. 1. The bore No. 2. is continued a few feet farther, until it is decidedly ascertained that it is has reached the stratum *d*. These two bores have thus proved the strata to the depth of 120 yards. No. 3. bore having been placed according to the rule before given, it passes through two coals near the surface, and after being put down nearly to its proposed depth, it strikes the stratum *h*, which is the upper stratum found in No. 2. bore; but as a coal was found in No. 2. under the stratum *h*, the proof is rendered more complete by continuing the bore through that coal. This bore, with the two former, proves the strata to the depth of 180 yards. No. 4. bore having been placed in the same manner as the former, a coal is found after passing through a few yards of the strata, and the bore is continued downwards until the two coals found near the surface in No. 3. have been passed through. This, with the three former bores, ascertains the strata under examination to the depth of 240 yards, so that to reach the lower stratum *a* of No. 1. the bore No. 4 would require to be put down to the said depth of 240 yards. The bore No. 5. being placed in the same manner as the former, a coal is found within a few yards of the surface; but, after reaching the depth at which the coal at the top of No. 4 bore should have been found, strata altogether different occur. In this case it is usual to go on with the bore ten or twenty yards farther than the intended depth of the bore, to ascertain the alternations of the strata. In some cases no coals of any value will be found, as in the present example, the cause of which is, that a slip or dislocation B of the strata has occurred, throwing up all the coals passed through in the former bores, and that of such a magnitude that the strata *b*, *a*, of the bore No. 1. are found immediately after perforating the slip; and within a few yards of the surface, in place of being found at the depth of 300 yards, as would have been the case had the strata continued at the regular dip of 1 in 10, and no dislocation had taken place. Since dikes, slips, hitches, and troubles of every kind and degree, as formerly mentioned, occur in coal-fields, examples of which are given in the preceding part of this treatise, it will easily be seen, by an inspection of these figures, what difficulties may occur in boring a coal-field which is much dislocated and troubled. Some coal-fields are so intersected with these as to bewilder the ideas even of the oldest and most experienced miners; for instance, since slips are of every magnitude, as regarding the extent or distance the particular strata are separated in a vertical direction, it not unfrequently happens that a lower coal is thrown upon one side of a slip, directly opposite to an upper coal situated upon the other side of it; so that if the two coals are of the same thickness, erroneous conclusions are most inadvertently formed, and mistakes with the most cautious will take place. Very many instances might be given of these anomalies found in the practice of mining, but it would be endless to elucidate them by figures. In the example given of a progressive set of bores, it is evident that the first coal likely to be found to the southward of No. 5. bore, and in the new coal-field formed by the upthrow slip, will be that found in the bottom of No. 2. bore; and if so, there is reason to conclude that all the other superincumbent coals will be found in succession southward, excepting some great dislocation or off cut of the strata takes place to interrupt their regularity. Caution must also be observed, in approaching primitive or secondary rocks, it being found, as before mentioned, that coals and their accompanying strata flatten in the line of dip towards these rocks, form a trough or bason, from which they rise suddenly, and form edge or half edge strata upon the face of those rocks.

If a line of bores is to be conducted from the dip of the strata towards the rise or direction of the crop, the same rules hold as to the placing the bores at the proper distances from each other, according to the dip or the angle of inclination made by the strata with the horizon; with this correction, that the bores are placed some yards nearer each other than the distance resulting by multiplying the dip by the depth of the bore, in order not to overstep the last strata passed through in the preceding bore; for if any of the strata are overstepped, several of them will not appear in the journal, and a valuable coal may be in these strata which have escaped being bored through. The general rule in this case is to place each successive bore so that the first of the strata passed through shall be the last which were passed in the bore immediately preceding. The bores No. 4, 3, and 2, elucidate this principle in boring from the dip to the crop; but suppose that the bore No. 2. had only gone to the depth of the stratum *f*, and that the bore No. 1. was put down in the position as marked in the Figure, in this case the stratum *e*, with the coal immediately below it, would be overstepped, none of the bores would pass through them; of course they would not appear in the journal, and the existence of that coal would be unknown.

Having described the mode presently practised in boring in the crop and dip-line of direction, where the dip is known before the boring is commenced, the next operation to be described is the proof bores in the line of bearing, which are necessary in proving a coal-field in a district where coals were not known to exist before. The line of bearing being at right angles to the line of dip and crop, let it be supposed that these bores are to be put down at right angles to the bore No. 4. at the distance of four to six hundred yards; the one on the west, the other on the east side. (Plate CCCXC. Fig. 2.) After making the requisite allowance for the difference of level betwixt the top of these bores and No. 4. bore, the two coals found in the bottom of No. 4. ought to be found at the same depth in each of the bores put down in the line of bearing if the strata are lying regular and free from dislocations; having, however this correction in view, that as all coal fields are bason-shaped, and of very various magnitudes, the absolute line of level along any bed of strata deflects either inwards or outwards from the line of bearing, which is at right angles to the line of dip and crop; and, therefore, referring to the shape of coal-fields formerly discussed, it will be seen that bores put down in a proper bason-formed field, in the line of bearing, will strike the coals sought after sooner than calculated upon; and, in the case of the form being an inverted bason, the coals will will be deeper than calculated; in large basons this difference in the line of bearing will not be much when at a moderate distance from the dip-bore, but in a small bason the difference will be found considerable, for this very evident cause, that if the bason is not broken by dislocations of the strata, all the coals crop or come to day in the line of bearing. Having these corrections in view, if the coals are found at a depth corresponding to the calculations made from practical data, it may be concluded that the coals are lying in that field, so far as proved, fair and regular; but if these bores require to be put down to a much greater depth than was calculated upon before striking the coals found in the bottom of No. 4.; or if these coals are found much sooner than was expected, it may be then concluded that a slip or dislocation of the strata exists betwixt the two bores, throwing down the strata in the first instance, or throwing them up in the second. Under such circumstances a few additional bores will be required, to ascertain the coal-field still farther, and the line or direction of the slip, particularly if the dislocation is of considerable magnitude. The position of such bores can only be determined on by weighing every circumstance which may occur while the operation of boring is carrying forward.

If in proceeding with a series of bores where the line of dip is not known, nor consequently the line of bearing, it is an important and primary point to ascertain this, not only as regarding the situation of the coal-field, but how it ranges within an estate or particular property. The mode practised is by putting down three bores in the following position. Suppose a bore No. 1. (Fig. 3. Plate CCCXC) put down, which reaches a coal at the depth of 50 yards, at the distance of 300 yards a place is marked for No. 2. bore at B, and a place for No. 3. bore at C, equidistant from No. 1. and No. 2., so that the bores are placed at the angles of an equilateral triangle; then suppose the bores No. 2. and 3. to be put down, and that the coal is found in No. 2. at the depth of 30 yards, and in No. 3. at the depth of 44 yards; from this it is evident that neither of the lines AB, BC, or CA, are in the line of level, which in short distances, as before mentioned, approximates to the line of bearing, particularly in coals which have a very moderate dip. As No. 1. is the deepest of the three bores, and No. 3. the next in depth, this shews that the line AC is nearer the line of level, than either the lines AB or BC. The question therefore is, at what distance upon the protracted line BC, is the point at which, if a bore were put down, it would reach the coal at the same depth as at No. 1. viz. at 50 yards. It is thus resolved: as 14 yards the difference of depth betwixt the bores No. 2. and No. 3. is to 300 yards the distance betwixt them, so is 20 the difference of depth betwixt No. 1. and No. 2. to the proportion resulting, which is 428 yards, 1 foot, 8 inches; this distance, measured from No. 2. reaches to the point D on the protracted line BC, at which point D, the coal will be found at 50 yards deep, as at A; hence the line AD is the true level line of the coal or strata. A line drawn at right angles to AD, such as BF, is the true dip line of the coal. In this example, the dip, in the miner's language, is 1 in 14½, that is, in each distance of 14½ yards, measured along the line from B to F, the coal is found one yard deeper. Hence a calculation is easily made at what depth the coal would be found at any point of distance from B, along the protracted line BG, viz. by dividing the given length by the dip. If the distance from B to G in the line of dip is 455 yards, this, divided by 14½ the dip, gives 30 yards, which, added to 30 yards, the depth of No. 1. gives 60 yards for the depth at which the coal would be found at G. As any line drawn at right angles to the line of level AD, is the line of dip, so any line drawn parallel to AD is a level line. Hence, if from No. 3. bore, a line CE is drawn parallel to AD, the coal at the point E will be found upon a level with the coal at C, viz. at 44 yards. The point E may, however, be found on a level with No. 3. by a rule of proportion similar to the former, viz. as 20 yards the difference of depth betwixt No. 1. and No. 2. so is 300 yards the distance betwixt them, to 14 yards the difference of depth betwixt No. 2. and No. 3. the proportion resulting is 210 yards; which distance, measured from B, is found to be at E. Had this proportion been first tried, then A D drawn parallel to EC would have given the point D, upon the protracted line BC, where the coal would be found on a level with the coal at the point A. In this example, the surface is supposed to be level; but as this is seldom the case, the relative situation of the bores at the surface with each other must be accurately ascertained. If No. 1 is situated higher than either No. 2. or No. 3. the difference of altitude must be added to each bore, so as they may be equal to No. 1. which correction brings them to the same horizontal plane, and then the projection and calculations are made as before exemplified. It is by this theorem for finding the line and dip of level, that the most eligible spot in a coal-field or coal property can be selected; where, by sinking a pit, the coal, under all circumstances, can be wrought to the greatest advantage, particularly as to the drainage of the coal-field.

The process of boring, as before described, is the same which has been long practised, and which is in common use at present. A new mode was invented and brought forward under letters patent, some years ago, by Mr. James Ryan, from Ireland. The principle is very ingenious, and it is this. The common boring rods are the same as before described; but, in place of chissels, a forked cutting-tool is used, in the same way as formerly described in the process of boring; but, in place of the strata passed through being comminuted or ground to powder, a core or cylinder of the strata is formed; and as soon as the boring bit has advanced as deep as the shoulder of the fork, the rods are drawn up, and a pair of nippers substituted; these seize the core, break it off, and bring it up. In this manner the boring proceeds through the strata to the required depth, and each piece of core brought up, is laid in a horizontal direction, each piece regularly joining the preceding one at the line of fracture; by this means, a true section of the strata bored through, with the coals found, is as distinctly seen as if a pit had been sunk through them. Besides which, the dip or declivity of the strata is also ascertained. It is said that the true line of dip can also be found during the process of putting down a single bore, but it is apprehended that the accuracy of the result cannot be depended on.

Mr. Ryan made every proper exertion to bring his ingenious mode of boring into practice; a mode, the result of which was so satisfacfory, leaving no ambiguity as to the strata passed through, and particularly as to the thickness and quality of coals, in ascertaining which so great mistakes have unfortunately taken place, because by the new plan the strata and coals in their natural compact state are laid upon the surface of the ground. But highly satisfactory as this is, the plan has not succeeded, and is not yet known in common practice. Several eminent coal proprietors patronized Mr. Ryan, and gave his process a fair trial; the bores were not deep, but, so far as executed, they were satisfactory. The impression which the public has at present regarding this mode of boring is, that it is very expensive, and not practicable in deep bores. It is, however, but too well known, how much mankind are attached to old plans, strongly prejudiced against new ones, and that it is no easy matter to change particular habits; this may have operated against Mr. Ryan's invention, and have prevented success attending it. The bore-holes formed by the boring-bits are larger than those in common use, in order that the core may be about 3 or 4 inches diameter, and Mr. Ryan proposed by this plan to bore holes of more than one foot in diameter, to ventilate coal-mines, but it is supposed this did not succeed, or that the expense rendered it no saving. It is understood, however, that by this process, with boring-bits and wimbles of large size, alluvial cover mixed with gravel and boulder stones has been passed through, where the old plans did not succeed; and this kind of cover is the most difficult to bore through of any.

As boring for coal is always carried on in a line perpendicular to the plane of the horizon, and as coals and their accompanying strata, lie at every various angle of inclination to that plane, from nearly horizontal to the perpendicular line, it results that the thickness of the strata, or of any coal bored through, if lying at a great angle with the horizon, will measure considerably more than what they absolutely are, because the true thickness of any stratum or coal is only obtained by taking the measurement at right angles to the plane upon which each stratum or coal rests; for example, in boring through the flat-lying coal, Plate CCCXC. Fig. 4. the difference betwixt the line passing through it, perpendicular to the horizon, and that which is at right angles to the plane on which it rests, is so trifling as need not be noticed; but this difference betwixt the two perpendiculars, increases with the enlargement of the angle formed with the horizon so that in Fig. 5. the thickness of the coal, as ascertained by boring, is the distance *a*, *b*, whereas the absolute thickness of the coal is the distance *b*, *c*, that is, a line perpendicular to the plane on which the coal rests. In this example, the measurement of the coal by boring, is 16 feet, whereas its absolute thickness, *b*, *c*, is exactly six feet, producing an error of 10 feet. From these circumstances, it is not the practice to ascertain a coal-field composed of edge coals, by boring, because being nearly vertical, very few of the strata would be passed through, even with a deep bore; therefore, when edge coals are not laid open to view in a ravine where the alluvial cover is removed, it is the practice, if the cover is not thick, to cut a trench through it at right angles to the line of bearing of the strata, and as edge coals lie generally at a short distance from each other, a trench of two hundred yards in length will discover nearly that thickness of the strata; but if the cover is too thick for cutting a trench to the rock head, the plan is, to sink a pit a few fathoms into the rock, from the bottom of which two mines are carried in a level direction, at right angles to the line of bearing, the one to the rise, the other to the dip of the strata. By this plan, the thickness and quality of the coals will be accurately ascertained. Fig. 6. shews the plan of proceeding with edge coals, *a*, *a*, are the edge coals, *b* the pit, *c*, *c*, the mines which intersect the strata.

With regard to searching for coal in what is termed by Werner the second coal formation, composed of the newest flœtz trap rocks, it is attended with more difficulties than are found in any other of the coal-fields. In this formation the coals are found of uncommon thickness, in some instances 100 feet, the prevailing strata above the coals, are various alternating beds of soft slate clay having very little tenacity, with sometimes a few beds of sandstone; and over these, next the surface, thick beds of greenstone; which, where dislocations of the strata have taken place, form high precipitous cliffs, such as greenstone precipices always assume. The coals found in these fields do not extend over a great district of country; in some instances they do not extend to a mile in length, the coals lie irregularly, and in a short distance vary from lying moderately flat to very steep.

Coal-fields of this singular kind have been found more by accident than from regular surveys and minute searching, for this reason, that the masses of greenstone present such an unfavourable appearance, and so forbidding, that trials by boring would scarcely be recommended by a mineral surveyor, particularly as limestone is more frequently found under very thick beds of greenstone than coal, with this difference, however, that the strata accompanying limestone in such cases, are stronger and more compact. If, in such instances, no vestiges of coal can be found, where the alluvial cover can be cut through near the crop of the coal, the next step is to bore beyond the edge of the greenstone, and also to search for the softer strata lying under any of the greenstone cliffs, which when found, a bore may be put down to any requisite depth to ascertain the strata; and if coals are found there, it is probable they will be found under the greenstone in the flat part of the country, which also must be ascertained by boring. If coal is found in one place, its dip, line of bearing, and extent, require to be found according to the process before described. These uncommon beds of coal are of various quality, some parts of them being hard, others soft, of a rich caking quality; but by far the greatest part is of an inferior kind, having sulphur combined with it, and yields, when burnt, ashes of a dark reddish brown colour, which is one of the peculiar characters of all sulphurous coals. Such coals are very liable to spontaneous ignition, after being opened up and wrought for some time.

Glance coal, which is the blind coal of Scotland, and the stone coal of Wales, is sometimes found alternating with the other kinds of coal; at other times, the common coals pass into this kind; it is, however, more commonly found in Scotland, where greenstone abounds in the strata, and is very abundant in Ireland.

No rules can be laid down for searching a district for this coal, beds of it have generally been found by accident.

For particular information regarding the different kinds of coal. (See the Article Coal.)

Bovey coal, being wood, or great collections of trees found in the alluvial cover, semi-mineralized, and lying nearly horizontal, it cannot, in strict mineralogical language, be named coal, though some of it is so like coal, as to be termed brown coal. The only considerable extent of this kind of coal which has been found, and continues to be wrought in Great Britain as fuel, is near Exeter in Devonshire. As its existence in any district of country cannot be traced by analogy, as coals can be, from a regular series of rocks, no rules can be given as to searching for it; and it is apprehended that this kind of ligneous deposit is but sparingly scattered over the globe. It is found in Europe, in the districts of Germany, Denmark, Prussia, Italy, Greenland, and the Faroe Islands; and probably exists in other quarters of the globe. The drift-wood which has greatly accumulated, and continues to accumulate, along the sides of some of the great rivers of America, will, it is very probable, at no very distant period, be covered with alluvial soil, and be converted into bovey coal. From this view of its geographical position, it is more likely to be found in the recent than in the old alluvial cover; and more probably not very distant from the line of junction betwixt them, where the rising grounds point out to the eye great districts of country, which very evidently were occupied by water previous to the extensive districts of rich alluvial lands being formed by deposits from the rivers.

In surveying a district for coal, both lime and ironstones may be discovered. In some instances, limestone forms the roof of coal, but in the extensive coal districts, the thick and valuable beds of limestone are found in the lower series of the strata, under all the main beds of coal. Limestone being very hard, and not easily decomposed, frequently crops or bassets out to day, hence more lime rocks have been discovered by surveying the surface than by any expensive process of boring.

In searching for ironstone, it is frequently found exposed to view in the broken ground; but if this is not the case, numerous small pits must be sunk along the district under survey, and a series of bores put down if necessary. Few fields of ironstone have been fitted to a great depth, and drained with machinery. The greater part of the ironstone mines in Great Britain are either wrought level free, or are drained and wrought in connection with coal mines in the same stratification.

Having thus described the position of coal in a geological point of view, particularly its relation to the other strata composing the upper part of the globe; and having also stated the kinds of alluvial cover which rest upon it, the dislocations incident to the strata, the changes in the beds of coal termed troubles, the mode of surveying a country for coal, the process of boring for it, and asertaining the different strata, the next department of mining to be described is, the manner pursued to render a coal workable; termed the fitting or winning of a coal.

If a coal, or a number of coals, are found to exist in a coal-field, the first obstacle which prevents a pit's being sunk to any considerable depth is water, which is generally found in great quantity, particularly in the first opening of a coal-field, (if the pit is sunk near the crop.) which water, whether found in pits of very moderate or very great depths, proceeds from the surface of the earth, though a contrary opinion was once held; it being evident and certain, that the source of all water found in mines is rain, which percolates through the alluvial cover, excepting in those cases when coals are wrought under the waters of the ocean; for, it was shewn in the vertical section of the strata, that every stratum, however deep it may be from the surface in any one place of a coal-field, always rises till it meets the alluvial cover, comes to day, or crops out, as it is termed, excepting it is met by a slip or dislocation of the strata. If the crops of the strata are covered with alluvial matter containing water, such as gravel, quick sand, or any kind of soil pervious to water, this water will percolate through the pores, fissures, and beds of the strata, and force its way into that place of the pit or mine where the lateral resistance is taken away. If the strata crop out into beds of rivers, this circumstance produces, in general, an uncommon growth of water in the coal and adjoining strata.

From the circumstance of the water being so abundant in coal-fields, and presenting such an obstacle to the operations of the miner, coal-fields are divided into two kinds, viz.

1. Level free coal.
2. Coal not level free.

The level of the surface of the ocean being the lowest point for drainage upon the surface of the globe, all coals and strata situated at a higher level than this surface are physically level free; and all coals and strata situated under that line are physically not level free. Therefore, in a general point of view, the surface of the ocean is strictly the line which divides these portions of coal-fields which are level free, from those which are not level free.

Though this definition is true in a philosophical point of view, many coal-fields, though level free, are situated at such a distance from the shores of the ocean, or arms of the sea, that the expence of bringing up a level or mine would be so great as to render such an operation out of the question; and therefore, in the practice of mining, if a coal-field, or portion of it, is so situated above the surface of the ocean, that a level can be carried either from that point, or from any hollow ground inland, till it intersects the coal, such field of coal, situated above the point of intersection, is termed a level free coal; whereas if a coal-field, though situated above the level of the ocean, cannot, on account of the expence, be drained by a level or mine, but by machinery, such coal-field, or portion of a coal-field, so drained, is, in the miner's language, termed not level free, though it is physically so.

From these principles, it is obvious that all coals and minerals situated under the level of the ocean must of necessity be drained by machinery; and that all coals situated above that level may be either wrought level free, or by machinery, as may be thought most expedient. This expediency is a matter of calculation; viz. whether, in draining a given area of coal-field, the estimated expence of driving the level, and upholding the same in repair, is less than the estimated expence of erecting an engine with all its appendages, taking into calculation the annual expence of working and upholding the same; to which must also be added, a sum for contingencies. It must also be considered, that the level is constantly effectual in its operation, and is not affected by additional feeders of water; whereas each additional feeder of water to an engine always produces an additional expence; besides, the engine wears out, and must be renewed, or, if sold at any time, does not in general bring one-third of the first cost. In these calculations must be considered the time required for completing the winning in both ways; and if the time required for executing the level greatly exceeds that for erecting the engine, this circumstance alone may, in some cases, produce a determination to erect an engine in preference to making a level, though the latter was found in calculation to be absolutely less. There are instances, however, where, in order to save time, it may be expedient to make a partial winning, of little depth, either by a day-level, or by machinery; and while the coal laid dry by this winning is working, a deep day-level is progressively bringing forward, which, as soon as it intersects the coal, and communicates with the engine level, supersedes the use of the engine.

Besides these levels which drain coal-fields of water, and render them workable, there are other levels of more limited operation, used in mining. These are named off-take levels, or drifts. The object of these is, that when a coal is to be won by an engine, the mouth of the engine pit is so situated as to the ground adjoining, that, at a moderate expence, a level can by brought up to intersect the engine pit a number of yards under the surface, so that the water of the mine, in place of being delivered at the surface, is discharged into the off-take drift. The lower down this kind of level, or off-take drift can be procured with ease, the greater will be the advantage in lessening the column of water to be lifted in the pumps by the engine. From 20 to 30 fathoms off-take is a considerable object, as that depth saves what is termed a lift of pumps; even 10 fathoms off-take is of consequence to have. These levels are not only of use in lessening the load of water on the engine, but if coals are intersected by them, they will intercept all the crop water to the depth of the point of intersection, and prevent it from going down upon the dip part of the coal, where it would be a heavy load on an engine, if, after intersecting the engine pit, the level is carried forward till it intersect the coals, through which the pit is sunk, all the crop water of these upper coals will also be intercepted. Such levels are not only of use in the winning described, but if a new deep winning is made to the dip, the crop water is not only prevented from descending to the pit bottom, but the advantage of discharging the water raised by the engine into the level is also obtained.

The most prominent advantages being thus stated, regarding day-levels, we have now to state the manner in which they are executed.

As, before the discovery of the steam engine, the coal-fields which could be drained by hydraulic machinery were comparatively very limited in number, and as the draining of water by men or horses was not only very expensive, but very limited as to the depth at which water could be raised, the driving of day-levels was a primary object with the early miners; and we are astonished when we survey the works of this kind executed by them, both as to depth and extent, and that before the application of gunpowder to the blasting of rocks. Without this powerful auxiliary of the miner, it is not easy to comprehend the extreme labour and patient perseverance required to pass through the very hard rocks which were met with. This seems to be the cause of the levels executed in the early periods of mining being of so small a size that a man has just room to creep through them.

Many of the levels of the present day are only three feet in width, and four and a half in height. Although these dimensions are in general sufficient to carry off the water which may be found in the colliery, they are too small when the mine is to be repaired, or when sediment and obstructions gather in them. They ought not to be less than four feet wide, by five feet six inches or six feet high; this is abundantly large for carrying off water. But there are some day-levels, which not only are driven for carrying off the water, but as a passage at the same time for bringing out the coals from the mine. In this case, the width would require to be at least four feet six inches, or five feet, so as to admit of an iron rail-way to be laid in it; besides which, there require to be, at proper distances, wider places formed in the side of the mine, to allow the loaded and empty carriages to pass each other. These by-pass roads are regulated as to the distance from each other, according to the quantity of work to be performed. When a day-level thus serves a double purpose, the water is either conducted in a covered drain, cut deeper than the sole on which the rail-way is laid, or it is conducted along the side of the rail-way.

In other instances, a day-level is not only made to carry off the water from the colliery, but is constructed of such size as to form a canal, by which boats can be carried into the coal mine, and loaded for the market. These levels are of various dimensions, according to the extent of traffic calculated upon. The smaller kind is nine feet wide, by nine feet high, having from three to three feet and a half of water in depth. The larger dimensions in practice are nine feet wide, twelve feet high, with five feet depth of water.

In driving a common day-level, for the sole purpose of draining the coal, the point having been fixed for commencing it, if the ground is flat, part of it at first will be executed as an open cast or ditch, securely laid with flag stones in the bottom, and built in the sides with sufficient stone walls. The sole to be conducted in a line as nearly level as possible. If the alluvial cover continues, and becomes too deep for open cast, the mine or level must be arched, and the work conducted under cover. If the alluvial cover is soft, it will require to be secured in the sides and roof with timber, which can be drawn out, and used again, if the nature of the case admits of this being done; but if this is not the case, the timber must be so placed as to admit the side walls and arch to be built within it. In this way the level is carried forward until it has proceeded some yards under cover of the rocks, or strata of the coal-field, when, if the strata are strong, no more mason-work is required. The next point is the proper line of direction, so as to reach the coal to be drained in the shortest distance. This line is that of the true dip and rise of the strata; and that the mine is going correctly in this line is known when the divisions of the strata seen in the forehead of the mine, are parallel to the sole of it, which ought always to be level. If the strata form an angle with the sole of the mine, the direction is going oblique to the line of dip; and the greater this obliquity, the greater will be the protracted distance, before the coal can be intersected. In all cases where the strata are not soft and friable, the roof of the mine is cut in an arched form, which adds considerably to its strength; and wherever the strata are soft and friable, or where the level passes through slips and dislocations, the sides are built up and the roof arched with stone or bricks. The latter are generally preferred, on account of their occupying less room, are easily carried into the mine, and the work more expeditiously executed; it being a rule that the mine shall, in all such cases, be made of such a size as to admit the building, without narrowing the fixed dimensions of it carried through the rock. As a day-level proceeds forward, the air begins to fail, from the breath of the workmen, the use of gunpowder, and the issue of carbonic acid and hydrogen gas, which are sometimes found in great abundance; to remedy this, deal boxes or pipes, from eight inches to a foot square, are carried in from the mouth of the mine to the forehead, and lengthened as the mine proceeds. This generally produces a sufficient circulation of air, until it is found necessary to sink an air pit upon the level, by which a strong circulation of air is not only produced, but the mine stuff is more easily drawn up than taken out to the mouth of the mine. Formerly these air pits were sunk directly upon the level, but that mode is now given up; for this reason, that if any part of the sides of the pit gave away, the rubbish instantly choked up the level, and frequently occasioned much trouble and expence to get it cleared again. The practice now is, to sink these pits about eight or ten yards from the side of the level, and connect them by a side mine. In this manner, day-levels are carried forward for miles, and may be carried to any distance. If, in the progress of the level, workable coals are intersected before reaching the coal which is the main object of the mining adventure, an air pit may be sunk of such dimension as to be suitable for a coal-pit, by which coals may be drawn. Air pits generally do not exceed seven feet diameter; and they ought always to be of the form of a circle. Plate CCCXC. Fig. 7. represents a coal-field, where the fitting is made by a day-level; *a* is the mouth of the level at the surface of the sea, *b*, *c*, *d*, *e*, are coals intersected, and drained by the level. All the coals lower than the level can only be drained by machinery. A is a coal-pit sunk upon the coal *e*; if the level is carried forward, the coals *f*, *g*, and any other coals which lie in that direction, will also be drained, and may be wrought by means of the pit A. The effect of the level would be the same if the coals and strata had dipped in an opposite direction to that represented in the figure.

The chief difficulty or obstacle which has occurred in executing day-levels, is thick beds of quicksand which are found in the alluvial cover. Instances have been found in practice where ingenuity, determination, and resolute perseverance, could not command success; for although thick beds of quicksand can now be passed through in a perpendicular direction, by adopting approved of plans, the difficulty of passing through them in a horizontal line has not yet been surmounted. If such a sand-bed is found to obstruct the driving of a day-level; and if it is an object to carry forward the level from that particular point, the mode of proceeding is as follows. Fig. 8. represents the strata of a coal-field A, with the alluvial cover *a*, *b*, containing the bed of quicksand *b*. B is the lower part from which the level is required to be caaried in the direction B, *d*. But the quicksand renders this mode of operation impracticable. The pit BC is sunk through the quicksand by means of tubbing, as will be described when treating of pit-sinking; and when the pit has been sunk a few yards into the rock, the level mine or drift is carried forward to the point D, when the pit ED is put down, it having been previously ascertained, by boring through the alluvial cover, that the rock-head at F is a few yards higher than the mouth of the pit B. During this operation all the water and mine stuff are drawn at the pit B; but the instant the pit ED communicates with the mine, the water is allowed to fill the mine CD, and grow up both pits until it finds an issue at the mouth of the pit B. From the surface of the water at G, in the pit ED, a mine is begun of the common dimensions, and carried forward until the coal in search of is intersected. By this plan no level is lost. This kind of level is named a drowned level, a blind level, and also an inverted syphon. When a coal, or any number of coals, are intersected by a day-level, the operation of working the coal proceeds in the usual manner, as will be described when treating of the manner of working coal.

In carrying forward levels into a coal-field of such dimensions as to be used as a canal, the same general rules are observed as in driving a common-level, the only difference being in the dimensions; but, from the width being great, a greater proportion of the sides and roof requires to be built and arched for security, which greatly adds to the expence of the operation. When such under-ground canals or levels extend to a great distance, they can be easily ventilated without air-pits, on account of their width; or, if ventilation is necessary, it is accomplished either by air-pipes, or by wide bore-holes put down from the surface; so that if air-pits are found necessary, they are placed at a great distance from each other, and as the stuff produced in driving the mine is in great quantity, it is brought to the mouth of the mine by canal-boats; but rail-roads must be used at the forehead. This part of the operation is not commenced until the level has advanced about half-a-mile under cover. This mode of proceeding is represented Fig. 8. Plate CCCXCIV. where A is the canal which enters under cover at B, the stuff from which is taken out by means of rail-roads as far as the point C; at this place a step is left a few inches higher than the depth of the water, and the canal is filled. From the level of this step the mine is carried forward to the forehead D, and all the stuff produced is brought in carriages along a rail-road, and emptied into the boats at C. When this operation has advanced to a convenient distance, the rail-roads are lifted, and the step at C is formed with a platform C, *a*, having an inclined plane formed of the rock *a*, *b*, which reaches to the bottom of the mine. The sole is then carried forward in a true water level line in the direction *b*, *c*, until it is as far advanced as the forehead D. The stuff produced by this last part of the operation is carried along rail-roads; and the loaded carriages are drawn up the inclined plane *a*, *b*, by means of a jack-roll, or windlass, placed at *a*, where they are emptied into the boats at C. The next operation is to remove or cut out the step or bench of rock left at C. For which purpose, a temporary dam-head, made of deals, is placed across the canal at C, as high as the water, having clay at the back to prevent leakage; the step *a*, C, is then cut out as low as the bottom of the canal, and upon removing the temporary dam, the water fills the canal to the forehead D, to which point the boats navigate; and the same operation goes on successively to any required distance, viz. until all the coals or other minerals of the district, proposed to be laid dry, and wrought by the mine or level, are intersected.

When a coal-field is so situated as not to be rendered level free, the winning has to be made by means of machinery.

In the early periods of mining, the drawing of water from the mines was most laborious, when either men or horses had to be employed; and when this was the case, the mining operations were very limited, both as to depth and extent below ground. The chain and bucket engine was the most powerful of the machinery then employed, and when wrought with a water wheel, raised a great quantity of water; but the greatest depth to which it was applied, was from 40 to 50 fathoms. The machines or engines presently in use for the drainage of coal-mines are.

1*st*, The hydraulic engine, or water wheel, with cranks and vibrating beams.

2*d*, The common atmospheric steam-engine, invented by Newcomen, known by the name of Newcomen's engine.

3*d*, The steam-engine invented by the justly celebrated Watt of Glasgow.

4*th*, The high-pressure steam-engine, invented by Travethic.

As the principles of hydraulic and steam-engines, with their general application, are treated of under the articles Hydraulics and Steam-Engine, these heads are referred to for minute information; and therefore we shall only give a very short account of the engines used in the draining of coal mines, making such practical remarks as have arisen from seeing them applied to work.

The hydraulic engine now in use, seems to have been introduced into the mining operations of England about the year 1680, and into Scotland about theyear 1712; it was an improvement upon the chain and bucket engine, moved by a water-wheel. Several of the present hydraulic engines have wheels 30 feet diameter, and four feet wide in the water-buckets; the cranks are generally from two feet and a half to three feet and a half in length, and are fixed upon each end of the axle or journal; there are two beams of wood placed upon a pillar-head or frame of wood; each beam is about forty feet in length, three feet thick, and two feet broad at the centre, tapering towards the end, and firmly bound together with iron glands, and, to prevent them bending, they have each a king-post and martingale stays; one of the beams is attached to the crank on one side of the axle by a connecting rod, and the other beam is connected in the same manner to the crank on the other side of the axle, to the other ends of the beams which project over the pit mouth, the spears or pump-rods are attached, which work in the pumps. If the pit is from 20 to 30 fathoms in depth, then two piles or sets of pumps reach from the bottom to the mouth of the pit, where they both deliver their water; if the pit is from 30 to 60 fathoms in depth, then the depth is divided. One set of pumps reaches from the bottom to half way up the pit, where the water is delivered into a cistern, from which cistern the upper set or pile of pumps reaches to the top of the pit, where they deliver the water. This machine is of very simple construction; the working parts are few, and requires no attendance—it places a coal-field drained by it nearly upon as moderate a footing in point of expence as a coal-field which is *level free*, and in some instances even upon a superior footing. Many attempts have been made to improve this engine, and to render its powers more efficient, but without success.

Newcomen's atmospheric steam-engine being of very simple construction, is still generally used as a pumping engine in collieries, when the kind of coal used in working them is of little or no value, and when the depth does not exceed 120 yards; for a greater depth, and where pumps are used above ten inches diameter, the improved engine of Watt is preferred.

The steam-engine invented by Watt, known by the name of Watt and Boulton's engine, applied in draining collieries, is of two kinds, named single and double power engines.

In the single power engine, the cylinder is close at the top, and has the steam operating against the piston, as it descends, by means of the vacuum formed below it. This engine, like Newcomen's, only draws water by the descending stroke of the piston; but with much greater power, that is, a much smaller cylinder is required to produce the same effect.

In the double-power pumping engine of Watt and Boulton, the piston acts with equal force, whether ascending or descending, so that an arrangement altogether different is required for working the pumps, because one half of the pumps in the pit is worked by the descending, and the other half by the ascending of the piston in the steam cylinder.

Both the single and double engine of Watt have been applied in a different manner from that before stated; it had occurred to colliery engineers, that it would be a great improvement in the pumping steam-engine, to throw aside the great and massive lever beam, which in some instances exceeded ten tons in weight. This plan was accomplished by placing the cylinder in a perpendicular direction, directly over the pumps above the pit mouth; but this plan has not succeeded. It appears that nothing has been gained by laying aside the great lever beam, weighty as it is, because, when well constructed, very little power is required to move it.

Trevethick's engine is of unlimited power, with regard to the pressure upon each square inch of the piston. As it operates by means of steam raised to a great elastic power, it is employed either as a single or double engine, in the same manner as the engines of Watt. They were first applied to collieries in a very simple form, by allowing the steam, which had acted by its pressure on one side of the piston, to escape into the air, while the elastic steam acted on the opposite side of the piston, and so alternately. Mr. Woolf has applied the highly elastic steam principle of Trevethick to the principles of Watt's engine, and these engines of combined principles are now much used in draining the very deep and heavily watered mines in Cornwall. Some of these engines work with a pressure of more than four atmospheres on the square inch of the piston, that is, more than 60 pounds upon the square inch; but they are not in general use, as a considerable degree of danger attends them.

With respect to the general range of the power of the different kind of engines before described, mining engineers are in the practice of calculating their powers according to the weight of the column of water raised from the bottom to the top of the pit, independently of friction, and the *vis inertiæ* which has to be overcome at each incoming and returning stroke, at which points the whole power and movement of the pumping engine must be brought to rest, and the direction of the power altered.

The winnings or fittings of collieries are of various depths, from a few to two hundred fathoms, which is the deepest winning in Great Britain, that is, the deepest at which coals are wrought; but the deepest coal-pit is only one hundred and fifty fathoms. The depth of any winning or fitting is made to correspond with the capital to be employed, and the vend or sale of coals which may be calculated upon, according to the state of the demand for coal; it being very evident, that a very limited vend will not, at the ordinary rate at which coals are sold, admit of a great capital being invested in making a winning, either by a day-level or by machinery.

The depth of the winning having been determined upon, the manner in which a winning is made by a day-level has been described. We have now to state the manner in which a winning is made by machinery.

The depth at which the coal is to be won regulates the power of the engine to be applied, having in view the probable quantity of water which may be found, which last regulates the width of the working barrel of the pumps. In a district of country where coals are working by means of numerous winnings, the quantity of water which is likely to be found in a new winning may be estimated from what is found in the other works adjoining; and it has been found from experience, that even in opening up collieries in new districts of coal-fields, the water found in sinking is generally such as can be drawn by pumps of from ten to fifteen inches diameter, excepting in cases where the strata are connected with rivers, sand-beds full of water, or marshy ground.

In cases where feeders of water proceed from rivers or sand beds, they can be prevented from descending the pit, and therefore the growth arising from these sources needs not be taken into the calculation of the water to be drawn; and it is found in sinking pits, that although the growth, which cannot by any means be prevented from descending into the mine, may be very great, and even so great as to exceed the power of the engine for some time, yet, as the extra flow of water frequently proceeds from the drainage of fissures, these gradually abate to a moderate quantity. An engine having eight or ten hours work drawing water each 24 hours, is reckoned moderate and comfortable for a new colliery. In the course of years, as the workings advance, many fissures are cut, and as the coal is excavated towards the crop, and approaches the alluvial cover, a constant increase of water is found, so that a colliery which has been long at work frequently becomes very heavily loaded with water, and the machinery is required to go night and day. When a colliery is thus loaded with the ordinary daily growth of water, its situation is rendered dangerous and uncomfortable, to obviate which, the power of the engine is either increased, or additional engines erected. In practice, working barrels are seldom used of greater diameter than 18 inches, and in place of having pumps so large, many of the mining engineers prefer having two engines with less powers, and moderate sized working barrels, on account of the unwieldy nature of such heavy machinery, and the great extra tear and wear attending them.

The extent of the winning to be made, as to depth, and the power of machinery to be employed, having been determined upon, the mode of sinking engine pits has next to be described.

First, When the depth is moderate, and the process comparatively very simple.

Second, When the depth is great, and the process laborious and intricate.

In any winning, the figure of the engine pit is a primary consideration. In winnings of a moderate depth many forms are used, as circular, oval, square, octagonal, oblong rectangular, and long-elliptical.

In pits of inconsiderable depth, and where the alluvial cover is of a firm and dry consistency, any shape thought the most convenient may be used; but in all deep pits, no shape but the circular ought to be used. Indeed, when water requires to be stopped by tubbing or cribbing, no other shape will do, the circular shape being the only one which presents a uniform resistance in all points to the uniform and great pressure of water—even the elliptical shape, where there is but little difference between the two diameters, is not suitable; it has been tried, and has always given way when exposed to pressure of any considerable degree. Besides, the circular shape renders the pit stronger in the shaft walls, and is likely to be less injured than any other shape, in the event of the shaft being shaken by a sit or crush arising from the failure of the pillars left in working the coal. As to the sizes of engine pits, the smallest should be ten feet diameter, to admit the pumps to be placed in the lesser segment, and the coals to be drawn at the larger one, as in Plate CCCXC Fig. 9. which is termed a double pit; but if much work is to be done in drawing coals, and particularly if the coals are large, it would be an economy to have the pit wider than ten feet. When a pit is to be divided into three divisions, one for the engine pumps, and two for drawing coals, as in Fig. 10, which is termed a triple pit, it would require to be twelve feet diameter. If it is to be divided into four divisions, and made a quadrant pit, as in Fig. 11. with one division for the pumps, and three divisions for ventilation and coals drawing, it would require to be fifteen feet diameter. These sizes of pits are regulated by local circumstances, and by the output of coals proposed to be raised.

In sinking engine pits, the first point is the mode of passing through the alluvial cover. If it is of a firm and dry consistency, the process is easy, whether the depth be great or not. As all engine-pits require to be particularly well executed, and every part of the work done in a substantial manner, the shaft which passes through the alluvial cover ought to be secured with masonry of jointed ashler, with the joints accurately bevelled to the centre of the circle which forms the area of the pit. The stones used are from a foot to sixteen inches in thickness, about a foot in depth, and of any convenient length. The pit is therefore begun, and sunk of a circular form, through the alluvial cover, of such an extra width as to admit the thickness of the masonry or stone cradling, as it is termed. When the depth is about 12 or 15 feet, the bottom is made level, and a ring or crib of oak or elm, about four and a half inches thick, and ten inches broad, laid in the bottom. Upon this the ashler is built upwards to the mouth, and all the void betwixt the ashler and the earth walls firmly beat up with clay. The next operation is to sink again, keeping the sides about three inches inside of the perpendicular of the ashler walls. This sinking is carried down from three to nine feet, according to the consistency of the cover, and when the distance is fixed upon for another crib, the pit is widened out at the bottom, so as to admit the second crib to be laid exactly in a perpendicular direction below the other; and when this crib is laid in its place, about three or four feet in breadth is taken out from one of the sides, and in this a pillar of ashler is built, resting upon the lower crib, and supporting the upper one. The same thing is done on the side immediately opposite, and then at the other quarters of the circumference, after which the intermediate spaces are widened and built up. In this manner the pit is sunk until the rock head is found, when it is made level, and the lower part of the ashler rests upon it. When stones cannot be easily procured, hard bricks are substituted, ten inches or a foot in length, with a level to suit the radius of the pit. When ashler is built in stages, as before described, the under building may be sometimes done with three pillars, and then filled up around; but when no cribs are used, as is sometimes the case, very narrow pillars are built up, to secure the masonry above.

When the cover is not very firm, the stages sunk at a time, and built up with masonry, will not admit of being more than from two to three feet, and when the cover is of such a kind as not to admit of this mode of operation, a different plan must be adopted.

If the cover is of clay, with sand backs and oozings of water, so that it will not stand firm for even a foot or two, it may be sunk through, and secured by the following process.

For circular pits, circular fellies of wood, named cribs, and for square or octagon pits, square balks of wood, named bars, are prepared, and used as a temporary cradling until the mason-work is built. The width of this carpentry depends upon, whether the timber is to be drawn out as the building advances upwards, or if it is to be allowed to remain, and the mason-work built within it. The shape of the pit where the timber is used is either a circle, a square, or an octagon. The temporary cribs are formed of oak, ash, or elm, about seven inches in the bed, and five inches deep. The balks are of fir, and from six inches to a foot square, according to circumstances. The joints of the circular cribs are plain, and bevelled to the radius of the circle. The joints of the balks for a square or octagon pit are half checked.

If the timber is to be left in the pit, and the masonry built within it, the quality of the wood need not be much attended to; but if it is to be drawn and used again, it requires to be good, in order to bear the fatigue it is exposed to, without being rendered useless.

With circular cribs of wood, backing deals are used of about 1¼ inches thick; the pit is then sunk as far as the cover will admit with safety; a strong crib is placed at the top or pit mouth, in a level position; the backing deals are placed all around, and reach to the bottom of the space sunk; cribs are then placed about two feet apart, and the lower crib of the set is fixed the half of its depth lower than the ends of the backing deals; the cribs are secured at the joints by thin spars of wood overlapping them, and they are kept in their horizontal position, either by brackets placed under them, and nailed to the backing deals, or by a few deals placed inside of the cribs, and nailed to each. Particular care is requisite, in sinking through the cover, to have it no wider than necessary, in order that the backing deals may bear against it, and if there are any vacuities, these must be filled up with rubbish well packed. When the first or upper space is thus secured, another space is sunk, of such a depth as the cover will admit of; then backing deals and cribs are placed in the same manner as above described, the end of the second set of deals having a hold of half of the lower crib of the first set. In this manner is the cover sunk through and secured, until the rock head is found, when the masonry is begun, and carried upwards to the top; if the cover is of such a kind as to admit the cribs and backing deals to be drawn, these are taken out in such lengths at a time as are judged safe, and the space betwixt the masonry and cover filled up with any kind of rubbish, firmly beat in. If there is any risk of the cover slipping, then the carpentry, or the greater part of it, must be allowed to remain in the sides of the pit.

In sinking square pits through a firm cover, the same kind of process is adopted as that with the circular cribs, the only difference being in the joints, which are half checked.

In sinking through a firm cover with a pit of an octagon form, the bars or balks are half checked in the joints, and put in close to one another; this is termed being placed skin for skin. If the cover is of a very firm consistence, their scantling or dimensions are small; if it is less firm, they are made proportionally strong. The process carried on in sinking to the rock head is the same as before described, the depth of cover passed through and secured, each stage being regulated according to the tenacity of the cover. The masonry is carried upwards from the rock head in the same manner as before described.

It is a common practice to place two strong logs of wood at the top of the pit, parallel to each other, and at a distance equal to the diameter of the pit, resting on cross sills, laid upon the surface of the ground; these are termed the hanging sets. From them the cribs or bars are suspended, and prevented from slipping downwards, by a few planks placed in a perpendicular direction along the face of the bars, and to these planks each bar is nailed.

When the cover is of soft mud, which is a common circumstance in many coal districts, it is passed through either by bars laid close to each other, or, if this mode is not found practicable, the operation of tubbing is resorted to.

When bars are used, each set requires to be put into its place as soon as the pit is sunk the depth of a bar. In this manner the sinking proceeds till the rock head is found, when the masonry is begun and completed as before mentioned. It is necessary to remark, that there is great attention required in this operation; for if the pit is sunk below the last placed bars, and not immediately secured by additional bars, the mud will swell out into the area of the pit, and, when this begins, it is almost impossible to stop it. The consequence of which generally is, that a void is formed at the back of one part of the bars, the resistance is then lessened, and the pressure operating powerfully on the opposite side, the bars give way, and the pit is frequently lost. It is also found necessary, sometimes, before a bar can be placed into one side, to drive a row of thin sheeting piles, from three to four feet long, into the mud upon the other sides in face of the bars, which prevent the mud coming into the pit while the other bar is fixing; and when this bar is placed, one side of the sheeting piles is removed and driven at the face of the last placed bar, till the adjoining bar is fixed. In this manner the bars are placed progressively.

When the mud is found to be so very soft that the operation of tubbing must be resorted to, a circular tub is formed of the requisite diameter. It is made of plank, from two to three inches thick, with the joints bevelled to the radius, inside of which are cribs of hard wood, placed at from two to four feet asunder, according as the circumstances of the case may require. The cribs are made of the best heart of oak, sawn out of the natural curve of the wood, suitable to the radius, in segments of from four to six feet in length, from eight to ten inches in the bed, and five or six inches in thickness. The reed of the wood require to be clean, without any twist or cross grain, for the greater strength and security of the work. The length of the tub is made from nine to twelve feet long, if the mud is of that thickness; but if the mud is very thick, a succession of tubs is placed one above another. The tub first to be used has the lower end of the deals made thin all around, and shod with sharp iron in the face. If the pit is previously secured to a certain depth, then the tub is constructed to pass within the cradling, and lowered down with tackles till it rests among the soft mud, it is then loaded with iron at the top, so that it may sink as the mud is excavated. If the first tub does not reach to the rock, then a second tub of similar construction is placed upon the top of it, and the iron weights removed also to the top. In this manner the tubbing is sunk, till the cover is passed through and secured. If the mud is uncommonly soft, and pumps are used to draw the water, they must be hung with tackles, and not allowed to sink down so low as the bottom of the tub, as they would not only be liable to choke, but they would have a tendency to draw the mud from the back of the tubbing. It is therefore the practice to keep the bottom of the tub several feet in advance of where the workmen stand, and to keep about a foot of water upon the top of the mud. In this way the workmen stand upon pieces of board, to prevent themselves from sinking; and the mud is lifted with scoops or shovels under the water. If the mud is of great depth, the tubs must be strengthened with additional cribs to resist the pressure.

The most difficult operation in sinking, is when the cover has a bed or beds of quicksand in it, or has a great bed of quicksand from the surface to the rock head. This circumstance is, in all cases, productive of great additional labour and expense. In the early times of mining, a quicksand cover formed an insurmountable obstacle to the miner; and it is only within the period of a few years past, that the operation could be gone into with the hope of ultimate success. As this is one of the most important points in coal mining, and as very large sums have been lost by unsuccessful attempts to sink through the sand, the different processes which have been adopted, and most approved of, will be now described, so that a distinct idea may be formed of them.

In sinking a pit through any cover, the nature of which is not known, the first thing to be done is to prove it by boring; when that is done, the plan of operation most suitable can then be determined on.

Beds of quicksand are frequently found covering coalfields upon the margin of the ocean, or by the sides of rivers. One of the oldest plans for passing through them, is by what is termed casting out; this is still practised successfully. If the sand lies close to the surface, and does not exceed sixteen feet in depth to the underlying bed of clay or the rock head, the plan of casting out is adopted; if it is deeper than this, another process is required. When the depth is about sixteen feet, the first operation is to bring up a surface drain, as low as the situation will admit of, which, in most cases, from the flatness of the surface, is very little; then from the point where the centre of the pit is to be, a circular area is marked off, of such a width, that if the pit is to be twelve feet diameter inside when finished, the sand may be excavated in the form of the frustrum of a cone, having the sides sloping at an angle of 45 degrees, which slope is set off at such width as to uncover the impervious clay or rockhead to the width of twenty feet. In this case the mouth of the excavation would be about 52 feet in width. It is of great consequence to carry on this operation very expeditiously; in some instances from fifty to a hundred workmen are employed, and as much of the sand as possible is taken out by horses, carts, and barrows, and laid at a distance. As soon as the water begins to gather, sloping pumps are used, and the water never allowed to accumulate. When the slope renders the using of carts and barrows no longer convenient, then the sand is thrown out by various means, such as by men from one stage to another, by trams and tramrods laid along the slope, or by common jack-rolls or windlasses, with ropes and buckets erected upon framing supported by tresses. Horse-gins are also used, placed at a distance from the pit; and when the water is very heavy, a small steam-engine is employed; the framing over the excavation being either supported by tresses and stays, or by masts, from which the framing is suspended by tackles. No foundation can be got for the main pumping engine till the pit is built up and the cover made quite secure. If towards the bottom of the slope the water is likely to produce a running of the sand, the slope is carefully covered with compact turf, cut from a green sward, which, though a very simple remedy, is frequently quite effectual if applied in time; for it has been found from experience, that if once the bottom of the slope begins to run, it cannot be stopped in its progress, so that in a short time the whole labour of weeks may be lost. Plate CCCXC. Fig. 12. represents a bed of quicksand resting upon a bed of impervious clay, which clay is the immediate cover of the rock. When in this case the clay is found, the first course of ashler stones, jointed to the radius of the pit, is laid in a true circular position in the centre of the area, and about a foot into the clay; or in some cases where the clay is not very strong, a circular crib of wood is laid down; upon this the ashler is built, and as each course of stones is laid, about a foot or fifteen inches of well-wrought clay is regularly beat all around the back of the building, and whatever water comes from the sand, flows up at the back, and is allowed to run over the building into the area of the pit, in order to be pumped up. As the ashler and moating are progressively carried up, the space at the back is filled up with sand and rubbish, until the pit is completed at the top, and the surface made suitable for the operations of the colliery. By this plan none of the water found in the sand goes down the pit, but is kept back by the clay moating till it finds a natural issue at the surface. A is the pit, *a a* the quicksand, *b b* the excavation afterwards filled up, *c c* the ashler building, *d d* the moating of clay. When this is done, the impervious clay is sunk through to the rock head, and secured with ashler in the manner mentioned for sinking through compact cover. If the sand rests upon the rock head, and the rock be of a kind which is impervious to water, then the ashler is laid upon it as soon as a level foundation is made; but if it is a porous or jointed stone, it must be sunk through until a stratum impervious to water is found, from which place the building and moating commence.

If the quicksand is deeper than sixteen feet, it is thrown out in the first place to that depth, in the manner before described, and the additional thickness of sand is passed through by means of strong frames of wood, at the back of which sheeting-piles are driven down progressively as the sand is taken out; but this mode of passing through sand is uncertain of success, and is not in general practice.

The manner of passing through mud with tubbing having been before described, the same kind of operation is applicable to passing through quicksand; and if the bed of sand is thick, it is passed through by what is termed a drop tub, that is, after a number of tubs have been sunk by great weights, and begin to get body fast, so that they will not sink any farther, another set of tubs is let down through these, and continued till they reach the rock. These tubs are constructed of such strength, as to resist the pressure and be water-tight. If the tubbing is judged to be too weak at the bottom for the pressure, an additional number of oak cribs are inserted. During the operation, the bottom of the tub which is sinking is kept always a few feet lower than the spot where the men are lifting the sand, in order to prevent the sand flowing in from the back of the tubs; and it is necessary to keep about a foot of water upon the top of the sand, and to hang the pumps in such a manner as only to be a few inches into it. When these tubs are completely secured and wedged tight at their junction with the rock head, and where they join each other, the whole internal face of the cribs is covered over with close jointed deals, an inch and a quarter thick, which gives the pit an appearance of a smooth wooden cylinder.

The most effectual method for passing through beds of quicksand is by means of iron cylinders, termed cast-iron tubbing. If the pit is of small diameter, these are made about four feet in length, with strong flanges, and bolt-holes inside of the cylinder, with a counterfort ring at the neck of the flange, with brackets; the end of the lowest cylinder has no flange, but is rounded to render its sinking through the sand more easy. If the pit is of a large diameter, then the cylinders are cast in segments of two, three, or more pieces, joined together with inside flanges, having a jointing of white lead and oakum. If the sand-bed is thick, suppose eighty feet for example, the practice now is, to divide that space into three sets of cylinders, thirty feet each in length, and so constructed as to pass through each other like the tubes of a telescope. These cylinders are joined together, piece after piece, and pressed down by great weights, using the same precautions in keeping the lower part always farther down than the top of the sand where the men are at work, and where the bottom of the pumps is for drawing the water. When the first thirty feet of cylinders is put down, the lower part of the next set of cylinders is passed through the first set, and the sinking carried on until the additional thirty feet of cylinders are sunk, after which the third set of cylinders is passed down through the two former sets, until the lower part reaches the rock-head or impervious stratum; the joinings of the three sets of cylinders are made tight by wedging with wood. It is proper to remark here, that this mode of dividing the deep sand to be passed through into spaces, is an improvement but lately adopted at Newcastle. Before this improvement, almost every attempt to pass through very thick beds of quicksand was rendered abortive.

The engine-pit being thus secured by one of the several ways before-mentioned, the process of sinking through the rock is now ready to be begun; but, before commencing, the divisions of the pit formed of carpentay, named brattices, are made; this is done in several ways.

In common practice, and where great tightness of jointing is not required for ventilation, on account of inflammable air, bars of wood, named buntons, of about six inches thick and nine inches in depth, are fixed in a horizontal position across the pit; they are placed at different distances according to circumstances, sometimes at the length of a pump from each other, and at other times there are two or three in that space. These buntons, are all placed in the same perpendicular line, and upon these, deals of an inch and half thick are nailed, having their joints close; and each length of these deals takes in the half of the upper and under bunton to which it is nailed. In deep pits, when the ventilation is to be carried on by the brattice, the side of the buntons next the pumps is covered with deals in the same way, the joints made as tight as possible, and next the pit the irregular joining is caulked with oakum, and fillets of wood fixed all the way down on each side of the brattice; this forms a double pit.

When a pit is divided, so as to form three pits, it is a more difficult process to form the brattice, as none of the buntons stretch across the pit, the three which form the divisions meet, forming angles with each other near the centre of the pit; and in order to give them stability and strength in their position, they do not lie across in a horizontal line, but have a rise from the sides to the centre of about nine inches where they meet, and a three-tongued iron strap binds them together by means of a bolt at each tongue. Fillets of wood are carried down the whole depth, not only at the joinings of the brattice with the sides of the pit, but also at the meetings of the brattice at the centre of the pit; and, for farther security, a prop of wood reaches from the centre of one set of buntons to the centre of those immediately above; by this means a very strong piece of carpentry is formed, having its strength depending upon the principles of the couple of a roof. These buntons are clad on all sides with deals from top to bottom; and the ends of all the deals meet each other in the middle of a bunton.

In quadrant pits the buntons cross each other in the centre of the pit at right angles, and are generally only let in about an inch into each other, in place of being half checked. Plate CCCXC. Fig. 9 is a double pit, A the engine pit, B pit for drawing coals; Fig. 10 is a triple pit, A the engine pit, B and C pits for drawing coals; Fig. 11. is a quadrant pit, A the engine pit, B the pit for the ventilating furnace, C and D pits for drawing coals.

These methods now described, being such as are used in the practice of mining when sinking through the cover, securing the sides of the pit, and dividing the pits by brattices, it must be remarked, that several of these processes are attended with such immense expence, that it is only in districts where great returns of profit are made, that they can be attempted. It is at Newcastle and Whitehaven where by far the greatest capitals are employed, and where the very expensive methods of sinking through quicksand are adopted and prosecuted with vigour and success. As engine-pits are now sunk in winnings of collieries made from the depth of 20 to 150 fathoms, that is, with pits having one set of pumps, to those having five sets, the operation, though in most of the circumstances the same, is very different as to labour, difficulties, expences, and skill required. In winnings of a moderate depth, if the water found in the cover is kept from descending the pit, the feeders found in the rock are allowed to flow down. In deep winnings, the most minute attention is paid to prevent any water from descending, by methods to be described afterwards.

As 75 fathoms is reckoned rather beyond the average depth of winnings or of engine-pits in Great Britain, and as in practice it embraces three sets of pumps, by describing this operation, we describe also the more simple winnings of one and two sets.

As soon as the pit is sunk to such a depth that the engine must be applied to pump the water, the first set of pumps is let down the pit; these are termed the sinking set, they are jointed with strong flanges and bolts, having a jointing of lead of about half an inch thick, covered with tarred flannel. There are several methods for suspending them during the process of sinking, as they must rest on the bottom of the pit, and be lowered gradually as the rock is blown up and wrought away. The common practice in pits with one or two sets of pumps, and where the sets are of no great size or weight, is to have two shroud-laid ropes or cables, named ground ropes, of abundant extra strength to meet casualties and heavy strains. These ropes are made fast below the clack-seat door, and are passed up each side of the pumps, having a piece of service or lapping put round them, opposite to each flange, to prevent their being chafed or cut; and a strong lashing of pliable hand line acts as a collar at each pump, which connects the whole pile firmly together. The ropes are sometimes passed over two large pulleys at each side of the pit mouth, and several turns are taken round a strong circular post of wood, fixed deep and firmly in the ground. As the pumps sink down, the ground ropes are slacked off or eased away, care, however, being taken to keep a considerable bearing upon them, so as to have at least a fourth or a third of the weight suspended; this is a very rude and a very old plan, though still in practice. This method is greatly improved by having strong five-fold tackles attached to the top of the ground-ropes, and the fold of the tackles passed round the post as above described; by this plan the lowering is not only performed more correctly and easily, but the pumps can be lifted up immediately by applying the tacklefolds to crabs or capstans. In this process a caution is necessary while the pumps are lowering, that their flanges do not catch any of the timber-work in the pit, as the weight would not only break them, but endanger the lives of the men at the bottom.

But the most complete and correct plan for lowering the pumps in sinking, is the following, which was practised and brought into use by the Newcastle engineers. There are attached to the wind bore, or suction piece, two very strong ears, (see Plate CCCXCI. Fig. 1.) having counterfort brackets upon the upper side; in each of these is a square hole, three and a half inches diameter, through which rods of iron are put and secured by a strong cotter at the under side of the ear. To these rods, U plates are attached; these plates are fixed to wooden spears, six or seven inches square, according to circumstances, and are connected together with side plates, in the same manner as pump spears. These spears are carried up the sides of the pumps, and close to the flanges, until they are as high as the top of the sinking set of pumps, or a few fathoms higher. Under each flange of the pumps, a lashing of pliable rope is passed round both the spears and the pumps; this keeps the whole very firm and in a perpendicular direction. To the top of the spears. U plates are fixed, having a large strong eye at top; to each of these eyes, a five-fold tackle is hooked, and the upper blocks or pulleys are suspended from strong wooden beams at the top of the pit. The tackle-folds pass upwards from the lower pulleys, over single pulleys at each side, and are hove upon capstans till there is an equal bearing on both tackles. To the arms of the capstans, sledges are attached with ropes or chains; these sledges are loaded with weights in proportion to the weight of the column of pumps, and as additional pumps are added, more weight is put into the sledges. By this very correct and mechanical arrangement, the sinking set of pumps, in the most gradual manner, and of their own accord, sink as the pit is sunk, and draw round the capstans. Before this method was adopted, the trouble, loss of time, and danger attending the lowering of sinking sets, were uncommonly great. As the sinking set is constantly going down, and the point for the delivery of the water always varying, a pipe of the same diameter as the pumps, but much lighter, is used, about eleven feet long, having a short pipe cast near the top, to which a hose or hoggar of leather is attached, of sufficient length to reach the cistern where the water is delivered. This is called the hoggar-pipe; and in the course of sinking, as soon as the top of the hoggar is upon a level with the top of the cistern, the hoggar-pipe is removed, a common pipe put in its place, and upon the top of this pipe the hoggar-pipe is again fixed. In this manner the operation of sinking goes on, until the column of pumps has reached either the bottom of the pit, or the place fixed upon for having another set of pumps. A, is the sinking set of pumps, *a*, *a*, the ears through which the iron rods pass connected with the spears; *b*, *b*, the spear; *c*, *c*, the lashings; *d*, the hoggar-pump; *e* the hoggar; *f*, *f*, the tackles; *g*, *g*, the single pulleys; *h*, *h*, the tackle-fold leading to the capstans; *i* the pump spears.

In a sinking set of pumps, the wind-bore or suction-piece, is not open at the bottom as in the other sets, which are fixed, but it is rounded and of a long form; it is perforated with holes of from one to two inches diameter, where, besides the small holes, there is a large hole for admitting a man's hand, in order that the cavity may be at any time cleared of rubbish which may gather within it. When the workmen are sinking, the large hole is filled with a plug, having a projection of such length as renders it easily drawn at any time; the workmen have a number of plugs for the small holes, and when the operation of sinking begins, the upper tiers of holes are plugged up, and the ingress of the water confined to the lower holes. By this plan, as the bottom of the suction-piece is kept in the bottom of the sump, or lowest part of the pit, the other part of the pit bottom is kept dry for the operations of the workmen. If the growth of water abates, more holes are plugged up; if it increases, an additional number of them are opened. When the operation of sinking is suspended for any time, all the plugs are withdrawn in order to give full water way to the regular working of the engine; and as much depends upon keeping the suction-piece safe, where it is exposed to violent strokes from the blowing up of the harder rocks, it is necessary either to wrap it round with old ropes, or to case it with staves of soft wood, which will not easily split. It is further to be observed, that as in sinking, a vast quantity of air enters with the water every stroke of the engine, the pumps are filled with air and water together. On this account, the engine is wrought upon air, as it is termed; and it is the object of the engine-keeper not only to make the lifting stroke very slow, but so to regulate the movement, that when the stroke is completed, the engine may stop several seconds before it makes the returning stroke, to allow all the air to ascend. If the engine is working as a double power engine, the same kind of halt must be made at the returning stroke. This mode of working the engine is now regulated either by water cataracts, or by air vessels attached to the gear of the engine; or in small engines, the working is regulated by a man upon the hands of the engine, when the improved regulators are wanting. As the working barrels are generally nine or ten feet long, and the full stroke of the engine from seven to eight feet, when at regular work, it is the practice to lessen the length of stroke in sinking to about six feet, because, as the pumps are constantly going down, the bucket in the working barrel progressively has its working space higher up. If the working barrel is ten feet long, and the restricted stroke of the engine six feet, and if the bucket is at the bottom of the barrel when the engine is ready to make its stroke, then the pumps can be lowered about four feet, ere the bucket be working at the top of the barrel. To this descent of the pumps particular attention has to be paid; and therefore, as soon as the pumps have sunk four feet, the spears and bucket are let four feet lower into the barrel, and this is done at the top of the pit, when the spears overlap, and are fixed laterally by screwed glands.

The common depth for a set or column of pumps being from 25 to 30 fathoms, when this depth is attained by the first set, preparation must be made for fixing the upper pit cistern, into which the upper set of pumps is to be placed, and into which the water of the second set is to be thrown. If a strong bed of sandstone is found, a scarcement is left of the rock projecting about three feet into the pit, and is formed, in the course of sinking, into a chin or strong bracket, to support that part of the cistern upon which the upper set of pumps is to rest; and a few feet under it, the pit is formed into its regular width. A recess is cut into the side of the pit backwards from the bracket, for holding the cistern into which the upper set of pumps is to be placed. For the greater security of the place where the pumps rest, the recess is formed dove-tailed, about eleven feet back from the face of the bracket, from three to four feet in breadth, and about thirty inches in depth. Into this, a pit cistern bunton is laid and firmly wedged, composed either of oak or of best foreign redwood pine, having the thick end laid into the back part of the recess, to prevent its coming forward into the pit, by the concussions and vibrations of the pumps, and in case of any failure of the bracket under the pumps. The inner end of this bunton is farther secured by blocks or chokes of wood, placed betwixt the upper side of the bunton and roof of the recess; similar chokes are placed upon the inner end of the cistern. When the rock is of such a quality as not to be fit for forming a bracket, then a cross bunton of wood is substituted, from one to three feet in breadth, and from two to four feet in depth, according to the weight of the column of pumps to be supported. This bunton is fixed into the sides of the pit, and has a hold at each end from two to four feet, according to the strength of the rock; upon this the cistern is placed, having a recess, as before described; sometimes logs eight inches thick are placed into the recess, at right angles to the cross bunton, firmly secured together, and upon these the cistern is placed.

Although from 20 to 30 fathoms is the common length of a lift or set of pumps, it sometimes is necessary to make it much longer, when no place can be found in the shaft for fixing a cistern, on account of the tubbing; from this cause a lift of pumps has been made of 70 fathoms in length; but this requires uncommon strength of every material, and such a length is only made from absolute necessity.

It is the practice to use the sinking set of pumps for sinking the whole depth, so that as soon as the first cistern is ready, a set of pumps, named a fixed set, is substituted for the sinking set. In common practice, fixed sets of pumps are joined together by flanges and bolts, but in the improved practice, all the fixed sets have spigot and faucet joints; and the joints are made water tight by lappings of tarred flannel. But the lower set of pumps of every engine has flange joints, with strong bolts, for the special purpose of their being connected in one firm column, so that if the water should grow up the pit, or any leak happen in them below water, the whole may be drawn up from the bottom, if necesssry, and repaired; which operation could not be effected with the other kind of joints, as they would not hang together. In the case where there is only one lift of pumps, the flange-joints are for the same reason used. The spigot and faucet joints render the drawing of pumps one by one, and placing and jointing them, a much quicker operation than when the other joints are used. In general, the operation may be performed in less than a tenth of the time required for the other kind; and it may be frequently of great service to have the upper half of the lower set with spigot and faucet joints, if there is no risk of the water rising very quickly up the shaft, of which there is generally little danger after the colliery is opened up and a sufficient reservoir formed for the water.

With regard to the mode of collaring the pumps in the pit, keeping them steady, and in a true perpendicular line, the old practice is, to have two buntons of about nine inches deep, and six inches in breadth, to pass close to the side of each pipe under the flange or joint. The ends of these are fixed into the shaft wall, and the other ends rest on brackets fixed to the brattice wall; the other sides of the pipe are collared by pieces of wood, named rackings, and in some cases stretch only the breadth of the buntons; or, if the pit admits of it, one or both of them are fixed into the side of the shaft wall. The improved plan, in order to give as much room as possible for the operations which are so frequently carried on in the engine pit where the pumps are, is to fix a strong bunton under the joint of each pipe; to which buntons the pipes are firmly attached by a collar of iron, with screws and nuts, as represented Plate CCCXC. Fig. 13. By this plan there is much more room in the pit.

Though this mode of fixing the pumps is very suitable for all the upper sets of pumps, it is not so for lower sets, where from accidents to which they are liable, the pumps are sometimes to draw up bodily. The mode of fixing with buntons and rackings is therefore preferred in the lowest set, and the fixtures are so made, that if there is not time to remove the buntons and rackings, the whole may be hove up. In cases where the buntons hold fast, they must be cut away under water by chissels fixed upon loaded spears.

With regard to the water which is found in sinking through the several strata, in ordinary cases it is conducted down the walls of the shaft. If the strata are of a firm consistency, a hollow ring is cut into the sides of the pit in a spiral line down the shaft, and when the ring can hold no more water, the water is either conducted down in a square spout to the nearest pit cistern, or a groove is made in a perpendicular direction in the shaft wall, and a squere box either inserted into it, flush with the sides of the pit, or it is covered with deal fitted tightly to the cavity. Similar spiral rings are formed in succession downwards, and the water conducted always into the nearest pit cistern. The improved plan is, to insert rings of wood or cast iron, flush with the sides of the pit, and the water is conducted from one ring to another, by means of perpendicular pipes, until the under ring can hold no more water. When the water from that ring is carried in pipes to the nearest cistern, then a new set of rings is inserted under these, and the water conducted in the same manner all the way down. As keeping a pit dry is an important point, great attention is paid to the doing of it well. When it happens in an engine-pit that there are a great many beds of coal found in the shaft, a mine a few yards long is driven into each coal, and a bore put down from one coal to another, the water is gathered into each coal, and descends through the bores to the pit cisterns.

The practice of keeping the shafts dry, as now described, is very generally adopted in Great Britain, when the pits are of a moderate depth, and when all the water found in sinking can be drawn by an engine of a moderate power. But in very deep pits, such as those in the counties of Northumberland, Durham, and Cumberland, where they are from 80 to 150 fathoms in depth, the preventing of the water found in sinking, from being a burden upon the engines, is most carefully attended to, and is one of the chief points in the science of mining. In this operation, much skill and resolute determination are displayed. The mode of passing through the cover, and the various modes for preventing the water from that source descending into the pit, have already been described. The next thing is, to point out the plans which have been successfully adopted for preventing the water found in sinking from flowing into the pit, and becoming a burden upon the engine. Those strata which generally produce the greatest feeders of water, are the sandstones, particularly those of an open porous texture, or those which have very open cutters. Sometimes both these qualities are combined, and then the growth of water is uncommonly great. Several of the sandstones are, however, impervious to water, and almost all the beds of light-coloured argillaceous schistus or fire-clays are particularly so, being very close in their texture. But some of the sandstones, though impervious to water in their texture, have wide and open cutters which produce much water. Feeders of water are also frequently found at the beds or partings betwixt two of the strata. Those strata which are impervious to water are said to be capable of turning water.

While the sinking of one of these deep pits is going forward, a regular journal is kept of every part of the operation, and each feeder of water is measured, not only after it is found, but daily, to find if its growth increases, abates, or is regular. The mode of measuring is by receiving the water into a vessel of 30 or 60 gallons content, and finding, by a seconds watch, the time required to fill it. Three experiments of this kind are made at each trial, and the average time of the three entered in the journal. When the feeders of water in one or more of the strata sunk through are producing such a quantity of water, as to render the stopping of it back absolutely necessary, the first thing to consider is, whether any of the strata passed through under the feeders are impervious, or capable of turning water; and if there are none, the pit must be sunk till a stratum of that kind is found; then the strata are to be examined upward, until a similar stratum is fixed upon. There are three methods of keeping back the feeders; viz. by plank tubbing, iron tubbing, or by oak cribs. As the pressure to be resisted is the next consideration, it becomes necessary to explain its extent or limits. To illustrate which, Plate CCCXC. Fig. 14. represents a pit sinking through the various strata, having a cover of sand with much water resting on the rock head. It is evident, from what was explained when treating of the forms of coal-fields, that each stratum sunk through in any pit, whether near the surface, or at the greatest depth, rises in one direction until it meets the alluvial cover; for which reason, the pressure of water at the bottom of the tubbing which rests on the rock-head, is as the depth of the water found in the cover; and if a stratum *a* is found to yield a great quantity of water, and that the stratum *b* above, and the stratum *c* beneath it, are impervious to water, if the porous stratum *a* is twelve feet thick, and no water found in the strata passed through from the rock-head, until that depth which is supposed to be fifty fathoms from the surface of the water in the cover, in this case, the tubbing or cribbing has not to resist the pressure of the water of twelve feet only, but must be made of strength sufficient to resist a column of water equal to a perpendicular altitude of fifty fathoms; because the stratum *a* meets the alluvial cover at *d*, the fountain-head from which all the water found in sinking proceeds. Upon this principle, though no feeder of water was found of any magnitude until the pit had been sunk 100 fathoms, if this water required to be tubbed off in a stratum only three feet in thickness, the tubbing would require a strength equal to the resisting of 100 fathoms of pressure; for although the water may only come through the open pores of the stone, yet, when the water is resisted, these innumerable tubes act upon the tubbing with the full effect of the whole hydrostatic column; for it is found from experience, that whatever water occurs in pits, or in the working of mines, proceeds from the surface. A clear understanding of this principle is an essential point in mining. Upon this principle, also, if the cover which rests upon the rock-head is of impervious clay, very little water will be found in the strata; but if sand beds rest upon it, or rivers run along it, the water will be very abundant.

From this view of the great pressure of water found in sinking, the tubbing it off is an operation of the first consequence, and requires much skill, attention, and practice. If several fathoms of the strata are to be tubbed, in order to resist the flow of water, the pit has to be widened regularly, to admit the kind of tubbing proposed to be put in. The greatest width being required for plank tubbing, and the least width for iron tubbing. Plate CCCXC. Fig. 15. represents a pit widened out for plank tubbing, where *a*, *a*, *a*, *a*, are the impervious strata, *b*, *b*, the porous strata yielding the water, the bottom of the recess *c*, *c*, is made level, and as smooth as possible, by means of mason irons. The same points are attended to in working off the upper part of the recess *d*, *d*. In this operation, wedging cribs, spiking cribs, and main cribs are used; besides the plank which forms the tub, a quantity of fine dry clean reeded deal is prepared for forming the joints, which is known by the name of sheeting deal. This sheeting deal is always applied in pieces laid end-ways; that is, with the end-reed of the wood towards the area of the pit. As much of the security depends upon the tub being water-tight at its jointing with the rock, several plans have been adopted for this purpose, the most approved of is represented, Fig. 2. Plate CCCXCI.

In order to give room for the lower wedging crib, the recess is cut a few inches wider, as at *c*, from *b* to *c* is laid with sheeting deals all around the circle, or with a thin uniform stratum of oakum. Upon this the wedging crib *d* is laid, and neatly jointed to the radius of the pit, each segment trained exactly to the circle. At each joint of the segment sheeting deal is inserted. This wedging crib is about ten inches in the bed, and six inches deep. The space *e*, at the back of the crib, about two and a half inches wide, is filled with pieces of clean reeded dry deal, inserted end-ways: and this is regularly wedged with one set of wedges all around; then with a second and third set in the same regular manner, the object being to keep the crib in a position truly circular, the wedges used in this operation are made of dry clean fir, very thin at the head in comparison with their length, openings are made for entering the points of these wedges by a steel wedging chissel; and the wedging is continued regularly around, until the steel wedging chissel cannot make an opening in the wood. By this operation no water can pass downwards by the back of the crib. The next operation is, to fix a spiking crib, *f*, to the rock, about 10 or 12 feet from the lower crib, according to the length of the planks to be used for the tubs. This spiking crib is about five inches square, and is only used for spiking the deals of the tub to it. They must, however, be set true to the sweep of the pit, as upon them the true circular figure of it depends. This spiking crib being placed, the tubbing deals, *k*, are to be fixed. These are made of deals three inches thick, and about six inches broad, planed on all sides, and the joints wrought to the true bevel of the circle of the pit. Sheeting deals are laid under the deal ends, and the tub deals are firmly set together, one by one, in a perpendicular direction, their upper ends reaching to the middle of the spiking crib *f*. Formerly these planks were fixed to the spiking cribs with iron nails or spikes, but as these were soon destroyed by corrosion, particularly when there was any salt in the water, treenails are now used, and found to be much better. When the planks are set around, and within less than three breadths of a plank from being closed, a plank is placed on each side of the opening, having a square joint next each other in place of being bevelled, which leaves a rectangular or parallel space for inserting the closer or closing plank. This plank is prepared so as just to enter by force, it is then rubbed on the edges with soft soap, and is, by main force, and heavy mallets, driven flush with the other plank. The sheeting deals under the ends of the plank, and in the joints of the wedging crib, are then wedged tight, in the manner before mentioned. The main cribs *g g*, are then to be placed as counterforts, for the security and strengthening of the tubbing. These cribs are made in the manner before mentioned; they are about eight or nine inches in the bed, seven inches thick, and are placed at distances from each other, proportioned to the column of water to be resisted. At great depths they are laid close together, and the distance from each other increases as the pressure decreases, care being taken to have always a decided excess of strength, and made to bear equally against the tub deals, by means of wedging at the joints. The first main crib is laid close to the foot of the tub deals, and resting on the wedging crib. During this operation, the growth of water at the back of the tubbing is allowed to flow freely through a plug hole at the foot of the tubbing, until the whole operation is completed. The upper ends of the first set of tub planks are then cut square, and level all around. The second spiking crib *l*, is then fixed, and another set of tubbing deals put around as the former, having sheeting deal inserted betwixt the ends of the two sets at *f*. When this is wedged, the cribs *h h* are placed in the manner before described. According to this plan, tubbing may be carried upwards to any height, until the water rising at the back of it would discharge itself into the natural reservoir above the rock head, as is frequently done; but if a tubbing of a few fathoms is to be formed in a recess at a considerable depth from the rock head, then a wedging crib must be placed at the top of the recess, and firmly back-wedged, as at the lower wedging crib *d*. When this kind of tubbing is completed, the plug hole is filled up, and the water quickly rises and produces its full pressure. Although, from the nature of the operation described, it might be supposed that nothing could shrink even in the least degree, yet, as the pressure accumulates, the wood and the joints are heard very distinctly creaking by the excessive pressure. From this it is evident that no form but that of a circle could resist such a weight. After the full pressure is obtained, it frequently happens that veins of water, not thicker than a fine hair, will be found springing from the sides of the tubbing; these generally take up in a few days by the swelling of the wood. When all is secured, sheathing deals, inch and quarter thick, are nailed to the cribs all around the pit, not only to preserve the cribs from injury, but to make a smooth wall for the ascending and descending baskets with coals. These sheathing deals are put on in regular perpendicular courses, and the but-ends meet flush on one of the cribs.

The solid cribbing, executed with oak cribs only, and no tubbing deals, is a more complete piece of work than the former. If the pressure is great, they are formed three to four feet long, ten inches in the bed, and seven or eight inches deep, of the best oak, as before described. The first crib is laid down, and back wedged, in the same manner as the wedging crib in the plank tubbing, with this difference, that it has been found, that when the wedging was made in lines parallel to the sweep of the cribs, the immense pressure had a tendency to press forward the lower part of the crib; and it has been found from experience, that, if the wedging is done in a diagonal manner, it is much superior, and quite effectual. After the back wedging is completed, the next tier of cribs is laid down in precise position, having sheeting deal along the bed, and at each end joint, the perpendicular joints are overlapped in each set by the position of the next segments alternately, so that the face of the cribs, with the jointings of sheeting deals, has the appearance of ashler work. A wedging crib is fixed in the upper tier, if next the top of the recess, and the back wedging completed, as before directed. Each crib is set true to the radius of the pit, and the back of it filled up with pieces of wood betwixt it and the rock. When the whole space proposed to be cribbed is filled up, then the wedging of the joints commences while the water flows by a plug hole at the bottom. All the horizontal and perpendicular joints are gone over completely with one set of wedges; and, in the same way, a second and a third set of wedging is done, till wedges can be no longer driven. The face of the wedgings is then made smooth, the plug hole filled up, and the full pressure sustained. In this kind of work, innumerable fine veins or filaments of water issue from the wedgings, the water being forced through the pores of the wood. If these do not take up, additional wedging must be attempted, till not a particle of water can be seen issuing. In this piece of work, much ingenuity is displayed, and it reflects much credit upon the inventor.

The third mode of tubbing is by means of iron cylinders cast into segments. These are different from the drop or sinking cylenders, because they are placed piece after piece in the circular recess of the pit cut out for them. The flange for the wedging joint is sometimes towards the centre of the pit, but the improved method is, to turn the flange inwards. In the latest improvements of this plan, executed by Mr. Buddle, where there was a pressure of several hundred feet, the segments were six feet long, and two feet deep, an inch thick, counterforted with raised work on the back; the lip of the flange was strong, and supported by brackets. These iron segments of a cylinder are set true to the radius of the pit; and every horizontal and perpendicular joint has sheeting deal in it. A wedging crib is fixed at the bottom, and the segments are carried regularly up, having the joints like ashler work. This kind of tubbing can be carried to any height, until the water finds an outlet at the surface, or strata containing water can be tubbed off, as by the other kinds of tubbing before described. A pit completed in this manner presents a smooth shaft wall of iron, the flanges being towards the outside of the cylinders. In this work no screwed bolts are used for joining the segments together. In a pit in the Newcastle district, 70 fathoms have been executed in this manner, under Mr. Buddle's directions.

When a thin bed or parting betwixt two of the strata which are impervious to water, produces much water, or when the cutters or fissures in the strata do so, this water can be completely prevented from flowing into the pit by wedging, for which there is a particular method. In place of attempting directly to wedge the fissures, as was the former unsuccessful practice, the fissure is cut open with chissels, and made about two inches wide and seven inches deep, as represented Fig. 16. Plate CCCXC.; the lips are rounded off about an inch and half; pieces of clean deal are then driven in, the face of which comes no farther than the contour of the lips; the whole is then firmly wedged, till all the water is stopped back. By placing the wedging back from the face, the rock is prevented from bursting during the operation, which always happened in the former process.

In sinking engine pits, besides contending with the water, ventilation has to be attended to, on account of the pernicious airs or gases found in the strata, and which at times come off in great quantities. These gases are carbonic acid or fixed air, and carburetted hydrogen or inflammable air. The first of these gases being heavier than the atmospheric air, sinks to the bottom of the pit, and filling it up like water, displaces the common air, until it flows over the mouth of the pit. This air instantly extinguishes flame, and destroys animal life. The other gas, being lighter than air, instantly ascends the pit, mixed with common air. If this gas is much diluted with the common air, the workmen suffer no inconveniency from it; but if pure and unmixed, it destroys animal life, or if mixed with certain proportions of common air, it suddenly explodes and burns the workmen. These gases will be particularly noticed when the ventilation of mines is treated of.

In ordinary cases, while pits are sinking, the brattice walls produce a circulation, by the air descending upon one side and ascending by the other. If this does not take place, the circulation must be produced by fire rarefying the air.

The most approved method is, to cover the engine-pit area of the shaft with deals, having apertures for the pump spears and tackling to pass through, with hatch-doors for the men going up and down; near the top of the pit, and immediately under this scaffolding, a tube of brick, at least three feet square, is carried in a horizontal direction, and connected with a furnace having a high chimney with double doors, where the person enters to throw coals on the fire, as represented Fig. 3. Plate

CCCXCI. where *a a* are the double doors, *b* the mouth of the horizontal tube from the pit, *c* the furnace, *d* the ash pit, *e* the furnace building 8 feet high, arched with brick, *f* the chimney, which is from 50 to 100 feet high, according to the draught required, from 8 to 10 feet square at bottom, and tapering upwards to three or four feet, inside measure. The chimney-wall needs not exceed nine inches in thickness, if built of brick, after passing the extreme heat of the furnace, which is about 12 feet high, where there is a lining of fire brick; furnaces of smaller dimensions may be sufficient, in cases where they are only to be used while the pit is sinking; but those of large dimensions are suitable, not only for ventilating the pit, but the workings of the colliery afterwards. In some cases the horizontal tube is connected with the chimney of the engine furnace, with good effect, for the operation of sinking.

Another process is, that in place of covering the engine-pit area where the pumps are, as before described, to connect with the horizontal tube, deal boxes, having an internal area of from two to four feet. These are carried down the pit to within a few yards of the bottom, and produce a circulation of air, by being connected with a furnace at top; for as the air ascends through these pipes by entering at the lower part, the fresh air descends to supply its place. A temporary expedient is used in pits of a very moderate depth, by means of air boxes carried from the bottom of the pit to 12 feet above the surface, upon the top of which a hopper-shaped funnel is placed in a horizontal direction, which being turned with its aperture to the wind, sends a supply of fresh air down the pit. This plan is of no use in deep pits, or where the gases are very abundant. If a great quantity of gas issues from one place in the pit, it is found expedient sometimes to confine it in a tube, and conduct it to the top of the pit, where it dissipates into the air.

In those pits where it is proposed to draw a great quantity of coals, and with very considerable velocity, it is the practice to widen them at the place where the ascending and descending baskets of coal pass one another, which is termed the meetings. If there are two or three beds of coal in the pit, there will of course be different places for the meetings, as they are placed at half-way betwixt the mouth of the pit, and the coal which is working. The common practice is to make the pit 32 inches wider in the middle, that is, 16 inches wider on each side. It is evident that these cannot be made when there is tubbing in the way; and if there are many beds of coal to work in the same pit, it is better to make the pit of sufficient width from top to bottom.

These stones and rubbish produced in sinking are drawn up with horse-gins, when the pit is not deep; but in all pits of any considerable depth, the rotatory steam engine is used, and the workmen have now more confidence (as to their personal safety,) in these machines, than in the horse-gins.

The great collieries of Newcastle are frequently wrought by one shaft, divided in the manner before mentioned, which serves as an engine-pit and coal-pits, and by these the whole ventilation is carried on to an extent altogether astonishing. This system is followed on account of the immense expense which requires to be laid out upon a pit of this kind, an expense amounting in some cases from 40,000*l.* to 80,000*l.*, including the machinery. In general, however, the collieries of Great Britain are wrought by means of an engine-pit, and a series of pits, sunk at regular distances, suitable to the system of the colliery. The expense of these pits being comparatively very little, they are of various shapes, as before mentioned. When circular or octagon, they are about eight feet in diameter; when rectangular, they are eleven feet long by five feet broad. The long elliptical pits are eleven feet long by seven feet wide.

Common pits are in general easily sunk after the rock head is found, and the cover secured, particularly when the growth of water is such that no tubbing is required. The process followed is, to drive a mine to the place where the pit is intended to be, and having fixed the spot above ground from a survey made, the instant the pit is sunk to the rock head, a bore is put down to the mine, by which all the water descends, which aids the ventilation of the pit. In all rectangular pits, a small counterfort or bracket of rock is left at each corner, termed a pane, which strengthens the sides of the pit, and renders the sinking or walling of the pits easier. When the alluvial cover is secured by masonry of ruble work in square pits, it is the practice to throw arches of ashler stone in a vertical direction at every three or four fathoms distance. These strengthen the sides against the lateral pressure.

In the course of sinking, if any very soft strata are found, which have not consistency to form a firm shaft wall, a recess is cut out betwixt the firm strata upon the lower and upper side of the soft strata, and walls of masonry substituted, either of brick or of stone; and if beds of greenstone occur, or any very hard rock which will not wall smooth, but which, in blowing with gunpowder, leave large angular projections, such strata require to be walled down an extra width, in order to admit of masonry to form smooth sides. In all cases great attention is necessary to have the shaft walls as smooth as possible, that is, free from all projections and hollows, in order that when coals are drawn up with velocity, the basket or hutch may pass in a line as truly perpendicular as possible, otherways, if they touch, they are thrown first to the one side and then to the other, and continue a destructive oscillation, both in the ascent and descent, and do much injury to the coals, baskets, and pit. Where hutches are used made of deal, the injury thus produced is uncommonly great. When the workmen ride the shaft in going and returning to their work, the greatest attention must be paid, in order to have the shaft walls not only very smooth, but all the friable strata secured, because in deep shafts a very small bit of stone falling from a great height upon the head of a man proves fatal. In some shafts, when the strata are chiefly of the various kinds of clay and argillaceous schistus, they are cased from top to bottom with deals neatly jointed, and nailed to cribs or buntons fixed to the shaft walls; for the same cause some pits are built with brick or ashler from the bottom to the top.

The various processes pursued in working coal, and bringing it to market, have now to be detailed.

Coal, as one of the various strata of a coal-field, lies in a conforming situation with the other strata, like the leaves of a book; the stratum which rests immediately on it is named the roof, and the stratum upon which the coal rests is named the pavement, and in some districts, the thill. The terms roof and pavement are very appropriate, as the one is the roof or ceiling to the miner immediately above his head, and the other is that on which he walks. It is very remarkable in the natural history of coal, that the stratum upon which coals generally rest, is an argil or fire clay of various hardness, from the tenth of an inch to many feet in thickness. When coals rest directly on any other pavement, some trouble or dislocation of the strata is generally the cause.

A stratum bed, or seam of coal, is not in its texture one uniform solid mass, nor is it always of a homogeneous quality. Like the other accompanying strata, it is divided and intersected by what are named partings, backs, cutters, reeds, or ends. There are two chief partings in a coal, the one at the pavement, the other at the roof; these partings are the lines of separation betwixt any stratum and the adjoining one; sometimes it is only a fine line running horizontally, and scarcely visible, in other cases it is very distinct, and composed of either a dry powdery matter, or of clay, of about a twelfth or an eighth of an inch in thickness. Besides these chief partings at the roof and pavement, there are subordinate partings found in the bed of coal parallel to these, and sometimes very numerous; these vary in thickness from a line scarcely visible, to a parting of even more than half an inch. These partings in coal are generally composed of a glimmering fibrous substance, named mineral carbon, which is soft, and when touched blackens the hands very much. It is to be remarked, that this substance, though soft, is never found in the backs or cutters of the coal. These partings, backs, or cutters, are delineated in Fig. 4. Plate CCCXCI. where A, B, C, D; E, F, G, D represent a portion of a bed of coal, the parallelogram ABDC the parting at the roof, and EFG the parting at the pavement; *a b*, *b c*, *d e*, and *e f*, the subordinate or intermediate partings; *g h*, *i*, *k l m*, the backs; *o p*, *p q*, *r s*, *s t*, *u v*, and *v n* the cutters; from this it is evident that a bed of coal, according to the number of these natural divisions, is divided and subdivided into various sized solid figures, of a cubic or rhomboidal shape, according to the rectangular or oblique direction of the divisions to one another; the partings are always parallel to the roof and pavement, excepting where there are troubles in the strata, and the backs cross the partings at right angles to their planes. But though cutters are found sometimes running at right angles to the line of the backs, they more frequently cross them obliquely; so that in the one case the figures formed are rectangular solids, in the other case they are solids of a rhomboidal form.

Besides these common divisions in the coal, there are occasionally found accidental divisions in various directions, but generally in a line somewhat in the direction of the backs, and passing like them from roof to pavement; these are termed leips or glazed backs, on account of their glossy surfaces, which have no tenacity as to each other, and are the occasion of misfortunes, some of them fatal to the workmen. When the backs, cutters and partings are good, as the miners term them, they greatly aid their labour in working thick beds of coal, particularly where the coal is strong and works large; they are of less importance in the soft caking coals, such as are found in the north of England. In strong coals, where the divisions are good, they are termed back and end coals, and they break out into pieces of quadrangular form, with smooth planes, and produce comparatively little waste coal, culm, or dross, in the open burning coals; but where the partings, backs and cutters are bad, the coal is greatly injured in the working, and much culm is produced, which is of little or no value. When the partings are bad, the coal is said by the miner to have neither roof nor pavement; and when the cutters are irregular, the coal breaks in that direction very much serrated, or teethy in the miner's language.

Besides these chief and regular divisions, there are innumerable cracks and fissures crossing one another, so that when the coals are broken with force, the fragments are of a cubic form, particularly in open burning bright coal, named on that account cubical coal, in place of rough coal or cheary coal, as formerly. On the other hand, the coals named splint coals (slate coals) have few of these cracks, but have a slatey fracture parallel to the roof and pavement of the coal.

With regard to the tons of coal of 20 cwt. each, contained in an English or Scotch acre, the weight of a cubic foot of coal varies from 75 to 80 pounds avoirdupois, which gives a range in the cubic yard from 18 cwt. to very near a ton. In practice it is common to reckon the cubic yard 18 cwt. which is exactly half a hundred weight for each inch in height of the square yard; upon this principle a coal three feet four inches in thickness contains a ton in every square yard of the area, hence an English and Scotch acre of this thickness contain the following weight of coals:

	Tons.
An English acre -	4840
A Scotch acre - -	6084

From the above quantities, there falls to be deducted the proportion of coal to be left in pillars, besides an allowance for waste, before the exact produce per acre can be ascertained; from the above data, the quantity of coal of any thickness contained in an acre, may be very easily calculated, but the calculations must be corrected according to the kind of coal and peculiarities connected with it.

When the engine-pit is sunk, and the lodgment formed, the next thing to be done in collieries of a moderate depth, and where a number of pits are to be sunk for drawing the coals, is to run a mine in the coal to the rise of the strata, or a cropping from the engine-pit to the second pit. Where inflammable air abounds, the primary point of attention is the ventilation for the safety of the workmen; but as this is an intricate and important point in the mining operations, the opening up of a colliery will be described, where only carbonic acid or fixed air is found; where there is little danger, and where the means of ventilation are of the simplest kind. In many mining districts, the second pit sunk to the rise of the engine-pit, is named the bye-pit, that is, the pit farther up. The mine which is carried from the engine-pit to the second pit, may be 6 or 8 feet in width, and is either carried in a line directly to the pit-bottom, or it is carried at right angles to the backs or web of of the coal, until it is on a line with the pit where a mine is set off, upon one side to the pit bottom. This mine is carried parallel to the backs, or as nearly so as possible, till the pit is gained. Fig. 5. Plate CCCXCI. represents this operation; A the engine-pit, B the bye-pit or second pit, AC the mine run at right angles to the backs, CB the mine set off to the left hand parallel to the backs. Mines which are carried in this direction at right angles to the backs, or parallel to them, are the best, because the pillars which are formed next them are in equal areas, stronger than pillars formed by the sides of mines, which are driven oblique to the backs and cutters, particularly if they are of an open kind. The next operation is to drive the dip-head, or main-levels from the engine-pit bottom, or from the dip hand of the backset immediately adjoining the engine-pit bottom; for this work the best colliers are always chosen, as the object is to drive the mine in a true level direction, and that independently of all sinkings or risings of the pavement. This mine is generally not more than six feet wide in coals of ordinary thickness; the rule is, to have upon the dip-side of the mine a small quantity of water, like that of a gutter, so that it shall always be about four or six inches deep at the forehead upon the dip-wall. In coals which have a great dip, the water may be eight inches deep; and in very flat coals from two to three inches will be sufficient; for this reason, that if the dip is 1 in 3, then the water which is 8 inches deep will be in breadth 24 inches, whereas in a coal dipping 1 in 12, the water 3 inches deep will be in breadth 3 feet. When the level is driven correctly with the specified depth of water, it is said to have dead water at the forehead; the miner, therefore, in this operation pays no regard to the backs or cutters of the coal, but is guided in his line of direction entirely by the water, which he must alone attend to, and that without regard to slips or dislocations of the strata which may throw the coal up or down. In Fig. 5. the coal-field is a portion of a bason, from which it is evident from what was before stated, that if the shape is uniform and unbroken, and if any point is assumed a dipping from the crop as D, the level lines from that point will be parallel to the line of crop, as DE, DF, and the levels from any point whatever a dipping, will be also parallel to these; therefore, if the coal-field is an entire elliptical bason, the dip-head levels carried from any point would be elliptical, and parallel to the crop. If, however, and which is more commonly the case, the coal-field is only a portion of a bason formed by a great dislocation or slip of the strata, as represented in Fig. 6, where *a a a* is the crop, and AB a slip of great magnitude, forming another coal-field on the side C, then the crop not only meets the cover, but is cut off by the slip at A and at B. If, therefore, any point is assumed, as D, for an engine-pit, the levels from it will proceed in a line parallel to the crop, as D *d*, D *c*, and the level on both sides of the engine-pit will be cut off also by the slip AB. In this Figure, the shaded part is the breadth or breast of coal-field won by the engine-pit D: what is not shaded is termed the under-dip coal, and can only be wrought by one or more new winnings towards the dip, according to circumstances. Had the engine-pit been placed at the point E, close to the slip AB, it would have drained or won the whole of that coal-field, and no level mines could be driven, but a common mine run from E to B, and from E to A; which mines, in place of being level, would have a moderate rise from E to B and from E to A, where they would terminate with the coal where the crop meets the cover. In such a case, these mines are not carried close to the slip, but a few yards to the rise of it, in order to leave a barrier or chain wall of coal to support the superincumbent strata, which are ready to give way at the fissure of the slip where all the strata are disjoined and dislocated.

The third general case as to dip-head levels is, when the coal-field is a portion of an inverted bason, as Fig. 7. where *a a a* is the crop of a coal, and B any point assumed for an engine-pit to make a winning. In this case, the dip-head levels will proceed from B to *c* and from B to *b*, parallel to the crop, till they are cut off either by a slip AC, or reach a trough, where the coal rises in different directions. In extensive coal-fields, which are in general lying fair, if a conical swelling of the pavement is found of some considerable extent in the line of the dip-head level, the level will then, in keeping a true level line, assume the form of a horse-shoe, and, after passing the swell, will proceed in its regular course as before.

Having thus stated the general principles upon which dip-head levels are carried in the regular system of coal-mining, it will be proper to exemplify the effects of moderate swells and hollows of the pavement, as the levels proceed onward from the engine-pit bottom, as in Fig. 5. When a hollow occurs, the level is thrown to the rise, and, as the hollow decreases, the level sweeps again to the dip; whereas, when a swell occurs, the level is thrown a dipping, and, as the swell diminishes, the level gradually again turns to the rise. In these cases, a sudden turn, or a sharp angle, is never made in the mine walls, but the course is pursued by inflections as moderate as the case will admit of. From what has been stated, it is evident that if the miner holds to the dip hand more than the true level course will allow, he will make what is termed a drowned level; and if he keeps too much to the rise, he will produce what is termed lost level; and, if the lost level is not recovered, the breadth of the breast of coal-field won will be made narrower, which is a loss, as the expense of recovering lost level is often very great. Fig. 8 represents a portion of a dip-head level, where these errors have been committed. AB is the dip-head level in its true course, carrying dead water at the fore-head B, from the engine-pit A. *a* is the fore-head of a piece of drowned level, which must be abandoned, and left to fill with water; the proper level is regained by resuming the work at *b*, where the error commenced; *c* is the fore-head of a piece of lost level commencing at *d*. By this error, the triangle of coal B *d*, *d c*, *c* B, is lost in the winning; and to correct this error, the true level must be begun at the point *d*, and carried dead level to the fore-head B. Drowned levels can never be of great extent, as the water very soon incommodes the workman, and forces him to return. But lost levels sometimes go forward progressively for years, when at last the breast of coal-field becoming evidently much narrower, the true level must often of necessity be regained, which requires years of labour, and very great expense, all of which might have been saved by correct mining. This, therefore, shows, that the driving of dip head levels correctly, particularly in deep winnings, is a point of the very first importance. They ought to be kept clear of all stones, rubbish, and sediment, as these tend to cause loss of level, by damming the water, and throwing a greater depth of it at the fore-head, than would be if the level was clear and patent. Wherever the roof is bad, it ought to be firmly secured either by carpentry, or by masonry, which is better. These being the modes of driving dip-head levels in the different kinds of fair-lying coal-fields, the plans to be pursued when dikes, slips, and dislocations occur, have next to be pointed out. Fig. 9 represents a coal-field won by the engine-pit A. *a a* is the crop, and the double lines proceeding east and west from the engine-pit are the dip-head levels. B and C are two dikes traversing the coal-field in a crop and dip direction, but which do not throw the coal either up or down. When, therefore, the dip-head level is obstructed by the dike

B, and found to be of that kind which neither throws the strata up or down, then the level is carried through, as represented in the Figure, when the coal will be found on the other side at *d*. Upon the level proceeding to *e* another dike is found, throwing down the coal; but as the extent of this downthrow is not known, a mine is carried level course, not only through the dike, but several fathoms farther forward, as to *f*, where a bore is put down, and the downcast proved to be ten fathoms. This being the case, and if the coal dips 1 in 8, then 8 ×10 is 80, which shows that if a level mine is run in the strata in a direction parallel to the dike, or nearly so, a cropping as *g h*, the coal will be found at *h*, and the distance will be 80 fathoms as above calculated, provided the coal keeps the same dip and rise as formerly. The dip-head level then proceeds from *h* eastward in manner as before directed. It must, however, be observed, that though the stone mine and effect of the downcast have thrown the dip-head level 80 fathoms a cropping, the breast of coal from the dip-head to the crop is not narrowed, as the coal upon the east side of the dike will be found to go southward, at least as much farther than the crop upon the west side of the dike, as represented in the Figure.

In proceeding with the dip-head level westward from the engine-pit A, the slip *k* is found throwing down the coal and other strata. A mine is carried forward to *l*, and a bore put down where the slip is ascertained to have thrown down the coal 5 fathoms, hence 5×8 gives 40. Therefore, if a mine is carried dead level a cropping from *m*, the coal will be found at *n*, the distance from *m* to *n* being 40 fathoms, providing the dip of the strata continues the same; and, in this case, the crop of the coal extends 40 fathoms farther a cropping, as represented in the Figure. The coal having been found at *n*, the dip-head level proceeds from *n* to *o*, where an upthrow slip is found, but the extent of the upthrow unknown. Sometimes the coal is searched for, by mining upwards for a few yards; but the common practice, is to run forward a mine a few yards, and bore upwards, as at *p*, where the coal is found to be 10 fathoms up; then 10 ×8 gives 80. If, therefore, a stone mine is carried dead level through the strata a dipping, the coal will be found at *r*, at the distance of 80 fathoms from *q*, supposing the dip to be the same as formerly. But although the dip-head level is carried a dipping 80 fathoms, no additional breadth is gained to the breast of coal, as the crop is thrown an equal extent back, as in the Figure. From *r* the dip-head level proceeds to *s*, where a downthrow slip is found to be 4 fathoms; 4×8 gives 32. A mine is therefore set off a cropping from *t*, but in place of running 32 fathoms ere the coal is intersected, it is found at the distance of 20 fathoms at *u*, which shows that the coal is dipping 1 in 5, in place of 1 in 8, as formerly. This slip runs out, or comes to nothing, as it is termed, in the crop, consequently narrows the breast of coal 20 fathoms. Had the dip been rendered less, suppose 1 in 20, then it would have required a mine of 80 fathoms in place of 20 fathoms to intersect the coal, and it is probable that the breast of coal would have been broader, but this depends upon the situation of the slip towards the crop. When the dip-head level, as at *v*, meets with a slip throwing down the coal; and if upon cutting forward the coal is troubled, the mine must be continued still forward, till the strata are found lying regular. In the example given, there are five slips or dislocations very near one another, throwing the strata at one time up, and at another down, but only a few feet in extent. If, upon reaching the point *w*, the coal is not found by a bore either up or down, and if no clear view can be formed of the coal-field in that direction, it may be necessary to explore the field by a series of bores put down from the surface. In the Figure referred to, examples are given of the effects produced upon the line of direction of the dip-head level by dikes and slips, and the modes practised in passing them; but as these slips and dislocations lie in every direction as to the dip and rise of the coal, there are of course very various modifications of the examples given, to enumerate which would be of little use, although the example given appears to be a coal-field much troubled, as it is termed. We have seen in practice coal-fields even with more numerous dislocations. On the other hand, we find coal-fields lying fair and regular to a very great extent.

If, in working the coal from dip to rise, slips or dislocations of the strata occur, they are passed over in several ways, according to the size of the slip.

When the slip is only a few feet down to the rise, the coal is regained at the face of the slip by an open cutting like a trench, named a hassan; but when it is several yards down, and not exceeding the depth of 25 feet, an inclined road or mine is made down the face of the slip, or at such an angle as may be most suitable for bringing up the coals; and in order to take away the water, a syphon is sometimes used in place of a pump, as the column of water to be raised is less than the pressure of the atmosphere; for although water will rise over a height of more than 25 feet by a syphon, it runs feebly, and will not discharge much water. The long end of the syphon is carried down the slope of the coal towards the engine-pit, where the discharging orifice is immersed in a trough of water, each end is furnished with a stop-cock, and at the neck or highest part of the syphon, an upright pipe is attached, upon the top of which is a funnel, and a stop-cock below it. These syphons were formerly made of lead; but the mode of joining cast-metal pipes air-tight being so effectual, syphons are now made of that metal.

When a slip is of considerable magnitude, it can be levelled out by a cross-cut mine, begun sufficiently to the dip. These cross-cut mines are made of a size sufficient to allow the coals being brought down through them to the pit bottom. When the coals are very flat, and the running of cross-cut mines may not be judged expedient, the coal is regained, either by cutting a sloping mine, or by sinking a pit clear of the rise or slope of the slip, to the coal. Sometimes the water is drawn up in pumps connected with machinery at the top of the pit, or is drawn by machinery wrought by men, horses, or steam, by which means the coals are also drawn. Of these plans there are various modifications, according to the magnitude of the slip, and its particular direction as to the dip and rise of the coal. When the slip is of great magnitude, it is frequently judged expedient not to attempt to connect it with the established fitting, but to make a new fitting for the coals on the other side of the slip, the slip serving as a complete barrier betwixt the two coal-fields, which in many instances is an important matter to attend to, on account of the water. When the slip is up to the rise, which is not a common occurrence, the operation of connecting the coals on the other side of it with the main workings is very simple, as there is nothing to do but updrift a mine to the coal, and then open it out to a proper width for a pit. By this pit the water descends, and the coals are lowered down by a machine, with a rope-barrel regulated by a brake, by which the descending loaded corve draws up the empty one alternately. This mode of lowering coals to a lower level is very applicable in many cases.

As soon as the crop or rise mine is run to the second pit, in winning a colliery, and the dip-head levels extended from 30 to 80 fathoms on each side of the engine-pit bottom, the colliery is ready for working, or for producing an output of coal; but, before proceeding, an important point has to be settled, viz. the manner in which the mines are to be conducted, so as to insure, as far as possible, 1st, *The safety of the workmen;* 2dly, *The prosperity of the work;* and 3dly, *That a given area of the coal field be made to yield the greatest possible proportion of the coals contained in it.*

In the mining practice of Great Britain, there are four different systems of working coal mines, viz.

1st, Working with pillars and rooms termed post and stall, where the pillars are left of such proportion to the coal excavated, as is just sufficient to support the superincumbent strata.

2d, Working with post and stall, where the pillars are left of an extra size, and stronger than is judged to be requisite for supporting the strata, with the view of taking away a considerable proportion of each pillar, as soon as the regular working of post and stall is completed in the colliery.

3d, Working with post and stall, or with rooms or boards comparatively narrow, and very large pillars or rather walls of coal, whereby an uncommonly large proportion of coal is left, having in view, that as soon as the colliery is wrought to the extent of the coal-field in this manner, to work back towards the pits, taking away, if possible, every pillar completely, and allowing the whole superincumbent strata to crush, and follow the miners as they retreat.

4th, Working the long way, or the Shropshire method, which is to leave no pillars, but to take out all the coal progressively, as the work goes forward. In this method the superincumbent strata crush down, and creep very close to, and even over the heads of the workmen.

In practice the post and stall system is applied in the working of coals of every thickness. The Shropshire method, or long way, is more generally applied in the working of thin coals. When the thickness exceeds 6 or 7 feet, this mode of working has not yet been found practicable.

When a colliery is won in the manner as before described, the next important matter to be considered, is, By what plan of working the coal will that coal in particular, and the coal-field in general, produce the greatest quantity of vendable coals from a given area, having in view all local circumstances, and also the future as well as the immediate interest of the coal-field?

The local circumstances may be ranged under the following heads:

1st, That the lowest coal of the winning be wrought in such a manner as not to injure the working, or the value of the upper coals which may be in the coal-field; but if this evidently cannot be accomplished, the upper coals must be wrought first.

2d, The texture of the coal, as to hardness or softness, and whether the backs and cutters are numerous or not, open or close.

3d, The kind of pavement upon which the coal rests, whether it is soft or hard; and, if soft, whether it is only a few inches or several feet in thickness.

4th, The kind of roof, whether it is good or bad; that is, whether it is firm and strong, or very weak, and liable to fall down; also the kind of superincumbent strata, whether strong or tender.

5th, The kind of alluvial cover, whether of a dry nature, or composed of quicksands and much water upon the rock head.

6th, The situation of rivers or collections of water connected with the coal-field, particularly if these are near the crop of the coals.

7th, The situation of towns, villages, and mansion-houses upon the coal-field, whether they are likely to be injured by any mode in which the coal is proposed to be wrought,—having in view the thickness of the strata betwixt the surface and the coals to be wrought, also the thickness of the bed or beds of coal.

When coal-fields have been wrought in a district of country for a considerable period of time, the experience, gained by the miners directs them how to proceed in similar circumstances, and therefore, in mines opened up in new districts, it is difficult to lay down specific rules for the very various circumstances connected with a coal-field; and although general rules may be laid down, it may require years of experience, and the trial of many modes, ere the best system can be determined upon.

The following general rules are useful in determining the mode of working coal.

1st, If the coal, pavement, and roof are of ordinary hardness, the pillars and rooms may be proportioned to each other, corresponding to the depth of the superincumbent strata, providing all the coal proposed to be wrought is taken away by the first working, as in the first system; but if the pillars are to be winged afterwards, they must be left of an extra strength, as in the 2d system.

2d, If the pavement is soft, and the coal and roof strong, pillars of an extra size must be left, to prevent the pillars sinking into the pavement and producing a creep.

3d, If the coal is very soft, or has numerous open backs and cutters, the pillars must be left of an extra size, otherwise the pressure of the superincumbent strata will make the pillars fly or break off at the backs and cutters, the result of which would be a total destruction of the pillars, termed a crush or sit, in which the roof sinks to the pavement, and closes up the work.

4th, If the roof is very bad, and of a soft texture, pillars of an extra size are required, and the rooms or boards comparatively very narrow.

In short, keeping in view all the circumstanaes before mentioned, it may be stated generally, That when the coal, pavement, and roof are good, any of the systems before mentioned may be pursued in the working; but if they are soft, the plan is to work with rooms of a moderate width, and with pillars of great extra strength, by which the greater part of the coal may be got out, at the last of the work, when the miners retreat to the pit bottom, and there finish the workings of a pit.

When pillars are left haviog too small a base, though abundantly strong in themselves, but resting on a soft pavement, the sure consequence is, their sinking into the pavement by the weight of the superincumbent strata, which produces a creep over all the workings, and has the effect of shutting up the roads, destroying the air courses, and deranging the whole economy of the colliery operations below ground. Fig. 10. Plate CCCXCI. represents the effects of pillars sinking into the pavement, and producing a creep. Fig. 11. represents large pillars, and a room, with the roof stratum bending down before it falls at *a*.

With regard to the proportions of coal wrought, to the area left in pillars for support of the superincumbent strata, where all the coal intended to be wrought from a given area is taken at the first working, it varies from four-fifths to two-thirds; and in a general view these are about the proportions in the present practice pursued under the system, when the depth does not exceed 70 fathoms; but as the losing of a third of the whole area of coal is a great proportion, the superior mode of working, as stated in the third system, ought to be adopted.

The rule for calculating the proportion of coal wrought to the area left in pillars, is as follows: It is termed calculating the proportion wrought of a winning. Plate CCCXCI. Fig. 12. represents a small portion of the pillars, rooms, and thirlings, formed in a coal-field. *a a* are two rooms, *b* the pillars, *c* the thirlings. Suppose the rooms 12 feet in width, the thirlings the same width, and the pillars 12 feet on each side. Add the face of the pillar to the width of the room, $=24$, add also the end of the pillar to the width of the thirling, $=24$. then $24 \times 24 = 576$—then the area of the pillar, $12 \times 12 = 144$. And as 576, divided by 144, gives 4, the result is, that a fourth of the coal is left in pillars, and three-fourths wrought out. *d*, *e*, *f*, *g*, is one winning, and *g*, *e*, *k*, *h* another. From an inspection of the figure, the workings of a coal-field, if regular, resolve themselves into quadrangular areas, having the pillar situated in one of the angles.

As the backs in the coal do not generally lie at right angles to the dip and rise of the coal, but rather oblique to that line, the rooms or boards are begun or broken off at the dip-head level, so that the backs of the coal cross the sides of the boards at right angles. This by some is termed working right upon the plane of the coal, others term it right upon the web; but if cutters are more distinct and open than the backs, then that direction is termed the plane, and the boards are said to be wrought upon the end plane, or simply on the end, or in a level course direction.

In forming the pillars, and carrying forward the boards with regularity, particularly where the backs and cutters are very distinct and numerous, it is of importance to work the rooms at right angles to the backs, and the thirlings in the direction of the cutters, however oblique these may be to the backs, as by this plan the rooms are conducted with the greatest regularity with regard to each other, kept equidistant, and the pillars of a given area are the strongest when formed by this mode of working.

At the same time, it must be understood, that it seldom happens that a back or a cutter is found exactly at the place where a pillar is formed; but that is of no consequence, as the shearing or cutting made by the miner ought to be in a line parallel to the backs and cutters. This precise system is particularly necessary, where pillars are formed upon the calculation of just supporting the superincumbent strata, or when they are made a little stronger, to be winged afterwards. This preciseness is dipensed with where immense pillars or walls of coal are left in the first working, with the view of taking out the whole afterwards. At the same time, even in this system, the working of the rooms with their sides parallel to the cutters, is the best method of keeping all the rooms at equal distances from each other, so that betwixt each there may be a regular and uniform thickness of pillar. If the pillars are formed without attending to the above plan, their sides will intersect through the backs and cutters obliquely; and when the weight begins to bear upon them, and are winded by the air passing through the waste, large wedge-shaped pieces of coal fall off.

It frequently happens that the dip-head level, in its course, intersects the cutters at a very oblique angle. In this case, when rooms and pillars are set off, the face of the pillar, and width of the room, must be measured off an extra breadth in proportion to the obliquity, as in Fig. 15. Plate CCCXCI. Without attention to this, much confusion and irregular work is produced; on which account, the pillars are always formed much larger than in the common workings; besides, it is a general rule to make the first set of pillars next the dip-head level, even where there is no obliquity, much stronger, in order to preserve the dip-head level from being injured by any accidental crush of the strata.

Having thus described the manner of arranging the rooms and pillars, the various systems of working coal have now to be explained.

Fig. 13 shows one of the simplest modes of working coal. A is the engine pit, B the bye-pit, or No. 2 pit, CD the dip-head levels, always carried in advance of the rooms, E is the rise or crop mine, also carried in advance. These mines not only open out the work for the miners in the bed of coal, but, by being in advance, give plenty of time for any operation which may be required, if these mines are obstructed by dikes or hitches. In this example the rooms or boards are wrought from the dip to the crop; the leading rooms, or those most in advance, are those on each side of the crop mine E: all the other rooms follow in succession, as represented in the figure; consequently, as the rooms advance to the crop, additional rooms are begun at the dip-head level, towards C and D. If the coal is found to work better in a level course direction, then the leading rooms are next the dip-head level, and the other rooms follow in succession. In this manner, the rooms are carried a cropping in the one case, till the coal is cropped out, or is no longer workable; and, in the other case they are extended as far as the extremity of the dip-head level, which is cut off either by a dike or slip, or by the boundary of the coal-field. As to additional pits, these are placed at such distances from each other, as will best suit the economy pursued in working. When the winning is under 60 fathoms in depth, and the sinking of pits is of little expence, they are numerous; but when they are deep, and attended with very great expense, one shaft divided into two or more pits can be made to work out a very extensive coal-field.

In very deep winnings of from 80 to 200 fathoms in depth, the first workings are carried forward with rooms, pillars, and thirlings, but under a very different arrangement, both on account of the great depth of the superincumbent strata, the enormous expense laid out in sinking a pit, and the order, regularity, and strictness of discipline indispensably requisite for ventilating the mines, preserving the lives of the workmen, and prosperity of the whole establishment. In these deep winnings, the same general system is followed, as stated regarding dip-head levels, and crop mines, excepting those peculiarities connected with the ventilation, which will be treated of separately. In the early practice of working deep collieries, the system was, to work with pillars considerably stronger than was conceived necessary for supporting the strata, in order that when the workings were carried on to the full extent proposed, the workmen might begin with the pillars at the greatest distance from the pit bottom, and either work a certain proportion from each, securing themselves from the falls in the roof by prop-wood, or they sometimes wrought the heart out of a pillar, either in the one direction or the other, and sometimes in both directions. Though the size of the pillars and general arrangement of the work, were laid out with the view of taking out a great proportion of the pillars ultimately, yet it frequently happened, that, before the workings were extended to half the proposed extent, some part of the work gave way, and produced a crush; but the most common misfortune was the pillars sinking into the pavement, and deranging the whole economy of the work. When either a crush or creep commences under such a depth of strata, it is almost impossible to stop its progress; the pillars thus sunk into the pavemant are lost. But if a crush or creep did not take place during the working of the colliery, and the working of the pillars commenced, a crush or creep is expected very soon to come upon the weakened pillars. In this case it frequently has happened that the pillars, in their entire state, had not strength to keep back the crush, and therefore it overran the pillars, making the workmen abandon the work and escape for their lives. In this manner, also, much coal was lost. If the crush or creep was not so violent as this, it frequently was resisted for some time by the strength of the pillars, but it was impracticable to resume the work close to the creep; and therefore a great breadth and stretch of pillars had to be left as a barrier betwixt the crush and the next set of pillars which was to be wrought. In this manner were collieries carried on, and an immense proportion of the coal lost for ever. This loss amounted in many cases to no less than a third, and, in some instances, even to a half of the whole area of the coal-field. This great loss of coal was not only making an uncommon sacrifice of mineral property to the mine-owner, and to all concerned in the working of it, but the loss was great in a national point of view, as the coal thus left under ground was lost to all generations. An improvement, therefore, in the system of working deep mines became a great desideratum, and many plans were brought forward by mining engineers of the greatest experience.

Besides the loss of coal by the system before mentioned, there was another great evil which required also to be corrected. In carrying on the workings of an extensive colliery or coal-field of one or more hundred acres, the whole area or extent of the coal-field was one continued range of rooms and pillars, communicating with each other, without any divisions or barriers of coal left across the workings, excepting when formed to counteract a crush or creep already begun, or to strengthen the waste adjoining a slip or dislocation of the strata; the consequence of this system was, that if a crush or creep began when the workings were much extended, they overran very frequently the whole of the pillars, and were only resisted by the whole coal at the wall faces, so that the ventilation was entirely deranged, the roads leading from the wall faces to the pit-bottom shut up and rendered useless, and the recovery of the colliery by means of new air courses, new roads, and opening up of the wall faces or rooms, attended with uncommon expense and danger. Even when the pillars stood well, this system had other very great inconveniences attending it; for if water broke out in any particular spot of the colliery, it was altogether impossible to prevent it from proceeding to the engine pit, and if the ventilation was obstructed, no idea could be formed where the cause was likely to be found, there being instances of no less than thirty miles of air courses in one colliery; and if from such an obstruction an explosion of the gas took place while many workmen were employed along the extended wall faces, it was altogether impossible to form any judgment where the misfortune had taken place, and consequently the viewers or managers, with their assistants, could not direct their steps to that point where they were most likely to relieve the workmen who had survived the shock of the desolating explosion.

To the mining engineers of the northern counties of England, known in that quarter by the name of *Viewers*—the world is indebted for many great improvements which have been made in the most difficult and dangerout points of coal mining. They are a class of men who, to a knowledge of physical science, add patient perserverance, resolute determination, contempt of danger, and unwearied application; nor are these qualities called only occasionally into action, they are required every day of their lives, while they direct the operations of extensive and deep mines, where inflammable air abounds.

All the expedients proposed having failed to correct the evils attending the working of deep and extensive mines, where inflammable air abounded, and as one of the great objects was to raise as much coal as possible from a given area, in place of losing a third or a half, as before-mentioned, a system altogether new has been invented and brought forward, by Mr. John Buddle, of Wallsend Colliery, Newcastle. This system, the result of the greatest experience, and of much study, has, under his immediate direction, been put in practice with a success equal to his most sanguine hopes, and is now adopting by the mining engineers in the north of England.

This system of Mr. Buddle's is named pannel working, because, in place of the colliery, or winning of a coal-field, being carried on in one extended area of rooms and pillars, it is divided into quadrangular pannels, each pannel containing an area of from eight to twelve acres; and around each pannel is left a solid wall of coal of from 40 to 50 yards in thickness; through the pannel walls, roads and air courses are cut, in order to work the coal contained within the walls. In this way, all the pannels are connected together as to roads and ventilation with the shafts or pit; and for the more immediately distinguishing any particular part of the colliery, each district or pannel is named after places or countries, such as London, Edinburgh, Dublin, &c.; so that any circumstance regarding the operation of the colliery, accidents as to falls and crushes, ventilation, and, above all, the safety of the workmen, can be referred to a precise spot, under defined limits, viz. within the walls of any particular pannel. Fig. 1. Plate CCCXCII. represents a part of a colliery, laid off with four pannels, according to the improved method; and in order to render it as distinct as possible, the line of the boards is at right angles with the dip-head level, or level course of the coal. A, is the engine pit, divided into three pits, viz. an engine pit and two coal pits; one of the coal pits is the downcast, by which the atmospheric air descends to ventilate the works, and the other coal pit is the upcast shaft, at the bottom of which the furnace for rarifying the air is placed. BC is the dip-head level, AE the rise or crop mine, K the pannel walls, FG are two pannels completed as to the first work; D is a pannel, with the rooms *a a* in regular progress to the rise; H is a pannel fully wrought out, where all the coal is nearly got, the loss being in general not more than a tenth in place of a third, or a half under the old system. By this improved plan, the pillars of a pannel may be wrought at any time, as may best suit the economy of the work. In this system, the pillars are made very large, and the rooms or boards narrow—the pillars being in general 12 yards broad, and 24 yards long; the boards four yards wide, and the walls or thirlings cut through the pillars from one board to another, only five feet wide for the ventilation. In the figure, the rooms are carried from the dip to the crop, and the pannel walls act as barriers thrown round the area of the pannel, which prevents the crush of the superincumbent strata from overrunning the adjoining pannels. When the pillars of a pannel are to be wrought, a range of pillars, as at I, is first begun upon; and as the workmen cut away the farthest pillars, prop-wood is set up betwixt the pavement and the roof, in a perpendicular direction, within a few feet from one another, as represented by the dots, until an area of above 1000 square yards is cleared of pillars, having a thickness of strata, perhaps more than 130 fathoms, hanging clear and unsupported, excepting at the line of the surrounding pillars; this is termed working the goaff. It must however be remarked, regarding the prop-wood which is here used, and in many other places of the pit-workings, that it can have no effect in supporting the weight of the whole superincumbent strata, which is uncommonly great. The only use of prop-wood is to prevent the bed or stratum, which forms the roof immediately over the workmen's heads, from falling down and killing them; experience having shown, that before proceeding to take away another set of pillars, it is necessary to allow the last made goaff to fall. The workmen then proceed to draw the props, which is a most hazardous employment; they begin at the farthest props, and knock them down one after another, retreating always amongst the remaining props. During this operation, the roof-stratum begins to break by the sides of the pillars, and falls down in immense pieces. This does not intimidate the workmen, for they persevere drawing and retreating, until every prop is taking down; and if any props are so firmly fixed by the pressure of the roof that they will not drive down with the force of heavy mauls, they are cut through with axes, the workmen deeming it cowardly to leave a single prop in the goaff. When every prop is drawn, the workmen retreat betwixt the pillars for safety; the roof then falls in large tabular masses, and each superior stratum, in succession, bends down towards the middle of the goaff, and then breaks. The workmen then proceed to cut away the pillars next the sides of the goaff, setting prop-wood, drawing it, and retiring in the manner before described, until every pillar of the pannel is removed, excepting small parts of pillars which require to be left under dangerous stones, to secure the retreat of the workmen. While this operation is going forward, and the goaff extending, the superincumbent strata, having an enlarged area without support, break progressively farther up; and when strong beds of sandstone are breaking, the noise of the rending of the mass of rock is very loud, and the sound very different from any thing the ear has been accustomed to; at times it is loud and sharp, at other times very loud, but hollow and obtuse; this last kind of sound the workmen very emphatically term thudding.

It is the opinion of the most eminent of the Newcastle engineers, who have had the greatest experience, that when goaves are wrought under very deep cover, the rupture of the strata does not in general continue up to the surface, but that the upper part only bends down a little. As the pillars of the pannels are taken away, the pannel-walls are also wrought progressively backward to the pit-bottom, so that by this operation, only a very small proportion of the coal is lost. This is, as far as can be judged, the very best method of working such coals as those at Newcastle, taking into consideration their great depth from the surface, their comparative softness, and the great abundance of inflammable air. It is evident, that the larger the pillars and pannel walls are in the first working, the greater will be the security of the workmen, and the certainty of taking out in the second working the greatest proportion of coal. This system is applicable in many instances through the collieries in Great Britain; by it the saving of coal is uncommonly great, compared with any of the post and stall plans. Though we may view this wonderful operation as one which shows in a strong light the bold and determined spirit of man, even in the mechanical part of the operation, where the massive rocks are reft and torn to pieces over the head of the miner, a more difficult and delicate operation has to be attended to during the process, that is, in conducting atmospheric air to the workmen to counteract and carry off the excesive flow of hydrogen gas, which issues from every quarter ready to destroy them, as will be noticed when treating of ventilation; so that man may be considered in this case as contending with the elements of nature, which are every moment ready to overwhelm him. The consideration of these circumstances shows the importance and nature of that charge, which devolves upon a mining engineer in these deep and very dangerous collieries.

Under the fourth system of coal-mining, is that named the Shropshire method, long way, or long wall.

This system was first pursued in Shropshire, but the name of the person who had the merit of inventing it is not known; the plan must at first have been uncommonly hazardous, though now it is reckoned as safe, if not safer for the workmen, than the other system with rooms and pillars.

The object of the Shropshire system is to begin next the pit-bottom pillars, and at once to cut out every inch of coal progressively forward, and allow the whole superincumbent strata to crush behind and over the heads of the workmen. This system is confined chiefly to coals which are thin, and very seldom practised when the coals are seven feet thick; from four to five feet is reckoned the most favourable thickness for going on comfortably, when attended with ordinary circumstances, as to the kind of roof, pavement, &c.

When a pit is sunk to a coal where this method is to be adopted, the first consideration is, the situation of the coals which lie above the lowest one sunk to; if they are near to one another, it will be most expedient to work the upper coal first, and the others in succession downwards; but if they are about eight fathoms or more apart, with strata of strong composition betwixt them, the working of the lower coals first will do no injury to the upper coals, excepting the breaking of them a little more than usual. In many instances, upper coals are rendered by this operation in a lower coal much easier wrought. When the operation is begun by working in the Shropshire plan, the dip-head levels are driven in the usual manner as before described, and very large pit-bottom pillars formed, as represented Fig. 2. Plate CCCXCII. Along the rise-side of the dip-head level, chains of wall or long pillars are also formed, from eight to ten yards in breadth, and only mined through occasionally for the sake of ventilation, or the forming of new roads. In other instances no pillars are left upon the rise-side of the level; but in place of these, buildings of stone are formed four feet broad in the base, and nine or ten feet from the dip-side of the level; and although the roads are formed nine feet wide at first, they are reduced to half that width after the full pressure of the strata is upon them. When these points are secured, the operation of cutting away the whole of the coal commences. The place where the coal is taken away is named the gob, or waste; and gobbin, or gob stuff, is stones and rubbish taken from the coal, pavement, or roof, to fill up the excavation as much as possible, so as to prevent the crush of the superincumbent strata from making heavy falls, or following too hard upon the workmen. Coals which are wrought in this manner work easiest, according to the way in which the widest backs and cutters are, as explained in the post and stall system; and therefore, in the Shropshire method, the walls are sometimes in one direction and sometimes in another, the mine always turning out the best coals when the open backs or cutters face the workmen.

In many cases, when an immediate and great output of coals are wanted, the walls are carried forward to the rise and also level course on each side of the pit. As roads must be kept through the crushed strata, the miners in the first place cut away about 15 feet of coal around the pit-bottom pillars, and along the upper sides of the dip-head chain-walls; and at the distance of nine or ten feet carry regular buildings of stone three feet broad, with props set flush with the face of these, if necessary. As the workmen proceed forward, they set small pillars of roof or pavement-stone in regular lines with the wall face, and sometimes with props intermediate. In other instances, two, and sometimes three rows of props are carried regularly parallel with the wall-face, the front row being at the distance of four feet from it; as the workmen proceed forward, all the back row of props are drawn, the space adjoining them having been previously filled up with gobbing. These props are placed again next the wall face, so that the process of drawing and setting the props goes alternately forward every day. When the roof is strong, fewer props and stone pillars are placed; but when it is bad, they are set very thick. The intention of the props is for the security of the workmen, to keep up the roof-stone; they have no effect in resisting the crush of the superincumbent strata. When the gobbing is scarce, and the roof strong, it has been found a good plan to form the gobbing into wastes, which is, that in place of leaving the gobbing at a distance from the roof, to form it into long heaps at right angles to the wall-faces, as represented Fig, 5. where *a* is the roof, *b* the pavement, *c* the gobbing, and *d* the wastes. As the pressure comes on, the gobbing spreads out, and the wastes are made narrower; yet they frequently remain so open, as not only to form air courses in case of necessity, but they can be crept through to a great distance. There are two principal modes of carrying on the Shropshire system.

The first, or what is properly the original system, was to open out the wall in the manner before described around the pit-bottom; and as the wall-face extended in width, to set off main-roads and branches, very much in the form of the branches of a tree; these roads were so arranged, that betwixt the ends of any two branches there should be a distance of from 20 to 40 yards, according as might be most suitable, as represented in Plate CCCXCII. Fig. 2. Each space of coal betwixt the roads is named a wall; and one half of the coals produced from each wall is carried to the one road, and the other half to the other road; this is a great conveniency when the roof is bad, so that in many instances the distance of 20 yards betwixt the roads is preferred. In the figure, A is the pit, BB the wall-face, *a* the dip-head level, *b* the roads at from 20 to 40 yards asunder, *c* the gob or waste, with buildings along the sides of the roads, and *d* the pillars.

The other Shropshire method is represented in Fig. 14, Plate CCCXCI. where A represents the pit with the bottom pillars; *b* the dip-head levels; *c* the off-break from the level, where no pillars are left; *d* the off-break, where pillars are left to secure the level. All roads are secured in the sides by buildings of stone, if such can be had, laid off 9 feet wide. After the crush settles, the roads are generally permanently good, and can frequently be travelled through as easily fifty years after they have been made as at the first. When stones cannot be had in abundance, coals have to be used, and are built about 20 inches in the base. If schist is used, it requires to be from 2 to 3 feet square. In this method, the roads are also from 20 to 40 yards apart, but in place of branching they are set off in a direction parallel to each other. The workmen secure the waste by gobbing; and three rows of props are carried forward next the wall faces *a*, with pillars of stone or coal built betwixt them. This mode is more regular than the former, though not in such general practice.

The coal, when wrought in the Shropshire method, is carried on by the workmen very differently from the post and stall system, where each man has his own room, and performs all the labour. The Shropshire method is carried on by the division of labour performed by different sets of workmen, generally divided into three companies. The first set, curves or pools the coal along the whole line of walls, laying in or pooling always at least 3 feet, and frequently 45 inches, or five quarters, as they term it. Their work is measured as to length and depth by the oversman, the depth being gauged by an iron instrument, named a jack, 40 inches long, the knee of which must reach the wall face, if the curving is full; if short, the workman must complete it. These men are named Holers. As the crush is constantly following them, and working over their heads, which frequently has the effect of making the coal fall above them, for their security, props of wood are set at regular distances in an oblique direction between the pavement and wall face. Besides these, for farther security, staples of coal, about 10 inches square, are left at every 6 or 8 yards distance, until the line of holing or curving is completed. The walls are then divided into spaces of from 6 to 8 yards in length; and at each of these spaces a shearing or perpendicular cut is made as deep as the holing, and when this is done, the holer's work is completed. The next set of men who succeeds the holers are the getters. These begin at the divisions of wall at the centre, and drive out the gibbs and staples. They then set wedges along the roof, and bring down each division of coal progressively; or, if the roof is very bound, the coal is blown down with gunpowder. It frequently happens, when the roof has a good parting, the coals fall down the instant the gibbs are struck, which renders the work very easy. The getters are relieved by a third set of men, named butty-men, who break out the coals into pieces of a proper size for sending up the pit, and have the charge of turning out the coal from the wall face to the ends of the roads. When this is done, they build the stone pillars, fill up the gob, set the trees, clear the wall-faces of all obstructions, set the gibbs, and have every thing clear and patent for the holders recommencing their work. If the roads are to heighten, by taking down the roof, or lifting the pavement, these butty-men perform this work also, build forward the sides of the roads, and secure them with props when necessary. When both pavement and roof are hard, and the coal above 4 feet thick, a greater proportion of coal is lost by securing the waste, than when the pavement is moderately hard, or the roof easily taken down, as these afford plenty of gobbing. Frequently nothing but the large pieces of coal are taken out for the market, all the smaller parts of the coal and culm being required for the gob, besides a proportion of the great coal for the small pillars. When a coal has a following or roof stone, which comes regularly away with the coal, this renders the work easy, and saves much coal; and when it happens that a soft bed of fire clay is found a foot or two under the sole of the coal, the holing is made in it, and the stone betwixt the holing and the coal benched down, which serves for pillars and gobbing. By this plan all the vendable coal is saved.

The chief caution required in the management or conducting the Shropshire method, is the off-break from the pit bottom and levels, to produce the first break of the strata; the more the waste is filled with gobbing, the less is the risk of any misfortune to the works or the miners. When the superincumbent strata are strong, with thick beds of sandstone near the coal, the waste will sometimes advance many yards before the break takes place; and when it commences, which is known by the great noise heard over head, the greatest care is required, to prevent the crush making a break, or nipping along the face of the whole wall, which sometimes happens. This is termed *the wall coming in*; that is, the strata come down along the whole line of the wall faces, and shut up every opening. The consequence of which is, that the faces have all to be opened out again along the line of the break, and to the rise of the broken rock face. If, during the course of the ordinary working, when the crush comes regularly and progressively forward, care is not taken to keep the gob well and regularly filled up, in the manner already mentioned, the coming in of the wall is almost the certain consequence.

As to the setting of props, and the building of pillars in this work, if the roof and pavement are both very strong, the pillars of stone are built as usual, but not made very firm by any kind of wedging; and in place of setting the props firm betwixt the roof and pavement, it is of advantage to place under each a bit of stone, or small piece of waste wood, the object here not being to resist the absolute pressure of the strata, but to keep up the roof stone for the safety of the men, until the strata press down and rest upon the gob; for if, in this case, small pillars of coal were left in the working in place of built pillars, or the props set very firm, the consequence would be, that the instant the least pressure came forward, the coal pillars would fly to pieces, every prop would be instantly broken, the roof come down, and the workmen be killed; whereas by the pillars and props yielding gradually, until the gobbing receives the pressure, all points are kept right, and the props are saved for farther service. In Shropshire, some collieries use a great proportion of cast-iron props. This plan is a saving, when an iron work is connected with the colliery, that when a prop breaks it is recast at little expence, but in ordinary cases the expence will be found too great. When props will not drive out by applying the force of heavy mauls, a long chain with a hook is provided, the hook is fixed to the bottom or top of the prop, and the other end, having a small hook, is doubled up to form an eye or loop, which is passed over a strong lever of iron or wood, the point of which resting against a firm prop, gives the workmen great power in wrenching the other prop from its place.

Another modification of the Shropshire method is, for each workman to have from 6 to 12 feet of coal before him, with a leading hand man, and where every workman follows in succession like the steps of a stair. If the coal has open backs and cutters, this work goes on very regularly, as represented in Fig. 3. Plate CCCXCII. where the leading hand is at *a*, next the crop, and *b b*, &c. are the wall-faces of each workman, A the pit, B the dip-head level. In this case the roads are either carried progressively through the gob, or the gob is altogether shut up, and the whole of the coal are brought down the wall-faces, either to the dip-head level or to the road *c c*. This method may be varied by making the walls of a breadth to hold two, three, or four men; by this plan each set of men performs the whole work of holing, getting, breaking out, and carrying away the coals. This mode can be also equally well adopted by working the coals level-course with the leading hand next the dip-head.

It may be estimated, that from an eighth to a twelfth part only of the coal is left under ground by the Shropshire system, and in favourable instances every inch of coal can be taken out, the principle being to leave no solid pillars, or any coal below, excepting what may be indispensably requisite to secure the gob. This system might be applied to coals of almost any thickness, providing stuff could be got to fill up the gob. It is the want of it which limits this system to coals of a certain height. Various modifications of the systems now described are in use, but it would be endless to describe them; the general principles are the same; *The object and intention being always to produce as much coal as possible from a given area, as may be consistent with the safety of the workmen*, having all other circumstances as before mentioned in view.

Such being the general modes practised in Great Britain, of working coals of ordinary thickness and of moderate dip and rise, a general description will now be given of the methods pursued in working coals of the following description:

1. Very thin coals.
2. Very thick coals.
3. Coals having a great dip and rise, or what are termed edge coals.

Beds of coal in Great Britain are wrought as thin as 18 inches as a coal mine; if wrought thinner, the working of fire-clay or iron-stone immediately adjoining is connected with them. There are, however, instances of caking coals, of a fine quality for smiths, being wrought alone, only 12 inches in thickness. When the bed is 18 inches in thickness, it can be wrought by men of the ordinary size, but young men and boys are more suitable. Coal of this thickness can be wrought without lifting the pavement, or taking down the roof in the rooms; but for taking out the coals, roads are cut either in the pavement or roof. All coals under two feet three inches in thickness are wrought with the intention of taking out all the coal, either in the Shropshire system, or with pillar-walls and rooms; with this difference, that from the thinness of the bed the rooms are wrought as wide as the roof will carry up, or if a following or fall of the roof-stone can be brought on, it is an advantage, as it not only gives height, but, by filling up the waste, renders the roads easily kept for the working of the pillars. Where there is no following, small temporary pillars are left, about eight feet square, along the chain-wall side. The walls are from four to sixteen yards in thickness, according to circumstances, and only holed through occasionally for air. The rooms 20 feet in breadth, with the small pillars set six or eight feet from the pillar side or chain-wall, and eight feet apart from each other. When the workings are carried to the required extent, the chains of wall and small pillars are begun to be wrought at the most distant point, and finished off at the pit-bottom. Of this method there are also various modifications, depending upon the texture of the coal, the kind of roof, pavement, and superincumbent strata. The common post and stall work is not suitable for such thin coals, particularly as a given area yields so small a quantity of coals.

Coals which are from five to eight feet in thickness are the most suitable in every point of view for the full effective exertion of the miner, and for the general economy of under-ground operations. When they much exceed this height, they require very excellent roofs and pavements, to render the work safe and comfortable, or to enable those who direct the mining operations to take out a fair proportion of coal from a given area. In these thick coals the Shropshire method is impracticable for want of gobbing, and the length of the props would present but a feeble resistance to the pressure of heavy roof stones.

When coals do not exceed 20 feet in thickness, and have good roofs, they are sometimes wrought as one bed of coal; but if the coal is tender or free, it is wrought as two beds. In general, however, nearly a half of the coal is lost in pillars, and very seldom can less than a third be left. In working such a coal as one bed, two modes are adopted.

The first is, to work the roof-coal to the thickness of from four to six feet, the length of a pillar and thirling, and four feet more; then the ground coal is wrought as a bench under foot by the partings, as an open cast quarry above ground; but before the ground-coal is taken down opposite the thirling, the thirling is set in four feet in the roof-coal, and then the whole of the ground-coal is wrought away; this leaves a bench or seat of four feet broad in the forehead of the room, and in the mouth of the thirling, for the collier to stand on when he commences to work the roof-coal either in the room or thirling. Without leaving this bench, a scaffolding of timber would require to be erected for commencing his operations again.

The other method is, to work a portion of the ground-coal first, of from three to five feet thick, the length of the pillar and thirling, and then returning to the face, work the upper part of the coal overhead.

When the coal is free, and ready to crumble by the pressure and effect of the air, the upper portion of the coal is first wrought, then a scaffolding of coal is left, from two to three feet thick, according to the texture and quality of the coal; and the lower part of the coal is then wrought as represented in Fig. 4. Plate CCCXCII. When the workings are completed to the proposed extent, the scaffoldings of coal are wrought away, with the part of the pillars that can be removed with safety.

As the using of prop-wood in coal of so great a height is not found practicable, and as falls in the roof would be so exceedingly fatal to the workmen, if the roof is in the least degree tender, it is the practice in such cases to leave a roof of coal from two to three feet in thickness. This of itself not only makes an excellent roof, but, when it is breaking, gives warning by the noise it makes, so very different from the noise of roof-stones when they are giving way.

One of the thickest coals in Great Britain, which is wrought as one bed from roof to pavement, is the very remarkable coal in Staffordshire, close to the town of Dudley, known by the name of the ten-yard coal, a section of which, with the accompanying strata, is given in the preceding part of this treatise: this wonderful bed of coal is in extent about seven miles long, and four broad. No coal similar to it has been found in the island, and the mode of working it is altogether singular. It is wrought in a kind of pannel work, but altogether different from the improved Newcastle system.

Numerous pits are used in working a coal-field even of moderate extent at Dudley: and in place of one pit, with one corve ascending and another descending alternately, as in other collieries, two pits are always sunk, from ten to thirty feet apart, and from six to seven feet diameter, of a round form; for these two pits, one coal-drawing engine is employed, having a rope into each pit, the object being to draw the coals with a very slow motion, but a great weight of coals each time. A pannel or compartment formed in working the coal is named a side of work; and in each side of work sometimes only two pillars are formed. In other cases there are four, six, nine, or twelve, but the last number is very seldom adopted; two or four pillars in a side of work left for the support of the roof is the common practice, and what is most approved of. As the whole operation of working this coal is performed in one of the compartments, named a side of work, it will be proper to explain the mode of working out the coal from one of these, before describing the whole extent of the workings of a pit.

Fig. 1. Plate CCCXCIII. represents a side of work; A, the ribs or walls of coal left around, and forming the side of work; *a* the pillars, 8 yards square; *c* the stalls, 11 yards in width; *d* the cross openings or through puts, also 11 yards wide; *e* the bolt-hole cut

through the rib from the main road, by which bolt-hole the side of work is opened up, and all the coals carried out. There are two, three, or four bolt-holes opening into a side of work, according to its extent; they are about eight feet wide, and nine feet high. As the coal is divided into subordinate beds by common coal partings, or by bands of stone termed batt, of from an inch to above a foot in thickness, though in some instances bands are many feet thick, the working is in a great degree regulated by these divisions. Although the coal is 30 feet thick, the lower band, which is 2 feet 8 inches thick, is wrought first, the workmen choosing to confine themselves within this narrow opening, in order to gain the greater advantage afterwards in working the coal immediately above; as soon as the workmen cut through the bolt-hole, they open up the work by cutting a mine forward, four feet in width, as represented by the dotted lines. At the sides of this mine, next the bolt-hole, each workman in succession breaks off a breast of coal, two yards broad, as at *f f*, by means of which the sides of the rib-walls A are formed, and the area of the pillars. In this manner each collier follows another, as in one of the systems of the Shropshire method before described. When the side of work is opened out along the rib-walls, and the faces and sides of the pillars formed off, the upper coals are then begun to be wrought next the rib-wall, which is done by shearing up to a bed next the bolt-hole, and on each side, then the head coals are brought regularly down in large tabular masses, of such thickness as suits best with the free partings or subordinate divisions of the coals and bands, the shearings are made very wide when they require to be put up five or six feet, as in this case they must admit the head and shoulders of the miner. For the security of the workmen, props of wood are used to support the first of the upper coals, and temporary pillars of stone are also built at convenient distances; these are termed cogs. Besides these safeguards, if the mass of coal to be brought down is great, square spurs or spurns of coal are left, about 10 inches thick, at the lower part of the shearing, and at various distances, until the shearing is completed; the props and cogs are then withdrawn, the back spurns are cut away in succession, until the front ones are also cut away, then the cogs and props at the lip of the hanging coal are driven out, when the coal falls in a body, breaking off by the ends of the shearing. Besides the main pillars represented in the figure, temporary and intermediate pillars are formed, of from two to three yards square; these are termed *men of war*. In the first workings of the ten yard coal, these temporary pillars were formed when carrying forward the work in the coal next the pavement, but this was found not only a hindrance in carrying forward the work in the first opening, but, as the sides of work were extended, a certain degree of pressure came upon the work, when these pillars, or men of war, instantly gave way and were of no use. Experience has taught the miners a remedy for this, which is, to form none of these pillars until the first of the upper coals begins to be wrought, when square basements of stone are formed on the pavement at the places where the men of war are to be, of an area some inches or a foot larger than the intended size of the pillar; and when the building is within three or four inches of the coal, that space is filled up with pieces of wood, made moderately firm; the effect of this is, that when the pressure of the superincumbent strata begins to bear upon the whole of the pillars, the pieces of wood and under-building yield by degrees, and prevent the pillar of coal above from giving way. This principle is found effectual, and could only have been discovered in the course of much previous practice; it is a principle which is applicable in many instances to mining operations, when a degree of yielding to the pressure is more efficient as to ultimate resistance, than a rigid resistance at once applied. In this manner, about half the thickness of the coal, or rather more, is brought down in tabular masses of various thickness, having the men of war pillars left for the last of the work, which is taking down the coals next the roof; these are brought down in immense falls, of from 100 to 200 tons at a time, and in some instances even 300 tons. When the various sides of work in a pit-workings are in a prepared state, that is, prepared for taking down the upper coals, sometimes there are 6000 tons in this way ready to fall.

In the course of working and breaking out the coals for going up the pit, all the culm-coal, and a great proportion of excellent small coals, are left in the waste, upon which the colliers stand when working the upper coals, and when the height becomes great, ladders and various kinds of scaffolding are used. The last of the upper coals, in place of being wrought from the bolt rib wall forward, are wrought from the opposite rib wall towards the bolt rib, for the safety of the workmen. This operation is attended with great danger to the workmen, and therefore they are required to be very expert miners from practice in that kind of work, with much boldness and resolute determination. The first operation is to shear along the face of the back rib wall, and along the side ribs, leaving spurs at regular distances; the scaffolds are then withdrawn, the men of war cut away as the miners retreat; and the last operation is cutting away the spurs. As the danger is very great working under so large a mass of coal, no miner can approach to cut these away with a common pick; they are therefore provided with an instrument or tool named a pike, very like a boarding pike, 18 feet long, the shaft of wood, having a steeled iron sharp pike, with a hook at the one side, similar to a boat-hook. With this, the miners standing with their backs to the bolt rib wall, cut away with the point of the pike in the advance stroke, and with the hook in the back stroke, the side spurs next the back rib wall. In this manner the spurs are cut away in succession, the miners retreating towards the safe part of the mine, until all of them are cut. Sometimes the coal falls before all the spurs are cut, and before the last of the men of war are cut down; in many instances the upper coals do not only fall the height of the shearing, but up to the roof, by which masses of coal, from 10 to 14 feet thick, fall at once, and not only so, but immense pieces of the strong roof stone fall at the same time, of such a thickness, that before the coal can be broken out, the miners have to blast it with gun-powder, and remove many tons of it. From this description of working the ten-yard coal of Staffordshire, the very dangerous nature of such work may be conceived; but no correct idea can be formed of the operations, or of the immense excavations and caverns formed by the working of the coal, and particularly by the fallen roof. The accidents which take place in this coal are consequently very many; severe contusions and broken limbs are of frequent occurrence, and not a few workmen are snatched from life to death in an instant by the coals and roof falling when they least expect them; but, besides the danger arising from these falls, they have also inflammable air to contend with, by which also many have been killed.

Various modifications of the mode of working a side of work in this coal are practised, as best suits the nature of the coal, the superincumbent strata, the various local circumstances, and views of the manager of the colliery.

When the crop of this singular coal was first wrought, the miners only extended their operations to 20 yards distance all around the pit bottom, and then began a new pit; but as the pits became deeper and more expensive, the distance of the workings was extended, and the method of mining improved. The extent of a pit's workings is now in general 100 yards on all sides, that is, the area wrought is 200 yards upon the side, and in a number of cases 300 yards, or 150 yards of extent on each quarter of the pit. The greatest distance ever attempted was 450 yards from the pit bottom, but this distance does not appear to be suitable. A number of the sides of work, as of the side of work represented in the figure, constitute the workings of a pit. The roads leading from the pit bottom are from 3 to 4 yards wide, and the rib walls are of various thickness; the main ribs being 12 yards, the others about 5 yards in thickness.

This coal, in the course of working, is, like many, liable to take fire by spontaneous ignition, which is not only exceedingly dangerous and troublesome, but requires the greatest attention to prevent its formation. It is here termed the breeding fire, and will be treated of when stating the accidents to which coal-mines are liable. It is this which requires the workings to be laid off in sides of work, as represented in the figure, with one opening or bolt hole, which is securely built up and made air-tight as soon as the side of work is wrought out. When a pit is wrought to its full extent, then, if circumstances admit of it, it is wrought in the pillars and ribs, beginging at the most distant corners, and as much of the pillars and ribs are brought away as can be done, consistent with the safety of the workmen. If there are openings through the ribs to any other pit workings, they are carefully built up with double walls of stone, a few feet asunder, and the space is filled up with mine dust, (the refuse of calcined ironstone;) which mine dust is found the most effectual remedy for keeping the passage air-tight, in the event of a crush rending the walls, as the mine dust yields to the pressure without admitting the air to pass.

From this description of working the ten-yard coal, it is evident that a very great proportion of the coal is left under ground, not only in pillars and rib-walls, but there is an uncommon quantity of small coal produced in the operation of bringing down, and breaking out the coal, so that in general from four-tenths to a half of the whole is for ever lost; and it is also evident, that from the long habit of the workmen, it would be almost impossible to introduce any new method, though, to all appearance, it would be decidedly preferable to the present system. One plan has been suggested, which was, to work the upper part of the coal first, leaving a few feet of coal for a roof, and then work all the lower coals in benches, as described in the working of coals 20 feet in thickness, the roof to be supported with props. It is however questionable, how far this would be found in the end better, or whether less small coal would be produced.

The next method of working coals of uncommon thickness is by stages or scaffoldings of coal, as practised in that coal of astonishing thickness found at Johnstone, near Paisley in Scotland, and represented in the sections in the first part of this treatise, being from 50 to 60 feet thick in one quarter of the field, and in one part no less than 90 feet thick. There are, no doubt, several thin bands of stone in it, but there are only two of 27 inches thick each. The roof of this coal is so bad, and the height so great, that it was found quite impracticable to work it as one seam, as in Staffordshire; and therefore the method is, to leave about three feet of the upper coal for a roof, then to work a band of the coal from six to seven feet thick, as best suited the partings of the coal, or thin bands of stone, which band of coal is wrought in the post and stall system, with square pillars of extra strength, which are cut through afterwards. A scaffold or stage of about three feet thick of coal, or of coal and band stone, is left at the sole; and under this, rooms and pillars are set off and wrought in another portion of the coal, from five to seven feet thick, great care being taken to place pillar under pillar, and room under room, to prevent a crush. In this way, when the coal is thickest, 10 bands of coal are wrought, in the manner represented in Fig. 2. Plate CCCXCIII. When any band of the coal is foul, or of a quality not suitable for the market, it is given up, and allowed to remain along with the next scaffolding; a great proportion of the coal is consequently lost, as in the Staffordshire thick coal. The working of this coal requires very assiduous attention to keep the pillars and rooms in a perpendicular direction; the miners' compass has to be used daily, and bore-holes have occasionally to be put down through the scaffoldings of coal, that the pillars may be placed correctly under each other.

Having thus described the general modes or systems which have been adopted in working coals of various thickness, the system adopted in working coals which are named half-edge coals, and edge coals, shall next be described.

Half-edge coals are wrought either post and stall, or in the Shropshire system, as before described, with this difference, that the rooms are always, if possible, carried in a level course direction, for the safety of the workmen, and the more easily taking the coal to the pit bottom.

The working of edge coals, which are nearly perpendicular, are wrought in a peculiar manner, and different from any of the coals before described, as the collier, while working, stands upon the coal, having the roof upon his one hand, and the pavement upon the other, like two walls of stone. The engine-pit is sunk in the strongest of the strata, and in some instances, they are so directly vertical, that the same stratum is sunk through the whole depth. After the pit has reached the required depth, mines are carried across the strata from the pit bottom, until the coals are intersected, as represented in Fig 3 Plate CCCXCIII. where *a. a*, are the edge coals; A the engine-pit; *b. b*, the cross cut mines from the pit bottom; *c, c*, upper cross-cut mines for the greater conveniency of working the coals. All the rooms are wrought in a level-course direction, with openings made from one to another, for air and access to the pit bottom. The chief edge-coal works in Britain are in the vicinity of Edinburgh, where hitherto all the coals in such works are carried upon the backs of women from the wall face to the pit bottom; and, in general all the pits of a colliery, excepting the engine-pit, are only sunk one half the depth of the breast of coal to be wrought, in order that one half of the rooms may have their coals carried up to the pit bottom, and the other half carried down. This is effected by wooden traps or stairs, placed from one room to another. It is singular that no improvement has been yet made of this very rude plan; particularly as the edge coals are wrought at a great expence, and with great inconveniency.

Although various modes and systems of coal working have been described, there are very many modifications in all of them, which are regulated by the consideration of local circumstances joined to years of experience. These alone can determine the mining engineer as to his adopting the system best suited for working the coals in a coal-field.

With regard to the manner in which coals are brought from the wall face to the pit bottom, this is almost as various as the systems pursued in working.

The oldest mode, and that which it is presumed was used when coals were first wrought by ingoing eyes, or mines at the crop, was by women carrying the coals in baskets on their backs. This method, rude and severe as it is, was carried on very generally in Scotland till within these forty years; and it is to be regretted that a system so slavish and severe is even in this age (which boasts of being enlightened) adopted and carried on. It is admitted that it is a matter of free-will, and those women who carry coals may give it up if they choose. To young women the severity of the labour is less to be considered, in one point of view, but to the mothers of families the system is oppressive, deprives them of many comforts, and precludes them from advancing in their own scale of society. This system is, however, declining every year; and, on this account, no description is given of the arrangement of the workings of a colliery which are peculiar to this method.

The women who carry coals are named bearers; the weight each carries is from 1 cwt. 1 qr. to 2 cwt; in some instances they have carried 3 cwt. In the worst kinds of this system, they not only carry the coals from the wall face to the pit bottom, but ascend a stair to the top of the pit, and bank the coals. In the other case they carry from the wall face, and lay them down in bins at the pit bottom, in order to be filled into the baskets. In some collieries 60,000 tons annually have been carried in this way, and an extent of 160 yards from each quarter of a pit has been wrought by this plan, which is an area of 102,400 yards.

The next mode is to use hutches or baskets with slipe or cradle feet shod with iron, containing from 2 to 3 cwt. of coals. These are drawn along the pavement either by ropes and soams, or by harness of leather, over the shoulders of the workmen. The collier either performs this work as part of his daily labour, or persons are appointed for this work alone, and are thus drawn from the wall face to the pit bottom. This system is used in many small collieries, but it is among the worst plans; for in no instance can the strength of a man be applied with less effect than in this way; the exertion required is very great and unceasing, nor does any extra exertion of muscular force aid him the least in the next step of his labour; it is from beginning to end one continued dead pull, without the least spring or elasticity; and if he slackens his exertion one instant, the weight he is dragging that instant stops. It is painful to see men thus employed, and their strength so evidently misapplied. This system must daily decline.

The third method, as an improvement of the last, is to substitute hutches, or baskets, capable of containing from 4 to 6 cwt. of coals, and of the same form as those above described, but, in place of men horses are employed to draw them from the wall face to the pit bottom. This is also a very bad system; the same objections are applicable to it as to the former, and the strength of a horse is applied with the very worst effect.

The next improvement upon the system where men draw the coals, was either to set the corve on a small four-wheeled carriage, named a tram, or to have wheels attached to the corve. By means of this, more work was performed, provided the pavement was hard, but it was not applicable when the pavement was soft; in which case, an irregular kind of wooden rail-roads was laid.

When the distance from the pit bottom became considerable, regular and well laid wooden rail-ways were laid to a point near the wall faces, named the way-end. To this point the coals were brought down in the corves, either by men who draw the trams, named trammers, or by horses upon slipes. Upon the rail-way there were strong four-wheeled frames or carriages capable of holding two corves. At the way-end a small crane, with a wheel, pinion, and chain, was erected. With this the corves were lifted from the trams, and placed on the carriage; two or more of them were then hooked together, and one horse drew to the pit bottom from four to six corves at a time.

The whole system of bringing coals from the wall face to the pit bottom was greatly improved by the introduction of cast-iron rail-roads, named tram roads, in place of wooden roads. For this great improvement, we are indebted to Mr. John Curr of Sheffield, in Yorkshire, who first brought it forward. This system is universally adopted in all collieries of any considerable extent, and is equally applicable to the smallest mining concerns. The rails are named tram-rails, or plate-rails, it being a plate from three to four inches broad, with an edge at right angles to it, about two and a half inches high, and are from three to four feet in length. They are fixed either to cross pieces of iron named sleepers, or more generally to wooden sleepers; the strength of the rails being proportioned to the weight carried. For particulars regarding the construction and weight of these roads, see the article RAIL-WAY.

By this system, in some collieries, the colliers, after having wrought the coals, draw them along the tram-roads to the pit bottom. In other works, persons are employed to draw the coals, named trammers, when one in front of the corve draws with harness, and one pushes the corve behind, who is known by the name of a putter. The perfection of this system is to be seen in the Newcastle collieries, and in the collieries of Whitehaven and Workington in Cumberland. The main roads or rolley-ways, also named mother-gates, are laid from the pit bottom to a convenient central point near the wall faces or rooms where the colliers work. There a crane is erected. From this point tram roads are laid into each room. In bringing the coals from the wall face to the crane, a stout lad and a young boy are employed at each corve. The lad, who is in front, and draws, is named a headsman, and the boy is named a foal. As many of these are employed in a set or sheth of rooms as will keep the crane and rolley-way in constant work; the instant each corve arrives from the wall face at the crane, it is lifted from the tram, and placed on a rolley, each rolley holding generally two corves: Single corve rolleys are sometimes used, and as soon as three or four double rolleys are loaded, they are hooked together, when a rolley-driver, with his horse, takes them to the pit bottom, while the loaded rolleys are going to the pit. Rolleys with empty corves are returning, and these pass the loaded ones at given regular distances, where the rail-way is double, named an off-set, or pass-by road. The rolley horses, to prevent the carriages overrunning them, have a peculiar kind of shafts, named limbers, either made of wood or iron, but commonly of iron, as represented in Fig. 4. Plate CCCXCIII.; the hole at *a* passing over an iron stud in front of the rolley, and are quickly attached or detached. In this manner the work is carried on with astonishing regularity and expedition. The power of the engine for drawing the coals is constructed in proportion to the depth of the pit and quantity to be raised, taking two corves at a lift, and going at a velocity in the pit of 12 feet per second, on an average; and so very regular and systematic is the arrangement of this operation, that the corves are brought forward from the wall faces to the pit bottom, and sent up the pit as fast as the on-setters at the pit bottom, and the banksmen at top, can hook and dishook the loaded and empty corves to and from the engine ropes, so that 100 corves of coals every hour has been drawn up a pit 100 fathoms deep, which is equal to 27 tons per hour, or 324 tons in a day or shift of 12 hours. In short, any requisite quantity may be drawn up a pit by this highly improved system. It must, however, be remarked, that this system is more applicable to coals similar to those of Newcastle, which work small, than to coals which work in large masses, and which must be kept large, to suit the market, on account of their open burning quality.

When coals have so great a rise from the pit bottom to the crop, that horses cannot be applied on the rolley ways, the corves descend along the roads by means of inclined plane machines, which machines are either vertical rope-barrels, or horizontal rope-sheaves. The descending motion is guided by a brake, and while six or eight loaded corves are descending, as many empty corves are ascending. These inclined planes are either of great length, or divided into stages of from 200 to 300 yards long. At the end of each stage is an inclined plane machine, so that the coals are lowered in succession from one machine to another. The corves are brought from the wall faces to the planes either by men or horses. The whole of the system of bringing coals from the wall faces to the pit bottom, can be modified to suit the extent of any colliery. Inclined planes are much used at Newcastle, when the dip of the coal admits of it.

The wheels of the trams and rolleys, are from eight to sixteen inches in diameter, according to the thickness of the coal. In some, the axles not only turn round on their journals, but the wheels also turn round upon the axis; in others, the axles are fixed, and the wheels only turn round; and there are some which have the wheel fixed upon the one end of the axle, and the opposite wheel made to run round it; and the other axle has the fixed and loose wheels upon the reverse sides, the intention being to make the carriages go easily round the turns of the road.

With regard to the drawing of coals up the pits, various kinds of machines have been applied.

In shallow pits, where there is very little output of coals, the common windlass, or jack roll, with two men, is still used. In deeper pits, the common gin is used, or the wheel and pinion gin; these, however, are only applied at collieries of small extent, and every other machine for drawing coals has been superseded by the rotatory steam-engine with fly-wheel, fly-wheel shaft, and rope-barrels. These engines are of every variety of construction, and of Newcomen's, Watt's, and Trevethick's principles. They are applied from the power of three horses to that of forty. When they are of small power, they are generally constructed with a fly-wheel, and short fly-wheel shaft, upon which is a small pinion working into the teeth of a large wheel, fixed upon the rope-barrel, by which means the engine goes with great rapidity, while a slow and equal motion is produced in the ascending corves in the pit. But when the engines are of great power, and much execution of work required, then the engine is connected directly with the rope-barrel; and some of these for deep pits are of such a size, that each revolution of the barrel produces an ascent of 13 yards. In short, there seems almost no limitation to the execution of work by these engines. For all great outputs of coal, Watt's engine is in the most general use. The momentum of these machines is so great, and the fly-wheels are so heavy, and go at so great a velocity, that the mere suspending of the moving principles of the engine would not stop the movements at the instant wanted, on which account a very powerful brake is applied to the periphery of the fly-wheel, or rope barrel, so that the brakeman, by applying his foot to the regulating lever of the brake, while with his hands, he shuts the valves of the engine, can pitch the corve and suspend its rapid motion within a few inches of the required height at every delivery.

Many attempts have been made to apply the steam-engine to an endless chain or chains suspended from the top to the bottom of the pit. Several are in use, but it is questionable how far they are applicable to very deep pits; as they have hitherto been only applied in pits of moderate depth. The best principle we have seen is, that invented by Mr. Hugh Baird, civil engineer, and applied in practice at the Shotts Iron Work, which, though on a small scale, shows the effect most correctly. Two endless chains, having long stave links, are suspended from two barrels placed over the mouth of the pit. The diameter of the barrels is more than double the depth of the hutch; and to keep the chains regular, they pass under other barrels beneath the scaffold of the pit bottom; studs of iron project from the inside of each chain, at regular distances, according to the power of the engine, and the hutches have ears of iron, by which they are suspended on the studs of the chain. Upon the end of the chain-barrel is a toothed wheel, into which a pinion works, placed on the fly-shaft of the engine. The chains have guides to prevent them going off the barrels, and there are studs on the barrels which enter into the links, and prevent the chains slipping round, so as to keep the studs upon the sides of the chain exactly opposite and parallel. When the engine is set in motion, the chains ascend on one side and descend on the other. The loaded hutches, as they come to the pit bottom, are set forward, till the ends of them, having the iron ears, are in a line with the perpendicular of the ascending chain, the studs of which catch the ears and carry the hutch up the pit, which passes over the axle of the chain-barrel, and is set down on the strike-boards at the side of the pit. The empty hutches are attached in the same manner at the ascending side of the chains at the pit mouth, go over the barrel, and descend to the bottom. For attaching the empty hutches and detaching the loaded ones, there are moveable strike-boards, which are wrought by a mechanism attached to the machinery. The execution of this machine is very considerable with an engine of moderate powers, as the engine never stops from the beginning to the end of the day's work. Plate CCCXCIV. Fig. 11. shows the hutch passing over the axle at the pit top.

The other kinds of machines are those where water is the moving power. The oldest and most simple is a water-wheel, or rather two water-wheels joined together by the sides, the buckets set reverse to each, so that when water is applied on one side of the wheel, the wheel turns forward, and when applied on the other side, it turns backward. To the axle of the wheel a rope-barrel is attached, or a second power may be produced by a pinion and wheel, as in the steam engine.

The other kind of water engines for drawing coals, is strictly applicable only in pits level free, where the ascent of the loaded corve is produced by a descending cassoon filled with water. When the ascent and descent of both are equal spaces, then the rope-barrel for the cassoon and for the corves are of the same diameter; but when the pits from where the coals are drawn, are deeper than the point of discharge for the water into the dry-level, then the cassoon is made large, and its rope-barrel much smaller than the barrel for the corve-rope, so that by the time the cassoon reaches the half depth, for example, the corve may have ascended double the depth. The cassoon is filled by a valve at the pit top, and upon its reaching the place for discharging the water, a self-acting valve lets it off. The loaded corve is taken off at the pit head, and the descending rope and empty corve pull up the cassoon with ease, on account of its being suspended from a barrel much less in diameter. All the motions of this machine, which would be very variable and destructive, if left to itself, are regulated by a very powerful brake at the pit top.

As much coal and many corves are destroyed by the corves striking at the meetings, where the ascending and descending velocity together is equal in some cases from 20 to 30 feet per second, various plans have been devised to obviate this loss. One of the simplest plans is to divide the pit from top to bottom, so that each corve has a distinct pit for itself.

A second mode was invented by Mr. John Curr, Sheffield, which was to have guides of wood attached from top to bottom of the pit; these are long pieces, or spears of fir wood, about four inches square, attached perpendicularly to the sides of the shaft, and to buntons in the middle of the pit. Betwixt these guides, sliders with friction-rollers are placed, attached to the gin-ropes, and to these sliders the corves are suspended. By this plan the corves or hutches can be drawn with great velocity; but there is a considerable hindrance in striking or banking the corve at the pit top, as shutters or sliding boards have to be used. This plan is not applied in the Newcastle practice, but is highly beneficial where large coals have to be raised. A third mode, of a simple form, is to suspend four chains from the pit-head frame, or round rods of iron screwed together in pieces of 12 or 15 feet each; these are fastened to a strong beam or cill at the pit bottom, and are kept tight by a regulating screw at the top. The slider used for the chains or iron rods, is a double-eyed bolt or rod. Though these are in practice in pits of moderate depth, they are never applied in pits of a great depth.

In drawing coals, both ropes and chains are employed.

The round ropes are shrowd laid; and the best are those made upon the correct mechanical principles, invented by Mr. Chapman and Mr. Huddart, all the yarns being laid equally, so as to have uniform tension when the strain is applied.

The other kind of rope is known by the name of the flat rope, which is without doubt the best of any yet invented for drawing coals, and has proved an immense saving compared with round ropes. They are made of four ropes laid horizontally together, and are alternately right and left laid ropes. By this very ingenious plan, the ropes counteract each other in the twist, and hang like a ribbon down the pit; they are connected or sewed together by a small rope, which operation requires very powerful machinery to pierce the cordage. They have this great advantage also, that they are not only very pliable, which saves the heart of the ropes from being broken, but as they lap upon themselves, a very simple sheave suits for a rope-barrel. But the greatest advantage is, that by lapping upon themselves, they act as a compensation or balance against the weight of the descending corve and rope, superseding in many instances counterpoise chains, which are used to regulate the descent in deep pits. For this invention the mining interest of Great Britain is indebted to Mr. Curr of Sheffield, before mentioned, whose inventions and improvements in the mining system are highly important, as must be evident from those already mentioned.

The kinds of chains which have been tried are very various; some are of long links, termed two and three, or three and four, according to the mode of coupling the links together by a bolt. Many very ingenious plans have been devised to make the long links of correct and equal length from centre to centre of the bolt hole; and though these are applied at many collieries, yet the short pudding link chains are those most generally used. They are proved as to strength, and warranted; have given great satisfaction, and are an immense saving to collieries. These chains are now in general use, and for other purposes besides mining concerns. We have, however, to remark, that the colliers have hitherto declined riding by them in the pits, for this reason, that the fault in a rope is easily seen, but a great fault may exist in a link which cannot be observed.

Upon the corves being landed or banked at the pit top, they are either drawn to the bin or pit-heap by horses upon slipes, or by trammers on a tram road, which is now the common practice. When the coals are small, as at Newcastle, the pit head is raised eight or nine feet higher than the common level of the ground, and the heap proceeds from this height outwards from the pit mouth; and if the bins increase, the tram roads are laid upon the bin or heap as it advances outward.

When coals are wrought large, termed great coal, the pit mouth has only a gentle rise from the common level of the coal-hill adjoining, and the coals are built up in walls, piece by piece, the small coal is either thrown into the heart of the walls or bins, or laid apart by themselves, as may best suit the sale of the coals.

Having thus attempted to describe the various plans which have been adopted for working coal mines, a most important point in mining remains to be treated of, which is *ventilation*, or the means which have been adopted for supplying the workmen with atmospheric air, sufficiently pure for the support of animal life, and the flame of the candle or lamp which gives light in the mines.

The coal-mines of Great Britain were, as before mentioned, wrought on a very limited scale, and with comparatively little system, till after the beginning of the eighteenth century. It was not till the introduction of the steam-engine, for drawing water in the first place, and coals afterwards, that the coal-mines began to be wrought on an extensive scale; even to this period, the ventilation of mines was conducted in a very rude, uncertain, and irregular manner, and for many years afterwards. The air courses were confined to the dip-head levels, and wall-faces, or rooms where the miners wrought; the consequence was, that the wastes were frequently full of inflammable air, and became the cause of constant calamities. The only test the miner had, as to the state of air through the works, was by the appearance produced at the top of the flame of his candle, which appearance will be afterwards noticed.

When inflammable air accumulated in the foreheads, the common practice was to fire it regularly; this was done in many collieries every morning. When this air was in small quantity, the person appointed for the service approached each forehead or room, as near as he judged the air safe; then taking a long pole, he fixed his candle in an oblique position to the end of it with a bit of clay, and laying himself flat upon his breast along the pavement of the coal, he gradually advanced the candle towards the wall-face and roof of the mine, until the gas fired, and the blast passed over him. When the quantity of gas was very inconsiderable, it burnt slowly, with a bright blue lambent flame; when the quantity was more abundant it blazed, the greater part of the flame being blue, but fringed with yellowish white flame. The gas, in this case, burnt off with very little noise; but when the quantity was considerable, it ignited with an explosive sound, and then passed quickly off without extending its influence to any considerable distance. When the person who performed this service found the gas abundant, he put on wet jackets, to prevent the fire scorching him. This singular operation had, in many instances, to be gone through in the numerous foreheads of the same colliery every morning, previous to the workmen entering the pit. In other collieries, where this gas was so abundant that it not only accumulated in the forehead of every room during the time the miners were absent, but gathered in a connected body, filling a considerable space, greater caution had to be adopted. In this case, the fireman went amongst the inflammable air in the dark, leaving his candle at a considerable distance; then fixing a prop betwixt the roof and pavement, he passed the end of a long line, through a ring attached to the top of the prop, he retreated to his candle, with the two ends of the line with him, and having prepared a piece of deal, about fifteen inches long, and eight inches broad, shaped like a weaver's shuttle, he fixed his candle in a hole of the board, or by a bit of clay in an oblique direction; then tying one end of the line to the board, he lay down at the end of a pillar, off the line of the air course, and by drawing the other end of the line gently to him, the candle advanced to the foot of the prop, and if the gas was not so low as the pavement, the candle was drawn up towards the roof, when the whole of the gas instantly ignited with an explosion, and passed along the air course within a few feet of the fireman, and directly towards the upcast shaft. In Staffordshire, where the coal is thirty feet thick, and the excavations immense, this method was, till lately, in general practice. In place of a prop, a kind of mast was erected, fixed at the pavement, as the top of it did not reach the roof; and in place of a line, fine flexile copper wire was employed, which was not destroyed by the explosion. In these numerous and very extensive mines, and where the coal was taken down far above the air courses, the collections of inflammable air were great, and when ignited the explosion was frequently violent, and passed the fireman in his retreat, with a thundering noise, and with great velocity. This very rude, and very dangerous mode of clearing the mines of inflammable air, is yet to be found in practice, and is known by the name of the fire, or firing line.

Every bed of coal abounds less or more with deleterious air, which is of two kinds; the one is specifically heavier, the other lighter than common air; the natural consequence of which is, that the one rests in the deepest or lowest places, the other, from its levity, ascends to the highest places of the mine. The first is known by the common provincial names of choak damp, black damp, styth, or bad air; the other is known by the name of foul air, fire-damp, or inflammable air. The one is the carbonic acid, the other the carburetted hydrogen gas of the chemyst.

The precise qualities of the carbonic acid of coal mines, have been comparatively little attended to, as its destroying powers have not operated extensively.

The nature and composition of the carburetted hydrogen have closely engaged the attention of philosophers for the last ten years.

According to the best authorities, these gases are of the following specific gravity and weight.

	Spec. Grav.	Weight of 100 Cubic Inches.
Carbonic acid -	1.518	46.313
Carburetted hydrogen	0.555	16.99
Hydrogen - -	0.074	2.230

The common air being reckoned unity, the temperature at 60°, and barometer at 30 inches.

According to Dr. Thompson, the component parts of carburetted hydrogen are,

Carbon - - - -	72
Hydrogen - - - -	28
	100

In which there is always a mixture of carbonic acid.

It has been found that this gas has its greatest explosive power when it is mixed in the proportion of one part of gas to eight parts of atmospheric air; and when it is in the proportion of one part to fifteen of atmospheric air, a candle burns in it without explosion, but the flame is greatly elongated; it therefore ought to be diluted with common air considerably beyond that proportion, to insure the safety of the workmen.

Various theories have been brought forward regarding the formation of these gases, but more particularly of the carburetted hydrogen: both of them flow or exude from the cutters, fissures, and minute pores of the coal; and when in small quantity in the forehead of a mine in solid coal, they make a hissing noise.

The carbonic acid seldom comes off very suddenly in large quantities. From its weight it is not liable to a sudden change of place, and though it is invisible, its line of division from the common atmospheric air is most distinctly found by approaching it with a lighted candle or lamp; for though the candle burns with its ordinary brightness at the distance of three inches from the carbonic acid, the instant it is placed within this air, it is suddenly extinguished; it produces the same instant effect upon the strongest flame of coals; sometimes the upper part of the mine next the roof has the air perfectly good, while the pavement has a stratum of carbonic acid, of a foot or two in thickness, resting upon it. If a coal has a considerable dip and rise, this gas will be found occupying the lower parts of the mine, of a wedge form, as represented Fig. 5. Plate CCCXCIII. where *a* is the carbonic acid, and *b* the common air. When this gas is agitated by a current of common air, or by falls from the roof, it mixes with the mass of common air, and affects the candle by gradually diminishing the flame; and when a stronger portion of the mixture is entered into, the candle is extinguished, but not in the very sudden manner as before mentioned.

When a mine or forehead is driving in advance of the other workings, and a discharge of this air takes place, it very soon fills the whole mine, if the direction of the mine is in the line of level, and the mine is rendered unworkable until a supply of fresh air is brought to displace it.

As the flame of a candle is a correct index of the presence of this air, the miners have instant warning, and stop their advancing any farther, till means are used to drive it away. Comparatively few lives have been lost by this gas. Those who have perished from its effects, had generally gone amongst it without a candle, and of course were insensible of its presence, till they dropped down from its deleterious effects on the constitution. When men are rendered senseless by inhaling this air, they can be recovered, if brought quickly into good air, but if they remain any time in it, all attempts to recover them are ineffectual. It must be remarked, however, that as the air of these coal mines, which abound with carbonic acid, has always a very considerable mixture of it through the whole of the works, the air in this state is reckoned very salubrious, though mixed with a great proportion of moisture. The workmen who breathe it every day are generally healthy, and it is reckoned a specific in some complaints, it being a common practice to send down children affected with the hooping cough to breathe in it.

The carburetted hydrogen is not found in all coal mines, and is seldom seen where the carbonic acid abounds. It has hitherto been found in the greatest quantity in the coal mines situated in the counties of Northumberland, Durham, Cumberland, Staffordshire, and Shropshire. And from investigation we find, that it is generally much more abundant in coals which are of a fine caking quality, and which have a bright steel grained fracture, than in cubic coals of an open burning kind, and the cubic open burning coals yield spontaneously in general more of this gas than the splint coals. To these general cases there are, however, exceptions, some of them very remarkable; a few of which we shall now notice.

In the coal-fields of England and Wales, there are districts where this gas abounds, and other districts where it is never seen; not only so, but in some extended coal fields it will be found very abundant upon one range of the line of bearing, whereas upon the other range none of it is to be seen, but abundance of carbonic acid.

In Scotland the same general remarks are applicable, there being extensive districts where the inflammable air was never seen, and others where it is very abundant. In the numerous collieries situated upon the north banks of the river Forth, it is only found in one very limited district, and in only two districts upon the south banks of the Forth. In the very extensive coal-fields in the Lothians, south from the city of Edinburgh, it is unknown: whereas in the coal-fields around the city of Glasgow, and along the coast of Ayr, it is found very abundant; at the same time there are coal-fields in that very extensive range, where it never was seen; but where it is not seen, the carbonic acid abounds, as before mentioned.

It has been stated by some, that this gas has only been found in mines which are wrought under the level of the sea; it is admitted that it has been found most abundant in such cases, but it abounds also in districts much elevated above that level.

This air is either formed with the coal, or generated afterwards, according to the opinions of different philosophers. One thing is certain, that as soon as a coal containing this air is wrought, the air exudes from every pore with a hissing sound; if the coal is of close texture, and when a cutter or open fissure is struck, it comes off not only quickly, but with immense force, and with a noise similar to the issuing of steam from the safety valve of an engine boiler. This violent issue of gas is named a blower; and if by accident it is ignited, its force is such, that it will act like an immense blow pipe, and set on fire the coal upon the opposite side of the mine, and also at the mouth of the blower. And there have been instances, where, in working a bed of coal under another coal, with seven feet of argillaceous strata betwixt them, and when the upper coal abounded with inflammable air, this gas, from its elasticity, forced down the stratum seven feet thick, although the mine was only four feet in width. These facts clearly prove that this gas abounds in coal, in a state highly compressed, and consequently very elastic. From this cause it is generally found that the coals abounding with this gas are the easiest to work.

It frequently happens that cutters and fissures in the sand-stone, and other accompanying strata of coal, yield this gas in great quantity; but it is never once doubted but that all this gas flows directly from beds of coal. It has likewise been found uniformly in the practice of mining, that in most cases this gas abounds in uncommon quantity, when the miners approach a great dislocation or slip of the strata, and the fissure of the dislocation yields not only the gas in great quantity, but the issue will continue for years, and sometimes during the whole working of the colliery. This circumstance is easily accounted for, because these dislocations extend from the surface of the rock, to depths hitherto impenetrable. Hence a dislocation with an open fissure connects together every bed of coal to the greatest depth, and gives vent to the inflammable air of each, like a train connecting a number of magazines of inflammable matter together; whereas in the common fair lying coal-field, each body of coal is insulated from the other coals by strata which are frequently impervious both to air and to water. There are instances of coal-fields, where, in working the coals in various beds, a particle of this gas was never seen; yet, upon striking a slip or dislocation, it immediately issued, though seldom in such instances in any great quantity.

It is farther to be remarked, that this gas is not only found formed, and pent up in the cavities and fissures of the coal from which it flows freely, when these cavities and fissures are opened, but it appears to exist also in the minute and invisible pores of the compact body of the coal, especially in the caking coals, which have a bright steel grained fracture; besides which, it is chemically combined with the substance of the coal, which circumstances account, in some degree, for its constant formation in particular cases. In proof of which, we have to state, that after coals of the above description have been exposed above ground to the action of the atmospheric air, if a quantity of them are pounded under water, gas will escape in considerable quantity; which gas is the carburetted hydrogen. A singular circumstance has also occurred within these few years; when loading vessels with these coals, newly wrought, and allowing them to fall into the vessels from a considerable height, gas has been produced in such quantity, that after the hatches were secured, and the ships ready to proceed to sea, the gas has ignited at a candle, scorching the seamen, blowing up the decks, and greatly injuring the vessels.

When pillars of coal are forming below ground, for the support of the superincumbent strata, much gas flows from the fore heads of the boards or rooms; but as soon as the pillars are formed, or the mass of coal insulated from the main body of the whole wall, the issue of gas from the pillars almost instantly ceases; but when, by misfortune, a creep or crush comes upon the pillars by the enormous pressure of the strata, a great flow of gas is produced from the pillars into the waste, an effect which may be compared to the squeezing of water from a sponge.

The gas which exists in the coal in chemical combination, can only be driven off by actual burning in a common fire, or by distillation, to which a high degree of heat is applied, as in the manufacture of gas light.

All caking and open burning coals contain this gas in very great quantity, yet there are very singular anomalies regarding its combination with them. From what is before stated, the fine caking coals yield this gas in greatest quantity in the course of mining; but when exposed to the air it retains the gas in larger proportion than the other kinds of coal, yet on distillation, it yields less gas from a given weight of coal. On the other hand, the open burning coals, which generally yield much less gas in mining, when exposed to the air lose a great proportion of it, so much so, that after a twelvemonth's exposure they burn in a common fire-place with a dull flame, termed dead burning; and, in place of forming a good coke or cinder, produce a great quantity of ashes; yet these open burning coals, if kindled when wet from the mine, burn with a bright vigorous flame, an intense heat, and form a good coke or cinder. The pitch coal, known by the names of bottle, parrot, or cannel coal, yields little, if any, of this gas in mining, whereas in distillation it gives a much greater produce than any other of the coals, and is, on this account, greatly preferred in the manufacture of gas light. This gas being lighter than common air, always ascends to the roof or to the rise parts of the colliery, and where the dip is considerable, occupies the forehead of the mine in a wedge form, as represented Fig. 16. Plate CCCXCIII. Where *a* is the inflammable air, and *b* the common air, in this case a candle will burn without danger, near the point *c*, next the roof, whereas, if it is advanced a few feet farther, an explosion will instantly take place, it being well known, that at the line where the two airs are in contact, they mix and form a fringe of air highly explodeable.

When this gas abounds in the mines, and is mixed in great proportion with the common air, the workmen breathe it without suffering any inconvenience at the time, and although they work amongst it for a succession of years, their health does not appear to be affected by it; but if a miner enters amongst pure carburetted hydrogen, the instant he takes one inhalation he drops down as if shot, and the whole living principles are completely and instantly suspended; those who have seen such an accident take place, were greatly astonished at its instantaneous operation on the animal economy. Persons who suffer from these deleterious effects are recovered, if carried immediately into good air.

As to the formation of these gases in coal, many theories have been brought forward, but none of the conclusions are quite satisfactory.

It is the opinion of many, that the iron pyrites, which abounds so much in many coals, is the cause of the formation of carburetted hydrogen. The objection to this opinion is, that atmospheric air is not found issuing from the coal, and when the coal is opened up by mining, the pyrites is found in its natural state without any marks of decomposition.

That the hydrogen abounds already formed in the coal, is proved by this fact; it frequently happens, when searching for coal by boring, that the instant the boring-iron perforated the coal, the gas came off in great quantity, and continued to do so for a long period. These issues of gas from a bore-hole, have been ignited, and kept burning for months.

The production of these gases, renders the system of the ventilation of coal mines, a chief point in the system of mining, particularly where the inflammable air abounds, by which the lives of the workmen and the prosperity of the mining concern may be instantly destroyed.

It would require a long dissertation, and the most minute detail, to give a clear view of the almost infinite variety of cases connected with the accumulation of inflammable air in the mines of a colliery, and of the plans and methods which have to be employed and varied for the ventilation, corresponding to each particular situation of the mines, the workings of which may be either upon a very extended, or very limited scale; nothing short of a long tried experience is equal to the task. The safety of the workmen depends in a great degree upon the skill of the mining engineer who conducts the work. A high responsibility is attached to the charge; and there cannot be greater presumption than for any man, however intelligent and active regarding mining concerns, where there is no inflammable air, to undertake the management of a colliery infested with it; unless he has been regularly trained to the business, and has, in the course of that practical education, seen "the service" in all its intricate varieties. We shall endeavour to explain, in a manner as concise as possible, a few of the general plans of ventilation, beginning with the most simple, and going on progressively to the most intricate.

The least dangerous gas, and the most simple to manage by ventilation, is the carbonic acid.

In many instances, the ventilation of such mines, particularly where the depth is not great, is conducted with very little trouble, the practice being to work them with a number of pits sunk in succession. When an engine pit is sunk to the coal in the manner before described, the only difficulty is to convey air to the second pit from the bottom of the engine pit, which is effected in several ways.

If an air-pipe has been carried down the engine pit for ventilation while sinking, additional pipes are connected with the upright pipe, and laid along the pavement, or are attached to one of the corners of the mine next the roof. These pipes are lengthened as the mine proceeds; by which means the air at the forehead is drawn up the pipes, and its place is supplied by atmospheric air, which descends the shaft in a constant equal current, which is regulated by the draught of the furnace at the pit mouth. This operation is continued until the miners cut through upon the second pit, when the air pipes are no longer of any use; for it is a fact well known, that the instant such communication is made, as represened in Plate CCCXCIII. Fig. 6 the air spontaneously descends the engine pit A, and passing through the mine *a*, ascends in a constant current up the second pit B. The air in descending A is of the temperature of the atmosphere, and in winter will freeze water from the top to the bottom of the pit; but its temperature is increased in passing through the mine, and ascends the shaft B at a temperature greatly increased. When pits are of unequal depth, as represented in the Figure, the current of air is very uniform, and in one direction. If the second pit was of the same depth, and the bottom and mouth of each in the same level plane, the air would not remain stagnant, as in an inverted syphon filled with water, but would of its own accord circulate down one pit and up another, not regularly in one direction, but would sometimes circulate the one way and sometimes the other, according to the changes of temperature at the surface, modified by calms and strong winds. There is in coal mines an internal heat, which, from the experiments we have made, varies from the common average temperature of air, and springs of water at the surface of the earth, to a temperature of 77° of Fahrenheit. There are cases, where pits are sunk, and communications made, without a circulation being produced either by pipes or ventilation tubes; and if at any time the air became dull at the forehead, it was invigorated by pouring a few puncheons of water from the pit mouth down the pit. If this was not successful, there is a simple plan of carrying air from the pit bottom to the forehead of the mine, by cutting a ragglin or trumpetting, as it is termed, in the side of the mine, as represented in Plate CCCXCIII. Fig. 7. where A is a mine in the coal, and B the ragglin, which is from 15 to 18 inches square. The coal serves as three sides of an air pipe. The fourth side next the mine, is covered with thin deals made air tight, and nailed to small props of wood fixed betwixt the top and bottom of the lips of the ragglin. This is a mode very generally practised in running mines of communication, and dip-head level mines, where carbonic acid abounds, or when air is liable to become stagnant, and difficult for the support of the light by which the miner works.

When a circulation is not effected by the ragglin or air pipes, which proceed from the volume of fresh air at the bottom of the pit, the air is sometimes impelled through them, by means of ventilating fanners, the tube from which is placed at the pit bottom, and the vanes or leaves of the fanners are impelled with great velocity by means of a wheel and pinion wrought by the hand. In other cases, large bellows, similar to those used by smiths, with a very wide nozzle, are applied in the same manner as the fanners. These methods are only used as a temporary resource, when the mines have not to be carried to any great distance. The circulation thus produced by propelling, in place of educting the air, is very faint, and the pulses feeble. Trials have been made with the bellows, by inverting their common mode of action; that is, by attaching the air pipe to their under valve. By this plan the air is educted, and blown out or discharged at the nozzle. We conceive this plan would be very suitable for sinking shallow pits or wells, where there was no great accumulation of carbonic acid. The application of the ventilating fanners in the same manner, we presume, in many cases would be an improvement, from the great obstacles presented against the propelling of air through pipes, although a very strong force is applied.

Another of the simple methods pursued in ventilating mines which are level free, and where this gas abounds, is to allow a small quantity of water at the pit head, to fall freely down a pipe of a foot or eighteen inches diameter. This water carries down an astonishing quantity of air with it, and the water and air falling into a cistern at the bottom of the pit, the air separates from the water, and is by its accumulation and elasticity propelled along the pipes below ground to the forehead, or is allowed to diffuse itself freely along the mines, and through the workings of the pit.

Ventilation is also produced in collieries upon a small scale, by placing a horizontal funnel at the top of air pipes elevated a considerable height above the pit mouth. The funnel turns round upon a pivot, by means of a tail-piece moved by the wind, so as to present the mouth of the funnel always to receive the wind; or a circulation is produced by having fires of coal in iron grates, either at the bottom of an upcast pit, or suspended by a chain some fathoms down; and we have seen on an emergency, when there was a breeze of wind, a ventilation produced by placing an awning of canvas in a perpendicular direction, and in a semicircular form around the lee-side of the pit mouth; the canvas being suspended on temporary uprights of wood.

These are the ordinary methods generally practised in collieries of a moderate depth, where carbonic acid abounds, or where there is an absolute want of air. In such cases the circulation of air through the wastes, and along the wall faces, is very easily managed, and with very little expence the air descending the engine-pit, and ascending one to the rise.

In all coal-mines the circulation of air is regulated, as to its line of direction, by double doors, named main-doors or bearing doors. They act as air-valves, and cut off a current of air, going in one direction, from joining or mixing with a current of air proceeding in another. These doors are placed upon the main roads and passages in the mine, and are of great importance in ventilation. Their mode of operation is represented in Plate CCCXCIII. Fig. 8. where A is the downcast, B the upcast pit, sunk towards the rise of the coal, and C the dip-head level. If in this case the mines were wrought without any attention being paid to the circulation of the air, it would descend the pit A, and proceed in a direcline up the rise-mine to the pit B, where it would ascend; the consequence would be, that all the mines and boards to the dip of the pit A, and lying on each side of the pits, would have no circulation of air, or would be laid dead, as it is termed. To obviate this, double doors are placed in three of the mines adjoining the pit, viz. at *a* and *b*, *c* and *d*, *e* and *f*; all of which open inwards to the pit A. By this arrangement the air being prevented from passing directly from the pit A to the pit B, by the doors *a* and *b*, it would have taken the next and nearest direction by *c*, *d*, and *e*, *f*; but the doors in these mines prevent this, it therefore must proceed downwards to the dip-head level, where it will spread or divide, one portion taking a course to the right, the other to the left. Upon arriving at the boards *g* and *h*, it would naturally have ascended by them; but this is prevented by a building or stopping placed at *g* and *h*. By means of these stoppings placed in the boards next the dip-head level, the air can be carried to the right or left hand for miles, if necessary, providing there is a train or circle of communication of air from the pit A to B. Suppose the boards *i* and *k* are open, the air will ascend them, as shewn by the arrows; and, after being diffused through the workings, will again meet in a body at *a*, and ascend the mine to the pit B, having combined with it the deleterious air which it found in its passage. Without double doors on each main passage, the regular circulation of the air would be constantly interrupted and deranged; for example, suppose the door *c* removed, and only *d* remaining in the left-hand mine, all the other doors remaining as they are, it is evident that the instant the door *d* is opened, the air finding a more direct passage in that direction, would ascend by the nearest course *l*, to the pit B, and lay dead all the other parts of the work, there being no longer any circulation. As the passages upon which the doors are placed are the chief roads by which the workmen pass and re-pass to their work; and as the corves are also constantly passing from morning to night, a single door, such as *d*, would be so often shut and opened, that the ventilation would be rendered very languid. The double doors completely correct this fault; for when men, or horses with loaded corves, are proceeding to the pit bottom A, the door *d* is opened, and as soon as they pass, it is shut, so that they are in quiet or still air, contained betwixt the doors *d* and *c*, as *c* prevented the air from changing its course while *d* was open; when *d* is thus shut, the door *c* is opened, when the men and horses pass on to the pit bottom at A, the door *d* preventing any change in the circulation; while the door *c* is open; the men and horses, in returning from the pit, observe the same rule, first opening the door next them, then shutting it before they open and pass the other. By understanding this mode of separating and disjoining air courses from each other, the continuance of this separation in a working of any extent, will be easily comprehended. When carbonic acid abounds, or when the carburretted hydrogen is in very small quantity, the air is conducted from the pit to the dip-head level, and, by placing stoppings in the off-break of each room next the level, it is carried to any distance along the dip-head levels; and the farthest room on each side being left open, the air is allowed to diffuse itself through the wastes along the wall faces, and to ascend the upcast pit, as represented in Fig. 13. Plate CCCXCI.; but if it should happpen that the air becomes stagnant along the wall faces, stoppings are put up through the workings in such a manner as to direct the main body of fresh air to pass along the wall faces for the workmen, while a partial portion of the air is allowed to pass through the stoppings to prevent any accumulation of bad air in the wastes. In such cases as have been mentioned, the stoppings are made in a very superficial manner, with stones and rubbish, and frequently with rubbish alone, there being no danger from an explosion taking place.

The mode of ventilation thus described is very simple, and the consequences of any inattention or mistake, are generally not of a very alarming nature, nor fatal to the workmen, or very injurious to the interest of the concern. But where the inflammable air abounds, as in many of the districts in England, particularly in the counties of Northumberland, Durham, and Cumberland, a very different field of action is presented to the mining engineer. There a host of difficulties attend him at every step, from the moment he breaks the ground for the fitting, or winning of a colliery, to the day in which the last corve of coals ascends the pit. Water, mud, and quick-sands oppose his progress in passing through the alluvial cover; and in the rock strata, beds of stone yielding vast quantities of water, have to be stopped by cribbing or tubbing, and frequently much inflammable air issues from the cutters of the rock and beds of coal, which has to be attended to and carried off for the safety of the workmen; and no sooner is the coal gained at the pit bottom, which is the great object of all his labours, than an immediate and most careful attention is required, to secure a circulation of air, there being instances where the workmen dare not advance even six feet into the whole wall, or solid coal, without having the circulation of fresh air brought within three feet of the fore head where he works. When this is considered, and when it is known that, in practice, the air is carried for many miles in regular labyrinths, through the wastes, and along the distant and widely-extended wall-faces, where every room requires its ventilation to be attended to; and as upon the correct ventilation the lives of the workmen and prosperity of the mining concern depend, some faint idea may be formed of the important and arduous duty of the mining engineers in these districts, and of the severe application of mind, and laborious toil they incessantly undergo, and patiently endure.

The chief and general plan practised by these engineers, in those very deep and extensive collieries, to produce circulation, is by means of rarifying the air at the upcast shaft, by a very large furnace placed either at the top or bottom of that shaft. The latter is the best, and generally preferred.

Another method is by exhaustion, effected by an immense air pump, wrought by machinery; and, in extreme cases, the cascade, or water-fall, is resorted to.

When the furnace is placed at the top of a pit, it is constructed according to what is represented in Fig. 3. Plate CCCXCI. When it is placed upon a single pit, or upon one of the divisions of a pit, the pit which is thus to be the upcast is made air tight at top, by placing strong buntons, or beams across it, at any convenient distance from the mouth; upon which buntons a close scaffolding of plank is laid, and, for farther securing its being air tight, it is moated over with well-wrought plastic clay. At a little distance below the scaffold, a passage is previously cut, either in a sloping direction, to connect the current of air with the furnace, or it is run horizontally, and communicates with the furnace by a perpendicular opening. If there be any obstacle to the placing of the scaffold down in the pit, the pit can be made air-tight at top, and an air tube of brick carried along the surface to the furnace. These furnaces are made of a size corresponding to the extent of ventilation to be carried on, and the chimneys are constructed either round or square, from 50 to 100 feet in height, having an inside diameter of from 5 to 9 feet at bottom, and tapering to 2 feet 6 inches or to 3 feet diameter at the top, proportioned to the height and diameter at bottom. These chimneys, having so great a taper, require only to be 9 inches thick, or one brick in length, excepting a lining at the bottom of fire brick, where the heat of the furnace acts with force.

Although these furnaces placed at the surface are still used, yet they are in a great degree superseded by the more effectual plan of placing a furnace at the bottom of the pit, which is much more effectual than the former, for this reason, that the shaft through which the air ascends to the furnace at the top of the pit, is always at the ordinary temperature; from which cause, the instant the furnace is not attended to, and allowed to grow languid, the circulation of air through the mines grows languid in a corresponding degree, and consequently dangerous, whereas, when the furnace is placed at the bottom of the pit, the shaft is heated through its whole length; the consequence of which is, that although the furnace should be neglected, and grow languid, and although the fire in it be quite extinguished for a considerable time, the circulation will continue to be good, as the air in the upcast pit is rarified by the heat remaining in the shaft walls. When furnaces were first placed at the bottom of the pits, or at a little distance under the roof of the coal, the smoke which proceeded from them, and the air highly heated, rendered it impossible for the onsetters to work there. The consequence of which was, the pit in this case was of no use for drawing coals. Of late, this fault has been obviated, by adopting an improved plan, as represented, Fig. 9. Plate CCCXCIII. where *a* is the lower part of the upcast shaft; *b* the furnace built of brick, arched at top, and the sides insulated or built clear of the solid coal in which it is placed. Betwixt the sides of the furnace wall and the coal, a small current of air constantly passes to the shaft, to prevent the coal taking fire. The furnace is wide, and open in front, that the air may have a free passage over the burning coals; and the coals burn upon furnace bars, having an ash pit below them similar to the construction of furnaces used for engine boilers. The furnace is placed at any convenient distance from the pit bottom, such as forty yards. From the end of the furnace a mine is cut in a rising direction at *c*, and communicates with the shaft at *d*, at the distance of from 6 to 10 fathoms from the bottom of the pit. By this excellent arrangement, the furnace and furnace-keeper are completely disjointed from the pit. The pit bottom is not only free from all incumbrances, but is cool and temperate; and the shaft is at the same time as serviceable as any other for the drawing of coals. As the heated and vitiated air, with the smoke, are not only very unpleasant and troublesome to the banksmen, who work close to the pit mouth; but as much machinery is so frequently employed at a Newcastle pit having three or four divisions, with frequently one or two large water-drawing engines, with two coal-drawing engines, these, closely grouped together around a narrow pit mouth, not only greatly obstruct the ascending and descending currents of air, but the force of high winds has often had the effect of beating down the ascending current of air, and throwing the whole circulation below ground into a languid, dead, and dangerous state. To obviate this, the following plans have been successfully adopted, as shewn in Fig. 10, which represents the top of a Newcastle coal pit. *a* the upcast shaft, with the furnace at bottom; *b* the downcast shaft, by which the fresh atmospheric air descends; *d* the brattice carried above the pit mouth. At a little distance below the settle boards, a mine *c* is carried to communicate with the surface from the downcast shaft, over which a brick tube or chimney is built from 60 to 80 feet high, from 6 to 8 feet diameter at bottom, and from 3 to 5 feet diameter at top. Upon the top of this chimney a funnel, made of deal, is placed in a horizontal direction, which turns easily round, being hung upon a pivot. The vane *f*, made also of deal, keeps the mouth always opposite to the direction of the wind. An arrangement, exactly similar in every respect, is made at the upcast shaft *a*, with this difference, that the funnel is constructed to turn its mouth in the direction of the wind. From an inspection of the Figure, the effect of this arrangement will be seen, so that a high wind rather aids than injures the ventilation.

The principle of ventilation being thus obtained, the next plan in opening up a colliery, and in driving all advance mines whatever, is the *double mine*, or *double headways course*, upon the simple yet very ingenious principles of which, the circulation of air and ventilation depend at the opening of a colliery.

The double headways course is represented in Plate CCCXCIII. Fig. 11. where *a* is the one heading or mine, and *b* the other. The heading *a* is immediately connected with the upcast side of the pit *c*, and the heading *b* is connected with the downcast side of the pit *d*. The pit is rendered completely air-tight by the division made of deals from top to bottom, named a brattice wall, so that no air can pass through the brattice from *d* to *c*. and the communication betwixt the two currents of air is completely cut off by a stopping betwixt the pit bottom and the end of the first pillar; the pillar or walls of coal, marked *e*, are named stenting walls; and the openings betwixt them are named walls, or thirlings, the arrows show the direction of the air. The headings *a* and *b* are generally made about 9 feet in width, the stenting walls 6 or 8 yards in thickness, and holed or thirled at such a distance as is found most suitable for the state in which the air is. The width of the thirlings is 5 feet. When the headings are set off from the pit bottom, an opening is left in the brattice at the end of the pillar next the pit, through which the circulation betwixt the upcast and downcast pits is carried on; but as soon as the workmen cut through the first thirling, No. 1, the opening in the brattice at the pit bottom is shut, by which means the air is instantly drawn by the power of the upcast shaft through that thirling, as represented by the dotted arrow: this evidently brings a direct stream of fresh air close to the forehead where the workmen are. They then proceed with the two headings *a* and *b*; and as soon as they cut through the thirling No. 2, a wall of brick and lime, four and a half inches thick, is built across the thirling No. 1, which building is named a stopping; this, being air-tight, forces the whole circulation through the thirling No. 2. In this manner the air is carried forward, and circulated always by the last made thirling nearest the forehead, care being taken the instant a new thirling is made, that the last thirling through which the air was circulating be secured with an air-tight stopping. In the figure, the stoppings are placed in the thirlings No. 1, 2, 3, 4, 5, 6, and consequently the whole circulation passes through the thirling No. 7, which is the nearest to the foreheads of the headings *a*, *b*. From an inspection of this figure it is evident, that by this very simple plan a circulation of air may be carried to any distance, and in any direction, however various; for instance, if, while the double headways course *a b* is going forward, other double headways courses are required to be carried on at the same time on both sides of the first headway, the same general principles have only to be attended to, as shewn in Fig. 12. where *a* is the upcast, and *b* the downcast pit. The air proceeds along the heading *c*, but is prevented from proceeding farther in that direction than the pillar *d*, where it is obstructed by the double doors at *e*, it therefore proceeds in the direction of the arrows to the foreheads at *f*, and passing through the last thirling made there, returns to the opposite side of the double doors, then ascends the heading *g* to the foreheads at *h*, passes through the last made thirling there, and descends the heading *i*, until it is interrupted by the double doors at *k*, the air then passes along the heading *l* to the foreheads at *m*, returns by the last made thirling there, along the heading *n*, and lastly descends the heading *o*, and ascends the upcast pit *a*, mixed with all the impurities which it met with during its circulation: this figure or diagram is an epitome of the mode by which collieries of the greatest extent are wrought. The air courses in some are from 30 to 40 miles in length, so that when the circulation of air is conducted by means of a pit divided by a brattice wall only a few inches thick, the air which is descending the downcast on one side of the brattice, at six o'clock in the morning, has to circulate through a course of perhaps 35 miles, and at six o'clock at night is only ascending by the other side of the brattice, a division only about seven inches in thickness. From this description of the system of ventilation of coal mines, it is evident that the furnaces which are the immediate cause of the circulation, require to be most particularly attended to, and kept in constant regular action night and day, and from year to year, during the existence of the colliery; any inattention to this duty, stagnates the circulation, and places in extreme hazard the lives of the workmen and the welfare of the colliery. Upon considering the principles explained in these figures, it is evident, that if any number of boards are set off from any side of these mines, either in a level, dip, or rise direction, the circulation may be extended to each forehead, upon the principle of an ingoing current to each, and a returning current from the same.

It requires particularly to be noticed, that although the circulation of fresh air is thus carried forward to the last made thirling next the foreheads *f*, *h*, and *m*, Fig. 12. and circulates through the thirling which is nearest to the face of every board and room, the discharge of inflammable air is frequently so great from the solid coal, that the miners dare not proceed onwards above a few feet from the current of fresh air, without the danger of being burnt from the gas igniting at their candles. To secure against this accident, temporary shifting brattices are used. They are made of deal about three quarters of an inch thick, from three to four feet broad, and about ten feet long, with cross bars for binding the deals together, and a few finger loops cut through them for the more expeditiously lifting and placing them in exact position. Every colliery, where inflammable air abounds, has a number of those brattices ready for service, and a great store of brattice deals for emergencies, when an explosion unfortunately takes place.

The manner of applying the temporary brattices is represented in Fig. 13. where the air circulates freely through the thirling *a* before the brattices are placed. *b* and *c* are two headings, boards, or rooms, which are so full of inflammable air as to be unworkable. Props are placed near the upper end of the pillar *c*, betwixt the roof and pavement, and about two feet clear of the sides of the next pillar, so that the miner can pass along betwixt the pillar side and the brattice. The brattices are then fixed with nails to the props, and while the lower edge of the one brattice rests on the pavement, the upper edge of the upper brattice is in contact with the roof, by which means any variation of the height in the bed of coal is compensated by the overlap of the brattices; and as the boards advance, shifting brattices are laid close to and along side of the first set. The miner sets additional props in the same parallel line with the former, and slides the brattices forward, in order that the air may circulate close to the forehead where he is at work, the distance betwixt the brattice and the forehead being regulated by the issue of inflammable gas and the velocity of the circulation of the air—*d d* are the props, and *f* the brattices. By this arrangement the air is prevented from passing directly through the thirling *a*, and is forced along the right-hand side of the brattice, and sweeping the wall-face, or forehead, returns by the back of the brattice, then passes through the thirling *a*; but is prevented from returning in its former direction by the brattice placed in the forehead *c*, by which it ascends, and makes the return close to that forehead. In this manner headways and boards are ventilated, until another thirling is made at the upper part of the pillar, when the thirling *a* is closed by a brick stopping, and the brattices removed and carried forward for a similar operation.

If a blind pit or stapple has to be sunk from one coal to another, or to regain a coal upon the other side of a slip, the ingoing current of air must be carried to the side of the pit, and conducted down one side of a brattice, which is lengthened progressively as the pit grows deeper, and the circulation or return air passes up the other side of the pit, by which the rubbish is drawn up, the brattice is carried down close to the pavement, after which the coal is opened up with double headways courses in the manner as before described.

Sometimes pits have to be mined upwards, in which case the inflammable air, from its specific lightness, keeps always about the heads of the workmen. The circulation is produced in this case by a brattice carried up the shaft to produce a current of ingoing and returning air, exactly the inverse of the above.

When blowers occur in the roof, and force down the strata, so as to produce a large vaulted cavity, it is necessary to sweep away the accumulated gas, which would not only lodge in the cavity, but would descend in an undiluted state under the common roof of the coal. The mode of doing this is represented, (Plate CCCXCIII.

Fig. 14. where *a* is the bed of coal, *b* the blower, *c* the cavity formed by the falling of the roof strata, *d* is a passing door, and *e* the brattice; by this plan the current of air is carried close to the roof, and constantly sweeps away and dilutes the inflammable air of the blower as fast as it issues. The arrows show the direction of the current; were it not for this direction of the ventilation, the accumulated gas would mix with the current of common air, and produce an explodeable mixture. The gas issuing from blowers is sometimes conducted in pipes into other air courses, where the air is returning to the upcast shaft, which prevents it troubling the miners, by contaminating the ingoing air.

There is another plan in the system of ventilation, which is, the crossing of air-courses, that is, when in the progress of ventilating a colliery, one air-course is brought forward at right angles to another, and has to pass it, in order to produce ventilation in works upon the other side. This is effected in the manner represented in Fig. 15. where *a* is a main road with an air-course, over which the other air-course *b* is to pass. The sides of the air-course is built with bricks, arched over and made air-tight, and a mine is driven in the roof strata, as represented in the Figure. In some cases, the roof of the air-course *a* is laid over with plank made air-tight; by this method, air-courses can be made to cross and recross each other with great facility. It has been found, from the practice of the most eminent engineers, that these air-courses, thus contracted, should be in general six feet, or at least five feet on the side, that is, the area to be 36, or at least 25 square feet, and that the general velocity of the current of air through the works should be from three to four feet per second, or about 2½ miles per hour.

Another method has also been brought forward for rarefying the air in the upcast shaft, by means of steam produced from a large boiler, such as is used for steam engines. The steam from the boiler is conducted in deal tubes, in preference to iron pipes, on account of deal being a very slow conductor of heat; these pipes are carried at least half way down the pit, and the intention is, that the steam be made to issue from the lower end of the tube as hot as possible. The steam, immediately on coming in contact with the air, is condensed. The caloric or latent heat is disengaged, heats the air in the shaft, and produces a constant ascending current, while the condensed steam falls in a shower to the pit bottom. This mode of producing an ascending current of air has not the energy of the common furnace; and although it allows the upcast shaft to be used as a pit for drawing coals, the dropping of the condensed steam keeps the shaft walls wet, which is not only uncomfortable, but in some degree counteracts the power of the rarefying process.

It has frequently been suggested by men of science, and by mining engineers, that ventilation might be produced, both strong and effective, by propelling a current of air down a shaft by means of large iron cylinder bellows wrought by powerful machinery. From every experiment yet made, this appears to be the least effective of all the plans of ventilation.

It is well known, that when the least advance is made towards forming a vacuum, the remaining part of the air, instantly acting by its great elasticity, produces an equilibrium through the mass of air. It is this principle, brought into constant action by means of heat applied to the ascending current of air, that the before-mentioned systems of ventilation act.

An exhausting machine, which may be termed a Hydraulic Air Pump, has been applied to the ventilation of mines of a moderate extent, and where there was no dangerous quantity of inflammable air. It is the invention Mr. John Taylor of Tavistock, in the county of Devon, and has been applied with complete success. The construction is very simple, has very little friction, and shows the ingenuity of the inventor. It is represented in Fig. 1. Plate CCCXCIV. where *a* is a large cistern, nearly filled with water, made of wooden staves, hooped with iron, circular, and from six to eight feet in depth. Through the bottom of this vessel a pipe *b* passes from the mine to be ventilated, and passing up through the water, is carried about a foot above it. Upon the top of this pipe is an air-tight valve, opening upwards. Over this pipe, and within the sides of the cistern, a cylinder of plate iron is placed, open at the bottom, but close at the top, in which top an air-tight valve is placed, also opening upwards. This iron cylinder is made to move in a vertical direction, by guides or sliders, and its upper end is attached to a lever, which is moved, either by a water-wheel or a steam engine. When the cylinder descends, the value *c* at the top of the pipe shuts, and the air contained in the cylinder opens the valve *d* in the cylinder top, and escapes, but the instant the cylinder ascends the valve *d* shuts, and the valve *c* opens, by which means a quantity of air, equal to the contents of the cylinder above the surface of the water, is drawn from the mine through the pipe *b*. This repeated exhaustion causes a regular circulation of air through the mine, to supply the circulating current produced by the working of the machine. An exhausting machine of this construction may be made, from the smallest size to be wrought by the hand, to any requisite size to be moved by machinery.

These are the general plans which have been put in practice for the ventilation of collieries with success.

The ventilation of coal-mines, where inflammable air abounded, was conducted on the old principle of ventilating only the foreheads and wall-faces, where the men were at work, until the year 1760. The consequence of which was, that the process being irregular and uncertain in its operation, the accidents from explosions were frequent and fatal. To obviate these misfortunes, the ingenious Mr. Charles Spedding, a native of Cumberland, contrived and brought into practice the present system of ventilation, that is, he converted each room, board, or mine, as soon as it was formed, into an air-course; by which means, he not only ventilated the wall-faces where the miners wrought, but also the whole extent of the old wastes. This was a very great and important improvement, and the mining interests of Great Britain have been highly benefited by it. To the memory of Mr. Spedding every tribute of respect is due.

The general system, as to the distribution of the air, after passing down the downcast shaft, is to give the first of it to the stables where the horses are kept, then to the workmen in the foreheads, when the air, loaded with what mixtures it may have received, traverses the old wastes; and, lastly, passing over the furnace with all the inflammable air found in its course, ascends the upcast shaft, and is dissipated in the common air.

Mr. Spedding's system is termed, "coursing the air;"

and, according to the abundance of the inflammable air in the mines, the coursing is either conducted up one room, and returned by the next alternately, through the whole extent of the works; or two or three rooms are connected, so that the air passes up two or three rooms, and returns by the same number alternately, as above mentioned.

The most ingenious system has been greatly improved by the mining engineers of the Newcastle and Whitehaven districts collectively; and, in particular, by Mr. Buddle before mentioned, who, in his report upon the ventilation of coal-mines, has shown, in a very clear and explicit manner, the result of an extensive practice, the manner of applying the system effectually, and of guarding those points when the greatest danger is likely to arise. Several of the following remarks and examples are taken from that report.

The improved system of ventilation upon an extended scale, by which the current of air sweeps every corner of the workings, is represented, Fig. 2. Plate CCCXCIV. where *a* is the downcast, and *b* the upcast shaft. By following the course of the arrows, it will be seen, that the air passes first along the two rooms *c*, *d*, having free access to each through the walls, but is prevented from entering into the adjoining rooms by the stoppings which form the air-courses: it sweeps the wall faces of the rooms *c*, *d*, and makes a return down the rooms *e*, *f*, but is prevented from proceeding farther in that direction, by the stoppings *g*, *h*; it proceeds to the foreheads *i*, *k*, and single courses all the rooms to the foreheads *l*, *m*; at this point it would go directly to the upcast pit *b*, if it were not prevented by the stopping *n*, this throws it again into double coursing the rooms, until it arrives at *o*, when it goes direct to the furnace, and ascends the shaft *b*. The lines across each other, represent the passing doors; and these may be substituted in any place for a passage where there is a stopping. The stopping *p*, near the bottom of the downcast shaft, is termed a main stopping, because, if it was removed, the whole circulation would instantly cease, and the air, in place of traversing in the direction of the arrows, would go directly from the downcast pit *a*, to the upcast pit *b*, along the mine *q*. The consequence of which would be, every mine and room of the workings would be laid *dead*, as it is termed, and be instantly filled with inflammable air, which, if not guarded against, would either fire at the miner's candles, or at the furnace next the upcast pit *b*. In the same manner, a partial stagnation in a district of the colliery, would be produced by any of the common stoppings being removed or destroyed by accident, as the air will in that case always take the nearest course to the upcast pit. Main stoppings are made very secure by strong additional buildings of stone, and they are made at different places, to keep the main air-courses entire, in the event of an explosion,—by means of these many lives have been saved. This system may be extended almost to any distance from the pit bottoms, provided the quantity of fresh air which is circulating can sufficiently dilute the inflammable air which issues from the mines, and keep it under the firing point. In this manner, the air ventilates first one pannel of work, and then others in succession, the air passing from one pannel to another through the barrier or pannel walls, by means of mines, as in Fig. 1. Plate CCCXCII. and may either be single, double, or triple coursing, according to the quantity of gas in the mine.

If several coals are wrought in the same shaft, the ventilation is first completed in one coal, and from thence is carried by means of stapples or blind pits from one coal to another, it always being the study of the mining engineer to give the first of the air to the working foreheads, and that it latterly traverses the old wastes. When, however, the flow of inflammable air is too great, separate ventilations are made for each coal.

In ventilating the very thick coal in Staffordshire, though there is much inflammable air, less care and attention are required than in the north of England collieries, the workings being very roomy, and the air-courses of comparatively small extent. The air is conducted down one pit, carried along the main roads, and distributed into the sides of work, as represented in Plate CCCXCIII. A narrow mine, named the air-head, is carried in the upper part of the coal in the rib walls along one or more of the sides. In this instance it is carried all around, and the air enters at the bolt hole *e*. Lateral openings, named spouts, are made from the air-head mine into the side of work, and the circulating current mixed with the gas in the workings enters by the spouts, as represented by the arrows, and returns by the air-head at *g* to the upcast pit.

When blowers are met with in the first of the air, by which all the gas which issues from a blower is carried along the wall-faces where the men are working, so as to render their situation very dangerous, it is necessary to reverse the course of the air, in order that the issue of gas from the blower shall be diluted by the last of the air, and carried directly to the upcast shaft. This is effected by applying the general principles before laid down, and by removing the stoppings in one place of the air-course, placing others in a counteracting direction, and causing the one current of air to cross the other by an arch, as before mentioned. Sometimes these operations have to be performed at places at a great distance from each other. When this is the case, and the engineer has, from the plan of the colliery, laid down with precision the line of operation to be pursued, the men are divided into parties, each having a person of skill at their head. Their watches are set to one time, and at an appointed minute one set of stoppings is quickly driven down and new ones built up, which have the effect of reversing the current of air without laying any part of the works dead.

When at any time the gas comes off suddenly, and the air becomes foul at the foreheads, ready to explode, if no immediate remedy is found to be effectual, the working of the coal is suspended, and a flow of air is allowed to pass directly from the fresh in-going current, so as to mix with and dilute the air highly charged with gas, before it comes in contact with the furnace. This is termed *skailing the air*, otherwise the gas would ignite at the furnace, and go back like a train of gunpowder through the whole extent of the workings, carrying destruction and devastation in every point of its progress. By skailing the air, time is given for going forward with water, and drowning the furnace, so as to insure safety, until plans are adopted for rendering the ventilation safe. When the furnace is extinguished, and the inflammable air continues to fill the works, the only effectual remedy is the cascade, which is produced by working the steam-engine, which draws the water from the mines, and allowing the whole of the water to fall down the pit, which has such power in a descent of 600 feet in carrying air with it, that it forces a sufficient current through every part of the work. By these means the ventilation is corrected, and again put into its usual train.

In collieries which have been wrought for a considerable time, particularly where there are goaves, creeps, or crushed wastes, the inflammable air is much influenced by the state of the atmosphere. In the above case, when the barometer is low, or about 29°, the gas issues from every crevice of the old works, and incommodes and endangers the miners very much. For this reason, the state of the barometer is examined every morning.

It would require volumes to describe the infinite variety of circumstances connected with the system of ventilation. Where inflammable air abounds, they vary with the state of the atmosphere, the abundance of the gas, and, in a great degree, with the length which the air traverses. All that can be stated here are general principles.

In the manner now described, the ventilation of collieries has been carried on progressively to an astonishing extent from the year 1760, (when Mr. Spedding's important improvement in ventilation was brought forward,) to the year 1815; betwixt these periods, notwithstanding the well ordered regularity and complete system which had been introduced in coal mining, by the mining engineers of Northumberland, Durham, and Cumberland, and also notwithstanding their very active and unwearied attention, living out of the world, and devoted to the hazardous duties of their station, yet, independently of these circumstances, explosions frequently, nay, almost daily, took place, and catastrophes, the most melancholy which have occurred in civil life, were the consequences. Year after year passed away, and every year added greatly to the list of victims carried away by this fatal pestilence. Being in its nature subtle and invisible, and when at the point of ignition still capable of supporting animal life, and flame, it lurks like an assassin, and strikes deadly when least suspected. The elegant and figurative language of the Sacred Scriptures may be most aptly applied to it, as "The pestilence which walketh in darkness, and destruction which wasteth at noon day."

To describe the catastrophe attending an explosion of an extensive coal-mine, would require the pen of an able writer, guided by one who has been present at such a scene; but some faint idea may be formed from the following description.—We shall suppose a mine of great depth, perhaps from 100 to 150 fathoms, with the workings extended to a great distance, the machinery complete in all its parts, the mining operations under a regular and rigid discipline, with rail-ways in every direction; the stoppings, passing doors, brattices, and the whole economy of the mine so arranged, that every part of the work is performed like a well regulated machine. To see a mine of this extent at full work is a scene of spirited animation, and of wonderful industry; the "sound of the hammer" is heard in every quarter, and the numerous carriages, loaded and unloaded, passing to and from the wall-faces to the pit bottom, are seen driving and thundering along in every direction. At each door, a little boy, named a trapper, is placed to open and shut it. Every one is at his post; added to which, there is a degree of cheerfulness pervading the whole scene, which could scarcely be expected in a place of so sombre an aspect. While the work is thus going forward, it has but too frequently happened, that, from some unforeseen cause, part of the ventilation has become stagnant, or laid dead, as it is termed, by which a great body of inflammable air is gathered into one place, or the sudden opening of a blower has produced the same effect, the certain consequence of which is, that the unsuspecting miner enters it with his candle; ignition takes place; "sudden as the spark from smitten steel," the whole extent of the mine in that direction becomes one blaze of light and flame from roof to pavement, in which the miners are enveloped. It hangs for a few seconds; then from the evolution of immense volumes of gases, with much heat, this pestilence begins to move with the violence of a tornado, and with the noise of thunder, directing its course always in the nearest direction to the upcast shaft. Its power is awful and irresistible. Whatever obstructs its course is swept onward like smoke before the wind. The stoppings are burst, the doors are shivered to a thousand pieces; while the unfortunate miners and boys who are within its range, with the horses, carriages, corves, and coals, are swept along with inconceivable velocity; and when a pillar obstructs the direct course of the current, they are dashed against it, and there lie mingled in one common mass of ruin, desolation and death, as if they had been blown from an immense mortar against a wall! Others are carried direct to the shaft, and are either buried there amidst the wreck, or are blown up and over the pit mouth: So powerful is the blast, that even in the shaft it frequently tears the brattice walls to pieces, blows the corves, which are hanging in the shaft, as high into the air as the ropes will allow them; and not unfrequently the ponderous pulley wheels are blown off the pit-head frame, and carried to a considerable distance in the midst of a thick cloud of coals and coal-dust brought from the mine by the volcanic eruption, which absolutely shakes the solid mass of earth that confines it. The dust rises to a great height, and sometimes obscures the light of the sun in the vicinity of the pit. No sooner is this part of the catastrophe over, and an awful silence produced, than the *back draught* commences, by the descent of air down the shaft to replace the air of the mine as it cools. Every part of the mine is filled with the most deleterious airs, particularly azote and carbonic acid, the result of combustion. Those miners, who were in the direct line of the explosion, have their fate quickly sealed. Others who are not in the direct current are dreadfully burnt. But though the greater number of the miners are at a distance from either of these calamities, yet their fate is perhaps the most severe. They hear the explosion; they know well the certain consequences of it; every one thinks of his personal safety; and the great object is to reach the pit bottom. All the lights are generally extinguished, and they have to pursue their dreary path in awful darkness,—a darkness rendered terrible by the combination of uncommon circumstances. Some of them have been known to make most providential escapes, after clambering over fallen roofs, and the wreck where their fellow workmen lay entombed; but others, deviating from the direct course in the confusion of the scene, wander anxiously onward, dreading every moment to meet the returning pestilential air. At last they feel its power, and knowing the certainty of their fate, they cease to struggle with what is irresistible; they resign their hopes; fall down in a reclining posture; nature is soon exhausted, and they sink in death as if asleep! Such is the fate of the hardy and industrious miners, who venture their lives every day for the comfort of others: and such, frequently, is the misfortune, which, in a moment, comes, like a whirlwind, upon the best arranged mining concerns, after the most laborious exertions, and the most unremitting anxious concern of the mining engineers. The labours and plans of years are in an instant destroyed.

Sad and melancholy as the scene described is, perhaps it is the least part of the melancholy picture. From the general arrangements of collieries, it is found a matter of economy and conveniency to have the workmen's houses, where their families reside, near to the pits. The consequence of this is, that the instant an explosion takes place, the alarm is general, and the wives and relations of those who are in the mine rush to the pit-mouth in a state of distraction, where a heart-rending scene takes place,—a scene which may be imagined, but cannot be described. All the violent effects of sudden grief are the consequence. They look to the horrible pit where those who are most dear to them are entombed, and who but a few hours ago had left them in health and vigour, with the hope of returning happy to their homes.

In such a case the mining engineers have a severe and an imperious duty to perform. The pit, where they must descend, is either rendered dangerous by the wreck of loose timber torn away by the irruption, or the air is in a pestilential state; and, what is still more alarming, part of the coal may have taken fire from the explosion, or a blower may be ignited; either of which would produce repeated and violent explosions the instant the gas accumulated to that point so as to come in contact with the fire. Such a case is not unfrequent, and against this no human skill can guard. This fearful case, with the others before mentioned, is probably combined. All these have to be encountered by the engineer and his assistants. The hope of saving some of the workmen from death, and the ardent entreaties of the agonized relations, place the consideration of personal safety out of the question.

On descending to the bottom of the pit, it is perhaps with great difficulty the mine can be entered, owing to the wreck; if the descending current of air is good, part of the wreck is cleared away. The engineer then considers what are the best immediate plans to pursue, arising from his experience, and an accurate knowledge, not only of the general situation of the workings, but of the direct lines of the air-courses, so that he may in the shortest time restore the ventilation, and, if possible, relieve the miners who may yet be alive. Having formed his plans, he states them to his assistants, and hears any improvements they may suggest; a great quantity of prop-wood and brattice deals are sent down, and they enter the mine as far as the air will allow them; care being taken to have it with them every step as they proceed, and in particular before leaving the shaft, they see that the brattice of it is air-tight; for if any openings are in it, the air would pass directly through it and ascend to the bank.

As the violence of the explosion destroys many of the stoppings, and almost every door upon the air-courses, the whole circulation is laid dead, and the fresh air will of course take the most direct course through the first opening to the upcast shaft. All these must be replaced as they proceed forward with the air; and this work being in general executed with astonishing quickness, many lives are frequently saved.

As soon as the ventilation is restored by these temporary brattices, the stoppings and doors are replaced in a substantial manner, and the workings are resumed with all their former vigour and activity, as if no misfortune had ever happened. From what is stated, and from an inspection of Fig. 2 Plate CCCXCIV. it is evident, that the stability of the main stopping *h*, is an important point, on which account it is counterforted by strong walls of stone; and if stones are easily procured in the mine, it is of great service to counterfort as many of the stoppings as can conveniently be done, so as to resist the explosive force of the fire, and give a greater facility in recovering the ventilation in the promptest manner. The oversmen and deputies who are employed in this service shew a wonderful dexterity in placing temporary brattices. They will work in the dark, with the wreck of one destruction around them, and threatened every moment to be overwhelmed in another, in which the hope of saving a fellow-workman from death gives the most lively energy to their actions; and if they think that a bold effort will save life, they will rush without fear into the midst of pestilential air, and grapple with death. The mining engineers are always at the head of this service, and as they, with their assistants, frequently push forward in the dark, they are exposed to the deleterious effects of the gases, and it is no uncommon thing for those who take the lead, to drop down lifeless, while those who are in the rear seize them by the feet and draw them back into better air, yet no sooner are they re-animated, than the same generous impulse acts in its full force, and they make the same attempt again and again, till nature is exhausted. We need scarcely add, that many fall a sacrifice to the ardour of their generous exertions.

When it is ascertained that fire exists in the wastes, either by the burning of the small dusty coal which lies along the roads, or that the solid coal is on fire, from the ignition of a blower, the descent into the mine is rendered tenfold more hazardous, as a moment's safety cannot be depended on; for if the discharge of gas is great, it rapidly accumulates, and the instant it reaches the place where the fire is, an explosion again takes place, and that repeatedly as long as the causes exist. There have been instances of this kind where the most violent explosions have taken place, regularly within the space of an hour, and continuing to do so for thirty-six hours, each irruption vomiting out of the pit mouth like a volcano. In such cases, no man dare attempt to go down, as his destruction would be inevitable. As the case is desperate, desperate remedies must be applied, which are, either to moat up all the pits and exclude the air, or if this is not practicable, the colliery must be laid in and drowned, by allowing the water below ground to accumulate; and to aid the common growth, the tubbing in the shaft is tapped, and all the body of water from that quarter sent down: when the fire is extinguished, the colliery is refitted in the usual manner.

When fire exists in the waste, with less apparent hazard of life, the mining engineers, with their assistants, descend with portable fire-extinguishing engines. These are placed as near the burning matter as possible, and by playing upon it, the fire is speedily extinguished. It frequently happens, however, that although they see the fire before them, the state of the air prevents them from approaching near enough to allow the engines to play with effect. To remedy this, Mr. Buddle, with that ingenuity for which he is so conspicuous, conceived, that the concussion of air which is produced by the discharge of artillery, might be effective in extinguishing fire, which could not be approached with the engines. He accordingly had small cannons made, and by charging them with powder only, and approaching as near the fire as possible, he has succeeded in blowing out flame by repeatedly firing them. This principle has been proposed lately for extinguishing houses which are on fire.

Such is an outline of the misfortunes incident to coal-mines, and to the engineers and workmen employed where inflammable air abounds.

In the manner before described, and with daily misfortunes of a lesser or greater degree, were the collieries of Great Britain carried on, every one struggling against the direful ravages of the inflammable air; but it baffled the skill of the most experienced engineers, and all the precautions of their most unwearied diligence and anxious attention. The general question, and anxious inquiries were, Can no remedy be devised to avert these awful calamities, to deliver an industrious class of society from such desolating catastrophes? Many plans were proposed, but they were altogether inapplicable. The first person who stepped forward, a number of years ago, and wrote upon the subject, was Dr. Trotter of Newcastle. He published a pamphlet, wherein he proposed to neutralize the carburetted hydrogen as soon as it appeared in the mine, by chemical agents. Every praise is due to him, for his very humane intentions, and earnest endeavour to remedy an evil so great. But although the principles he brought forward were consonant with sound philosophy, and were practicable upon a small scale, they were totally inapplicable to the extended workings of a coal-mine, where there were excavations of many hundred acres, and where the issue of gas was not only incessant, but in great abundance; hence, the principle was not only inapplicable in a general point of view, but the expense of the neutralizing substances must have been so great, even had the principle been applicable, as to render the plan altogether out of the question. After Dr. Trotter's pamphlet, nothing particular appeared for years upon this important subject, the mining engineers, therefore, applied their whole skill and energies in producing a circulation by the means before mentioned, particularly upon the principles of rarefaction and exhaustion by fire.

In some cases, fish, which in the incipient stage of putrefaction, give a strong phosphoric light, had been tried to give light to the miner in very dangerous cases; and the light produced by the collision of flint and steel was universally employed, when candles could not be used without producing an explosion. The machine for producing this light is named a steel mill, which will be particularly noticed afterwards. Philosophers proposed the various kinds of phosphorus, but these were altogether insufficient for the purpose. When tried in the mines, they only produced a most melancholy light, and rather tended to render the "darkness visible:" In the mean time the mines were extended, and the melancholy catastrophes constantly increased. At last an explosion and catastrophe took place at Felling colliery, near Gateshead, in the county of Durham, about a mile and a half distant from Newcastle, more dreadful and melancholy in their consequences than any which had ever taken place in the collieries of Great Britain. This colliery was working with great vigour, and under a most regular system, both as to the mining operations and ventilation; the latter was effected by a furnace and air-tube placed upon a rise pit on elevated ground, south from the turnpike road leading to Sunderland. The depth of the winning was above 100 fathoms; twenty-five acres of coal had been excavated, and such was the execution of work, that from one pit they were drawing at the rate of 1700 tons of coal weekly. Upon the 25th May, 1812, the night-shift was relieved by the day-shift of miners at eleven o'clock forenoon, one hundred and twenty-one persons were in the mine, and had taken their several places, when, at half-past eleven o'clock, the gas fired, and produced a most tremendous explosion, which alarmed all the neighbouring villages. "The subterraneous fire broke forth with two heavy discharges from the dip-pit, and these were instantly followed by one from the rise-pit. A slight trembling, as from an earthquake, was felt for about half a mile around the colliery, and the noise of the explosion, though dull, was heard at from three to four miles distance. Immense quantities of dust and small coal accompanied these blasts, and rose high into the air, in the form of an inverted cone. The heaviest part of the ejected matter, such as corves, wood, and small coal, fell near the pits, but the dust, borne away by a strong west wind, fell in a continued shower to the distance of a mile and a half from the pit. In the adjoining village of Heworth it caused a darkness like that of early twilight, and covered the roads so thickly, that the foot-steps of passengers were imprinted in it. The heads of both shaft-frames were blown off, their sides set on fire, and their pulleys shattered in pieces. The coal-dust ejected from the rise-pit into the horizontal part of the ventilating tube was about three inches thick, and soon burnt to a cinder; pieces of burning coal driven off the solid stratum of the mine were also blown up this shaft."

Such were the fearful and volcanic effects in the mine and atmosphere; but we have yet to state the result of the melancholy catastrophe as regarding the unfortunate miners. Of the 121 persons in the mine, at the time of the explosion, only 32 were drawn up the pit alive; and of these, three died within a few hours after the accident. Thus were no less than 92 persons killed in an instant by this desolating pestilence. The scene at the pit mouth cannot be described.

The viewer, with his assistants, instantly descended, in the face of the most imminent danger, eager to save, if possible, any of the workmen; but the mine was found to be on fire, and they durst not proceed. In consequence of this fire, another explosion took place, and no alternative was left but to shut up the pits, and extinguish the fire, which was accordingly done. The pits were, after a considerable time, again opened, but it was the 19th day of September before the complete ventilation was restored, and the last of the bodies of those who had perished was found; a period of 117 days from the day on which the accident took place. A minute account of this accident was published by the Rev. John Hodgson, the worthy pastor of Heworth; who, upon this melancholy occasion, attended most assiduously, and performed the most painful duties amongst his suffering people. From his account of the misfortune, the particulars above stated are taken.

This fatal misfortune at Felling roused the minds of every one connected with coal-mines, in order to find, if possible, a remedy for preventing such catastrophes.

It appears that Dr. William Reid Clanny, of Sunderland, who, from his medical profession, had frequently to attend at the neighbouring collieries, when the workmen were hurt by the explosions of the gas, had, in the year 1813 turned his attention to the construction of a lamp which would burn amongst inflammable air, and though an explosion might take place in the lamp, would not communicate flame to the external surrounding air. This he accomplished by means of an air-tight lamp with a glass front, the flame of which was supported by blowing air from a pair of small bellows through a stratum of water in the bottom of the lamp, while the heated air passed through water by a recurved tube at top. By this process, the air within the lamp was completely insulated from the external air; and it appears that this was the first lamp that ever was taken into a body of inflammable air in a coal-mine at the exploding point, without producing an explosion of the surrounding gas. Dr. Clanny made another lamp upon an improved plan, by introducing into it the steam of water produced from a small vessel at the top of the lamp, heated by the flame. For these inventions the Doctor twice received the thanks of "The Society for preventing accidents in Coal-Mines;" and he also received the silver, and afterwards the gold medal from the Society of Arts in London. Although these lamps, invented by Dr. Clanny, were upon philosophical principles, displayed much ingenuity, and were absolutely safety-lamps for mines, yet their construction prevented them from being generally used. Nevertheless, Dr. Clanny deserves every praise for his labours and very zealous exertions in the cause of humanity. It appears that nothing farther was attempted in this important matter, until the accident at Felling colliery, as before noticed, when Sir Humphry Davy, Mr. James Stevenson, engineer, Killingworth colliery, Newcastle, and Dr. John Murray of Edinburgh, brought forward safety-lamps, in the year 1816, each constructed upon different principles. Sir Humphry Davy's lamp was made of fine iron wire gauze, without any glass; that of Mr. Stevenson's was made of a strong glass cylinder, having a metal plate at top, and another at bottom, perforated with very small holes, to permit the air to pass to and from the lamp; and that of Dr. Murray was a glass lamp, or rather lanthorn, to which good atmospheric air was brought by means of a long leather pipe from the air-course. Of these, Dr. Murray's lamp was not applicable but in a very few cases; the lamps of Sir Humphry Davy and Mr. Stevenson were both complete safety-lamps in their principle, and are applied in practice; but that of Sir Humphry Davy is decidedly the best, and is generally used in Great Britain. Having no glass, it is not easily injured, and sufficient light for the miner passes through the wire gauze. To each of these gentlemen the world is highly indebted, and in particular the mining interest of Great Britain, for their individual exertions.

The safety-lamp of Sir Humphry Davy was instantly tried, and approved of by Mr. Buddle, and the principal mining engineers at Newcastle. No one was more zealous to prove its safety, and introduce it into the mines, than the Rev. John Hodgson, of Heworth, before mentioned. He descended the mines, entered amongst the inflammable air, and fully satisfied himself of its absolute safety, in order that he might induce the miners of his parish to use it, half of whom he had seen so lately swept away by the dreadful explosion before narrated.

The invention of this lamp has produced a new era in the coal-mining of Great Britain. The steel mills were very expensive, and in certain cases produced explosions, whereas the safety-lamp can be carried without danger amongst inflammable gas ready to explode; and, although the wire becomes red-hot, an explosion of the gas will take place inside of the lamp, without communicating inflammation to the external gas. While we very much admire the great ingenuity of the highly celebrated inventor, we are not less astonished at the uncommon simplicity of the construction. For farther particulars regarding this important discovery, see the article SAFETY LAMP.

The state and purity of the air in coal-mines, from the earliest time of mining, until the discovery of the safety-lamp, were judged of by the appearance presented by the flame of a candle, and this test must, in many circumstances, be still used. When there is only a want of air, or the air is partially vitiated by a small quantity of carbonic acid, or by the perspiration and breath of the workmen, the candle burns with a very dull flame, the tallow ceases to be melted in the cup formed around the wick, and the flame is gradually extinguished. In this case, the candle may be kept burning, by inclining it less or more towards a horizontal direction, which has the effect of melting the tallow with the edge of the flame. By this method the candle is kept burning, but the waste is great, as sometimes more than the half of the tallow drops to the ground unconsumed; an oil lamp is therefore preferable in such a case, as it will keep burning where a candle would be extinguished. When the carbonic acid abounds, no management will make either the candle or lamp burn. In such a case, the mine is unworkable, and must remain so, till a circulation of good air is brought forward. The candles used by colliers in the mines are generally small, with a very small wick, as these are found to produce a more distinct flame than candles of a large size, with a thick wick. The size generally used is at the rate of 20 in the pound weight; but when inflammable air abounds, they are not thicker than a common black lead pencil, there being from 40 to 60 of them in the pound.

In trying the quality of the air by the flame of a candle, the candle is trimmed by taking off the coal or snuff from the wick, so as to produce a clear, distinct, and steady burning flame. If a candle is thus prepared and looked at in common air, a distinct well defined cone of flame is seen, of a fine sky-blue at the bottom next the wick, and of a bright yellow from thence to the apex of the cone; which cone of flame is vesicular, and not a full body of burning matter, as it appears to the eye. Besides this appearance, there is another surrounding the cone, which the brightness of the flame prevents the eye from discerning. This may be seen by placing one of the hands expanded as a screen betwixt the eyes and the candle, and at the distance of about an inch, so that the least point of the apex of the yellow flame be seen and no more. By this arrangement a top, as the miners term it, will be distinctly observed close to the apex of the yellow flame, from an eighth to a quarter of an inch in length. This top is of a yellowish brown colour, and like a misty haze. This haze is not only seen on the top, but it extends downwards and surrounds the flame fully half way, about a twentieth of an inch in thickness; here it assumes a violet colour, which passes into a beautiful blue at the bottom next the wick. The test of the state of the air in mines, or "trying the candle," as practised by miners, depends entirely upon the appearance this vapour or haze assumes as to shape and colour at the top of the flame. The top has distinct and different appearances when burning in atmospheric air, carbonic acid, azote, or carburetted hydrogen, with many variations and modifications, according to the abundance of any of these gases or their mixtures.

When azote, or carbonic acid gas abounds, the top is frequently an inch or two in length, of a decided brown colour, and the flame shortens and burns dimly. If these gases abound, the flame goes out, and the miners retire. No sudden catastrophe arises from these gases in the ordinary course of working mines; it is the carburetted hydrogen which requires the utmost attention and circumspection.

When inflammable air is supposed to exist in considerable quantity, the miner trims his candle and proceeds with cautious step, holding the candle with the left hand, and screening the flame with the other; as this gas floats in the upper part of the mine next the roof, he holds the candle as low as he can, and, keeping his eye fixed on the *top*, advances. If the gas is in very small quantity, he reaches the forehead without observing any material change upon the top. But, if upon advancing as before mentioned, the top begins to elongate and assume a bluish-grey colour, the miner is instantly on his guard, advances with additional caution; and, if the top begins to spire, he kneels on one knee, and, holding the candle near the pavement, gradually raises it up, and observes the change which takes place on the top as it approaches the roof. If the gas is abundant, the flame elongates into a sharp spire, and also the top. It is in general reckoned dangerous when the top changes from the bluish-grey to a fine blue colour, accompanied with minute luminous points, which pass rapidly upwards through the flame and top. When the symptoms are very evidently dangerous, a sudden movement of the hands or body is liable to produce ignition; the experienced miner, in this case, slowly and cautiously lowers his candle to the pavement, and then, turning round, makes his retreat slowly, or slips up his hand and extinguishes the flame. If the miner ventures too far, and approaches the body of gas at the exploding mixture, the top rapidly elongates, and the flame of the candle rises in a sharp spire, several inches in length, when in an instant the whole surrounding gas is in a blaze, an explosion ensues, and the extent of the destructive ravages depends upon the quantity of the gas.

This "*trying the candle*" requires caution, and great experience, particularly in not advancing too far with strong igniting symptoms upon the flame, where the lives of so many men, and the prosperity of the colliery, are at stake. No precise rule can be laid down which may be universally depended upon; all that can be stated here are general facts. Almost every colliery, after having been wrought for some time, gives a peculiar top to the candle; so that while in one colliery an explosion will take place with a top less than an inch long, in another colliery the top will be two inches long, and the air considerably under the igniting point. These differences depend upon several circumstances. If the gas has not run through a long course of ventilation, and is free from mixtures of air, it will ignite with a very short top; while, on the other hand, the gas which has run through a ventilation of 20 or 30 miles, will bear a long top without the least danger. From this it is evident, that a well-tried experience, and thorough practical knowledge, can be the only guides in these cases.

Formerly, when the air in a colliery was at the exploding point, and no thorough ventilation could be produced, it became necessary to carry forward the colliery by means of other light than that of a lamp or candle. This was effected by the collision of flint and steel, produced by an instrument named a steel mill. It is composed of a small frame of iron with a wheel and pinion, which produce a quick motion of a disk of steel placed vertically, against the periphery of which a piece of flint is held. This machine produced sufficient light to guide the miner in his operations; but it was very expensive, as every workman required a person named a miller, to give him light. This light was safe in comparison with that of the candle, when the air was dangerous; yet, in particular cases, explosions have taken place from it; and although the steel mill is now happily superceded by the safety lamp, the trial of the candle must in many cases be resorted to, particularly in sudden emergencies, arising from the inflammable air coming suddenly off while a colliery is working with candles, and judged perfectly safe. It is for this reason the detailed account is given, such test being less or more resorted to in many collieries every day, though it ought never to be tried in dangerous cases on any account whatever, except from absolute necessity, as safety lamps can be used with great expedition, and with the most complete security. Previous to the invention of the lamp, the whole mines of extensive collieries have been carried on with no other light but that produced by steam mills, as no candle could be taken into the mines without producing an explosion. This mode of working the mines was attended with an uncommon expence, great inconveniency, and imminent danger. This shews also the high value of the safety lamp in an economical point of view.

Having stated, in the preceding part of this treatise, the manner of working coals to the rise of the engine-pit shaft, we have now to state the plans which have been adopted for working coals a dipping of, and deeper than the engine-pit bottom. This has become an important point in colliery operations, and has been greatly improved within these last twenty years.

In the early periods of coal-mining, and when the running of day-levels and sinking of pits were attended with great loss of time, and uncommon expence, the working of coals under dip of the day-level and engine pit bottom was a common operation. The first plan resorted to, was running a downset mine in the coal, and carrying the water either out in pails by men, or by placing dams across the mine of about a foot or fifteen inches deep, at regular distances, so that the water was laved with scoops from the dip-head, and from dam to dam, until it reached the pit bottom, or day-level.

The next improvement was to raise the water by means of sloping hand-pumps from one dam to another, which slope-pumps had long wind-bores corresponding to the dip of the coal and range of the atmospheric pressure, with several valves to retain the water in the wind-bores in case of leakage when the pumps were not going, or pumps were placed in small pits, and the water carried in spouts from the top of one pump to the bottom of the next, until it reached the engine-pit, or day-level. This last plan was improved by laying a working barrel with a long wind-bore at the bottom of the downset mine, having a smooth rod working through a collar, at the top of the working barrel. At one side of which, near the top, a kneed pipe is attached, and from it pipes are carried to the point of delivery, either at the engine-pit bottom, or day-level, as represented in Plate CCCXCIV. Fig. 3 The spears are wrought sometimes by rods connected with the machinery at the surface, in which case, if the spears are of great length, they are either suspended from swing or pendulum rods, or move on friction rollers. But as the action of the spears, running with great velocity the full length of the engine stroke, very soon tore every thing to pieces, the motion of the spears below ground is reduced from 6 or 8 feet, the stroke of the engine, to about 15 inches; and the speed in the pump is produced by the centering of a beam, and the attachment of the spears to it, as represented in Plate CCCXCIV. Fig. 4. where *a* is the working barrel, *b* the beam centered at *c*, having an arc head and martingale sinking-chain. The spears *d* are attached by a strong bolt, which passes through the beam; and there are several holes, by means of which the stroke in the pumps can be made longer or shorter, as necessity may require. A strong iron quadrant, or wheel, at the pit bottom, regulates the movement of the spears. In level free coals, these pumps can be wrought by a water-wheel placed near the bottom of the pit; which wheel is moved by water descending the shaft, and is discharged by the day level. We have also seen a water-wheel used in the same manner, where the engine had great command of the water; and the wheel was moved either by water descending from the sides of the pit, or by water first pumped up by the engine, and allowed to discharge from the side of the pumps upon the wheel. The coals were brought up also by the same means. When water is very inconsiderable in these under-dip works, it is raised sometimes by a common forcing engine, such as is used for extinguishing fires, but of a small size; or by forcing pumps, wrought by one or two men, with a fly-wheel and pinion, the shaft having two cranks, which work two small reciprocating iron beams connected with two pump barrels. These machines have a spherical air-vessel attached, in order to keep the water in constant flow, which is a great relief to the workmen, as they have not the *vis inertiæ* to overcome every stroke or revolution of the fly-wheel.

But the greatest improvement for working under-dip coal has been brought forward by the Newcastle engineers. Their plan is, to run a mine a dipping of the engine-pit in such direction of the dip as may be most suitable; and both water and coals are brought up the rise of the coal by means of high pressure engines, which work with a power of from 30 to 50 pounds upon the square inch. These machines are quite under command, and as much power is produced in little space, they are the most applicable for under-ground work. An excavation is made for them in the strata above the coal, and the air used for the furnace under the boiler, is the returned air after ventilating the mines, the smoke is conducted in a room or board to the rise, until it is discharged into the upcast shaft, where it quickly rises to the pit top. In the dip mine a double tram road is laid, so that while a number of loaded corves are ascending, an equal number of empty ones are descending; and although this improvement has only been brought forward within these few years, under-dip workings have been already executed very nearly an English mile under-dip of the engine-pit bottom, by means of three of these high pressure engines placed at equal distances in the under-dip mine. Hence we conclude, that there is no limitation to this mode of working; and in place of contemplating the sinking of pits of excessive depth upon the dip of the coal, at an almost overwhelming expence, we are of opinion that much of the under-dip coal will now be wrought by means of the present engine pits. These great improvements in coal-mining are to be seen in full action in the Newcastle district, where coals are not only wrought under dip, and under the river Tyne, but where in an engine-pit of 115 fathoms in depth coals are now working under dip of the engine pit bottom above 1600 yards, and fully 80 fathoms of perpendicular depth more than the bottom of the pit. There are instances, where coals may be thus wrought from the dead crop and a dipping, by means of machinery placed at the crop, without cross cutting the strata by a pit, which in many situations would be a great saving, where the water and sand beds render it very difficult to pass through, and where the expence is great, amounting to above £100 per fathom. We see no physical objection to the carrying on of this system of under-dip working almost to any extent, provided the air can be circulated in abundance; and we think this can be accomplished equally well in this system as by the other.

Besides these plans of working under-dip coals, there are several others in common practice.

If an engine-pit is sunk to a particular coal, found at any given depth, all the other coals of the coal-field, both above and below the coal sunk to, can be drained and wrought to the same depth, by driving a level cross-cut mine, both to the dip and rise, until all the coals are intersected, as represented in Plate CCCXCIV. Fig. 5. where A is the engine-pit bottom reaching the coal *a*; and *b*, *c*, *d*, *e*, *f*, coals lying above the coal *a*; the coals which lie below it *g*, *h*, *i*; *k* is the forehead of the cross-cut mine intersecting all the lower coals; and *l* the other forehead of the mine intersecting all the upper coals.

An additional breast of coals, as in the above case, may be obtained, by sinking the engine-pit deeper, and running level cross-cut mines, as above mentioned. But this plan is not easily accomplished, if the water is heavy in the pit. If it is so, the plan is, to connect the wind-bore of the lower set of pumps with a kneed pipe, and make a lodgment for the water in the coal to the dip of the engine-pit bottom; to the dip hand of which tail pipes are laid from the kneed pipe, as represented in Plate CCCXCIV. Fig. 6. where the knee of the pipes rests on a strong bunton. By this plan no water descends the shaft while sinking. The additional depth is represented by the dotted lines; and the double horizontal dotted lines represent the cross-cut mines for the coals a dipping.

Another plan of working a coal under dip of the engine-pit bottom, is by means of what is termed an inverted syphon, known also by the name of a drowned or blind level, as represented in Fig. 7. where A is an engine pit sunk to the coal B, and C is a coal 10 fathoms deeper, and dipping 1 in 12. The pit is sunk to the coal C, and a mine is run in that coal a dipping to the distance of 120 fathoms to the point D. This distance is found by multiplying the distance betwixt the two coals by the dip, viz. $10 \times 12 = 120$. While the mine CD is driving, a similar mine is driven in the coal B immediately above, and in the direction of the mine CD to the point E, above the forehead D. From E to D a blind pit is sunk, or one or more bores are put down, by which all the water found in the coal from B to E descends, so that when the water rises to the top of the blind pit at E, it discharges into the engine-pit sump at C. By this operation, a new breast of coal is laid dry, of 120 fathoms in breadth, and the whole length of the coal-field. The same effect would have been obtained, by running a stone mine, or cross-cut in the direction of the dotted line CE; but the first operation being in coal, the expence is almost nothing in comparison with what the cross-cut mine would cost; and if a greater breast of coal was necessary, under-dip operations would commence at E, and the water thereof be delivered into the blind pit. This second portion of under-dip coal would require to have pumps from E a-dipping, and these could be wrought by any of the plans before mentioned.

Another method of gaining under-dip coal, where pits are not deep or very expensive, is to run a mine in the coal to any distance a-dipping, as from C to F; then to begin a pit H upon the surface, so as to be directly above the forehead F. As soon as the pit is secured to the rock-head through the alluvial cover, a bore is put down to the mine at F; by this means all the water found in the pit descends through the bore, and ascends the mine to the bottom of the engine-pit at C; by this method the pit is sunk to the depth G, without being troubled with water. G being on a level with C, the water or growth of the pit must then either be drawn up the pit H or the pit A, until the pit H is sunk to the coal at F. A set of pipes is then laid along the pavement of the coal from C to F, and carried up from the pit-bottom a few feet higher than G; there a trough is placed on the top of them. A set of pumps, of a diameter corresponding to the growth of the water, is placed from the pump at F to the height of the trough at G; and the pump-spears are connected with the coal-drawing engine at the mouth of the pit. Hence all the growth of water in the pit is conducted into the trough upon the top of the pipes, and into it also the water from the pumps is delivered. The water, by its own gravity, ascends the pipes from F to the engine-pit bottom at C, where it is drawn to the surface by the main engine.

The foregoing plans for working under-dip coals, are such as are in general practice. Of these plans there are many modifications and combinations, to suit the particular situation of a colliery.

In prosecuting the workings of under-dip coals, it requires caution not to carry the rooms or boards through upon the level or dip-head mine of the first winning, as in this case all the water of that winning would descend to the under-dip works, and drown them. This caution is particularly necessary when approaching the dip-head levels of a level free coal; for, if not attended to, the water of the level free coal, in place of going out by the day level, would go down upon the engine a-dipping, and overpower it; in all such cases, strong barriers of coal ought to be left upon the dip-side of the dip-head levels, not only to keep the water up, but to resist any crush or sit in the coal, which would have the effect of letting down the water also.

In the working of coal-mines, serious interruptions occasionally take place, even with every precaution in the management. These interruptions are, chiefly,

1st, Creeps.
2d, Crushes, thrusts, or sits.
3d, The coal taking fire.
4th, Water in extra quantity.

A creep is occasioned from the pavement being very soft, and the pillars of small area, so that they sink into the pavement, and produce a movement in all the superincumbent strata. If once the creep begins, it is almost impossible to prevent it overrunning all the workings. If the soft pavement is thin, it will only heave up a little, and no great injury will arise to the works; but if the pillars are very weak, they are liable to give way, and produce a crush. When the soft pavement is of considerable thickness, the pillars sink very much, until the upheaved pavement meets the roof, and shuts up the workings altogether. This misfortune is generally rectified by driving mines through the creep to the whole coal wall, and then opening up the works anew. From the improved system of mining introduced at Newcastle, the pillars in the creep are frequently wrought by taking away the upheaved pavement. This operation has been greatly facilitated since the introduction of the safety lamps. The only effectual plan for preventing creeps, is to work the mines with narrow boards, and very large pillars, which is no loss, as all the pillars can be got out afterwards.

A crush is produced in general by the pillars being left too small to resist the weight of the superincumbent strata; or it is produced sometimes where the pillars are abundantly strong, but where the strata in the roof are very soft, and composed of argillaceous earth or fire-clay; this kind of roof breaks along the side of the pillars, and falls down, after which the fire-clay above the heads of the pillars crumbles, from the pressure and exposure to the air, and a crush ensues. Crushes are prevented by keeping the pillars large; and where the roofs are bad, the boards must be very narrow. When a crush commences, it is almost impossible to prevent it overrunning all the work, except it is resisted by a barrier of coal, or by stronger pillars in another district of the work. In wastes of very great extent, the progress of a crush is sometimes stopped by cutting out a line of pillars betwixt the crush and the wall-faces, so that when the crush comes to the void, the superincumbent strata break down from the waste to the surface. When a crush overruns the whole work, the superincumbent strata break over at the wall-faces. When this happens, the works have to be opened up anew, by cutting roads and making air-courses through the crushed waste. When creeps and crushes are extensive, they derange the whole economy of the work, by destroying all the roads and air-courses; and the re-establishment of the works is attended with uncommon hazard, labour, and expense. The improved plan of working the mines in pannel-work, as brought into practice by Mr. Buddle, is highly beneficial in preventing creeps or crushes, and if they do take place in one pannel of work, the pannel-walls act as complete barriers against their extending to the other pannels.

When the pillars of a colliery are to be wrought by taking a part of every pillar, it sometimes happens that the remaining portions of the pillars resist the weight of the superincumbent strata for a considerable time. In this case there have been instances of the weak pillars giving way in a moment, without warning, and forcing the air of the waste up the shafts with inconceivable force; a case attended with imminent danger to the workmen.

Coal-mines take fire either from explosions of inflammable air, or spontaneous ignition, occasioned by the decomposition of pyrites amongst the rubbish of the mine. The method adopted for extinguishing such fire, when occasioned by inflammable air, has been already mentioned, when treating of ventilation. In coals liable to spontaneous ignition, the effectual plan of prevention is, to allow none of the small coal and rubbish to remain in the wastes; but if this cannot be done, the old wastes should be insulated from the new works, by buildings betwixt the surrounding pillars, to prevent the access of air to the rubbish. When wastes containing this kind of rubbish take fire to any considerable extent, the pplication of water has very little effect; for though it may in some degree extinguish the fire at that particular spot, it greatly promotes ignition amongst the adjoining rubbish, by bringing on a more rapid decomposition of the pyrites. The remedy in common practice is, to build off the burning waste with air-tight walls, and prevent all access of air. Though these remedies generally prevent the fire from spreading farther, a very slow combustion frequently goes on for many years in the ignited wastes. There have been instances of this kind of fire continuing for near a century. When coals which are free of pyrites take fire by accident, if they cannot be extinguished by any of the methods before mentioned, the last resort is, to allow the wastes to fill with water until the fire is extinguished. This method cannot be applied in coals liable to spontaneous ignition, for as soon as the water is drawn from the wastes, this ignition would take place through the whole extent of the works.

In prosecuting the workings of a colliery, the ordinary growth of water which is pumped up by the engine, is sometimes suddenly increased from fissures in the strata communicating with great bodies of water. Such additional feeders are measured as to quantity every day, in order to find if they abate or not. If they do not abate, and the engine is unable to draw this additional quantity, more machinery must be put on to keep the mine dry; but if this cannot be effected, and the growth of water be so great as to threaten the ruin of the colliery, this extra growth is frequently kept back by placing strong dams of wood in the mines leading to the district from whence the water issues. This may be done where there is a strong barrier wall, and a few narrow mines through it; but it is altogether impracticable along an extended line of pillars. These dams are made of very dry fir logs, about six feet in length, each log being dressed smooth and square with a plane. A seat is cut in the mine, where the dam will lie most secure, the inner head next the water being wider than the other end. In order the more effectually to resist the pressure, each log is dressed to this bevel, and the sole of the dam is laid with a bed of oakum before the logs are laid down, a strong cast iron pipe, of size sufficient to let a man pass through, is placed in the dam, which pipe is of a conical shape, the wide end being towards the inside, the whole space is then filled up with logs. The outer and inner heads of the dam are then wedged in a regular manner, in lines parallel to the joints of the logs, with very thin dry fir wedges, and that until no more wedges can be driven. The men for wedging the inner head, pass and repass through the iron pipe; and the last of these, when the wedging is completed, draws after him a wooden plug, which shuts up the iron pipe, and prevents the water from passing through. This plug is longer than the dam, so that a piece of it projects beyond the lower end, by which it is drawn tight into the pipe, and then made perfectly tight by wedging. If more dams than one have to be put in, the iron pipe is only necessary for the dam which is to be last wedged. Dams of this kind will resist almost any pressure of water; but if the roof or pavement is bad, particularly the latter, there have been instances of the water, from its excessive pressure, passing through the strata under the dam, and blowing up the pavement at the lower end of it, by which the colliery has been instantly ruined, and the lives of the men put in imminent hazard; the same accident is liable to happen by the water passing under the barrier walls, or bursting it where thin. It is not found expedient, where there is great pressure, to form these dams in the boards or rooms, the width being too great: mines of about six feet wide are preferred. Water has, by this plan, been kept back under a pressure of 130 fathoms. Plate CCCXCIV. Fig. 9. represents the plan of a dam in a narrow mine, for resisting a great pressure. Fig. 10. represents a plan of a dam placed in a room or board, where the pressure is much less.

In cases where the communication from an extra feeder of water to the engine pit-bottom, is through a staple or blind pit, such water is prevented from descending to the workings, either by a very strong water-tight scaffolding, made of timber, supported by diagonal stays from the sides of the pit below, or a stone arch may be thrown in the pit, and covered with a thick moating of clay; these are generally placed at a bed of the strata which is impervious to water.

In collieries where water is thus kept back with so heavy a pressure, the greatest caution is required in conducting the adjoining workings, in not approaching too near, the danger being so imminently great.

The working of mines of limestone and ironstone is conducted on the same principles as those of coal. The greater part of the limestones of Great Britain are wrought open cast, similar to a freestone quarry: When they are wrought under cover, it is always with post and stall; and, if the roof is good, the pillars are very small, and the mines very wide. The general system of working is the same as that of coal on the simplest form, little attention being required for ventilation.

Ironstone is sometimes wrought open-cast; and in hill districts where it abounds, as in Wales, the plan of damming and husshing is employed, that is, collections of water are made above the open-casts, and the water from above is allowed to pass through them, which carries down both the ironstone and the argillaceous clay in which it is embedded; when the water ceases to run, the ironstone is gathered at the bottom of the slope. When ironstone is found in the strata immediately above a coal, the practice is, to work the coal first, if in the post and stall system; afterwards to take down the roofs of the rooms and thirlings, and pick out the ironstone. In this way none of the ironstone above the pillars of coal can be got; but if the common roof-stone comes down in great quantity, the wastes can be so built up as to allow both the pillars of coal and the ironstone above them to be taken away. Ironstones in the roof of coals sometimes render the coal easily wrought in the Shropshire style, both the coal and ironstone being wrought at once, while the roof-stones fill up the waste, and serve as gobbing, so that none of the coal is required for that purpose. Much ironstone is wrought in the solids, that is, simply as an ironstone mine, and as the ironstone is in bands and balls of a few inches thick, much of the argillaceous schistus in which it is embedded has to be wrought, in order to give the men room. In this case the Shropshire style is universally adopted; but as the ironstone taken out bears so small a proportion to the waste which is formed, a great part of the waste stuff has to be brought out of the mine to the surface, there not being stowage for it below; this stuff covers so much ground, that it forms a great objection to the working of ironstone under valuable land. When it happens that a coal is working in the post and stall system, a few fathoms either above or below the ironstone mine, a cross-cut mine is sometimes run from the ironstone workings to those of the coal: through this cross-cut the waste stuff is carried, and stowed up betwixt the coal pillars, by which means the greater part of the pillars can easily be wrought out, which is a great advantage.

The most extensive collieries in Great Britain are wrought for sea sale, and are frequently situated at the distance of several miles from the place of shipping, to which the coals are conducted in waggons upon cast-iron rail-ways. Waggons of various dimensions have been adopted, containing from 10 cwt. to 3 tons. When the waggons contain a great weight, the rails require to be very strong, and are of course expensive. From 15 to 30 cwt. is perhaps the most suitable for colliery rail-ways in general. When the declination from the colliery to the shipping place is moderate, one horse can take down 8 waggons at a time, each waggon containing a ton weight of coals, and return with the empty ones. Where great declivities occur, inclined plane machines are used, by which the full waggons, in descending, pull up the empty ones; if steep ascents occur betwixt the colliery and the shipping place, the waggons are taken up by means of a steam-engine placed at the top of the bank. This is attended with considerable extra expense, and it is only at collieries where a great quantity of coal is to be vended that this expense can be repaid. Upon some rail-ways, high pressure travelling engines have been adopted for taking down the coals, and with very great effect, particularly by Mr. James Stevenson, engineer at Killingworth colliery, Newcastle, and by Mr. Blenkensop at Leeds. The former has made great improvements, both in the construction of the engines and rail-ways. By Mr. Blenkensop's plan, teeth are cast on the side of the rail, by which means, with a toothed wheel, the engine can draw the waggons up a declivity of considerable steepness. One of these engines can draw from 30 to 50 tons at a time. For the particular construction of rail-ways and travelling engines, see the article RAIL-WAY.

The dividing of great coal into separate kinds, termed great coal, chews, and small coal, is a very bad system: the best mode for the mine master and consumer is, to have only two kinds, viz. household coal and culm; the household coals being composed of large coals, and of a size downwards to about an inch, separated from the culm by a harp, or by a riddle, which is preferable. This correct practice is to be seen in all the collieries of the Glasgow district in Scotland; by it the greatest economy is produced, not only in respect of the coal, in a given area, producing the greatest quantity of marketable coals; but the open burning coals, when free from culm, are the best fitted for every general purpose; whereas the culm can be afforded at a very cheap rate for steam-engines, lime-burning, salt, and brick-making, it being well known that when culm is mixed with the round coal, it retards the burning in an uncommon degree. The great coal system, where three sizes are made, is attended with much loss of coal, and greatly enhances the price of what is termed great coals, these being generally 30 per cent. dearer than the chews, while, at the same time, they must be broken down to the size of chews by the consumer, before they can be put into the fire. This shews how very detrimental this system is.

At Newcastle, where the coals are of a rich caking quality, and where every particle of them is of equal value, a very bad system has been introduced, of separating the smaller part of the coal from the other, by means of skreens or harps. The small coal forms excellent smithy coal, very fit for glass-making, and indeed for almost any purpose. This separation of the small coal arose from the violent competition of the coal owners in the London market, in order to give the coals a better appearance. The system was very easily introduced, but it has now extended to such a degree, that it seems to carry ruin with it as to the economy of the coal-fields in the north of England, for the fine coals thus separated cannot be sold; the consequence is, that at every colliery they accumulate to such a degree, that they are either allowed to take fire by spontaneous ignition, or are actually set on fire in order to clear the ground of them. It is the burning of this kind of coal which astonishes all strangers who approach Newcastle at night, from the innumerable bright blazes seen in every direction. The waste and destruction of coal by this system has extended now to such an uncommon degree, that it is estimated that, upon the collieries of the two rivers Tyne and Wear, not less than 500,000 tons, or rather more than half a million of tons, are thus destroyed every year. This is a lamentable waste of our coal mines, and the cause of deep regret, not only to those concerned in the mines, but to every one who views the evil in its proper light; particularly when it is considered, that the mines at Newcastle have now reached the depth of 200 fathoms, and that the capital required for one colliery establishment amounts from 50,000*l.* to 100,000*l.* The coal-fields of Great Britain are, no doubt, of great extent, and the quantity of coal remaining to be wrought almost beyond calculation; but they have a limit, and are exhaustible. Although the coal-fields are indeed of great extent, the increased depth of the Newcastle pits, and the immense capitals now required for colliery establishments, demonstrate in the clearest manner, that, as to that district, its very wonderful magazine of the finest coal in the world is quickly exhausting, and cannot now be wrought but at greatly increased expenses. The proportion of coal thus wilfully destroyed by fire each year, is estimated to be from a sixth to a seventh of the whole annual output of coals in that district.

This destruction of coals is a direct, irretrievable national loss; for it must be allowed, by any one who contemplates the energies and physical powers of Great Britain, compared with those of the other empires and kingdoms of the world, that it is the abundance and cheapness of its coals, with its innumerable steam-engines, which constitute one prominent point of its energies and powers, and, as a manufacturing country, give its comparatively limited population an effective strength, far beyond any nation in the world. Without coals there could be no steam-engines; and the steam-engines in Great Britain do the work of many millions of people. If, in idea, we abstract the cheap coals and steam-engines from our manufacturing establishments, our superiority as a manufacturing country would cease; and if we lose this superiority, it is but too evident to any person of observation, that we would sink instantly from the very high point of the political scale to which we have attained amongst the nations of the world. From this view, the high importance of the coal-mines of Great Britain may be estimated both in a civil and political point of view; and, therefore, whatever system tends to waste so valuable a commodity is greatly to be regretted. Those who, by their industry and attention, bring forward plans by which any given area of coal produces the highest proportion of marketable coals, do the community a very great service, and they deserve well of their country. It is by the moderate price of coals and the steam-engines, that Great Britain, as a manufacturing country, can produce its manufactures at a more moderate rate than any other nation, although the wages paid for manual labour at the manufactories, are at least three times more than what is paid for labour in other parts of the world. In short, the prosperity of Great Britain has, in a very great degree, been maintained by the abundance and cheapness of its coals; and its future prosperity, to all human view, must depend upon this point of economy. Whatever tends to enhance the price of coals, tends to injure Great Britain in its vital principles. The government has, at various times, proposed *an excise upon coals at the pit mouth*, a proposition which has always been vigorously and effectually opposed. It must be very evident to any one who considers the subject, that a more impolitic tax could scarcely be devised, particularly when we compare the situation of Great Britain, as a manufacturing country, with the other nations of the world: The effects of such a tax would be immediate ruin to the whole manufacturing interest, and consequently to the empire.*

Erratum in p. 343. col. 1. line 9. from top, for *bluish* read *blush*.

MINERAL WATERS.

Waters are divided into different classes, according to the source from which they are derived, as, Rain, Snow, and Hail water, Spring and River water, Well water, and the water of Lakes and Ponds. The first of these is the purest, particularly if it be collected at a distance from town, and some time after a shower has continued. It contains air and carbonic acid, carbonate and muriate of lime; but the quantity of these is so small that rain and snow water may be used for many of the purposes for which distilled water is employed.

The other waters contain some of the soluble substances over which they pass. The quantity of foreign matter in these is in general not great; hence they are sufficiently pure for domestic purposes.

The water of some springs, however, often contains a considerable quantity of foreign ingredients, which impart to it particular properties. Waters of this kind are called *mineral waters*. Besides these, there are some waters called also mineral, which have very little foreign matter, such as the waters of Matlock and Malvern. These, however, strictly speaking, are not mineral waters.

Mineral waters occur in different parts of the globe, differing in the ingredients which they contain, according to the channel over which they have flowed; besides this, they also differ in their temperature. Most of them are of the same temperature with the surrounding medium; occasionally, however, they are warmer, and, in some rare instances, they are at a boiling heat.

Though the attention of man was early directed to these waters, particularly from their medicinal effects, it was not till about the end of the 17th century, that any chemical investigation of them was undertaken.

Boyle, in 1663, seems to have been the first who employed tests to detect the substances contained in mineral waters. To these there were various additions made by Duclos, by Hierne, and again by Boyle in 1678. In 1707 Geoffroy pointed out the method of procuring the solid ingredients by evaporation; and in 1726 Boulduc employed alcohol as the means of separating the saline substances from their solution in the water. At this time carbonic acid, an ingredient so common in mineral waters, and which is the agent by which many of the other substances are rendered soluble, was not known. After the discovery of this gaseous fluid by Dr. Black, the labours of chemists were directed to mineral waters, more particularly after the publication of the essay of Bergman in 1778. Since then, numerous mineral waters have been subjected to analysis, by Black, Klaproth, Westrumb, Fourcroy, and others; the result of whose labours, and the different methods of analysis used by them, were published in the works of Kirwan and Saunders, in 1800. Of late, Dr. Murray has brought forward a new view of the composition of these fluids, which threatens to overturn the results of the experiments of former chemists, and which has induced him to propose a method of analysis, more simple than those generally followed.

The examination of mineral waters, is perhaps one of the most difficult pursuits of the chemist. It requires an intimate knowledge of the action of bodies on each other, and the utmost nicety in the manipulation; the quantity of matter on which he has to operate being so minute. In the analysis of these fluids, the various processes recommended should be tried and compared, and, if necessary, repeated till they agree in their results.

The examination of a mineral water may be divided into two parts; 1st, The investigation of the physical qualities of the water, with an account of the surrounding objects; 2d, The chemical analysis of the fluid, so as to ascertain its component parts.

Of the Physical Qualities of the Water, &c.

Before proceeding to the chemical investigation of a mineral water, it is necessary to ascertain the source from which it is derived, the nature of the substances over which it has passed, and of the soil where it has its exit. We must likewise attend to any matter which may be deposited from it. Its taste, odour, colour, and temperature, must be observed, and the quantity of it discharged in a given time, and the rapidity with which it flows, must likewise be noticed. This examination of the water ought to be performed at different times of the day, and in different seasons, both before and after rain, as the quantity of the fluid discharged, and of

* The Editor has been indebted for the preceding valuable Article on Coal Mines to Robert Bald, Esq. F. R. S. E. &c.

course its properties, vary according to the state of the weather. By the knowledge thus acquired, some information may be gained with respect to the nature of the water, and of the substances which are contained in it; thus the odour and the taste point out whether it be sulphureous or contain iron, and its sparkling indicates the presence of an aërial fluid.

Having made these observations, the next step, is to proceed to the chemical investigation of the fluid.

Of the Substances found in Mineral Waters.

The substances found in mineral waters may be divided into the gaseous fluids, the acids, the alkalies, the earths, and the compound salts.

1. *Atmospheric air* is contained in almost all mineral waters, the quantity however is not great, as it seldom exceeds the $\frac{1}{28}$th of the volume of the water. It was first pointed out in those fluids by Mr. Boyle.

2 *Oxygen gas* was found in mineral waters by Scheele. It exists in small quantity, and is never contained in the same water with sulphuretted hydrogen or the compounds of iron.

3. *Nitrogen gas* was detected in the Bath waters by Dr. Priestley, in Buxton waters by Dr. Pearson, in those of Harrowgate by Dr. Garnet, and in those of Lemington Priors by Dr. Lambe.

4. *Carbonic acid* is a very common ingredient in mineral waters; it was first discovered by Dr. Brownrigg in those of Pyrmont. Its quantity varies considerably, though in general it seldom exceeds that of the water. According to Higgins, however, 100 cubic inches of Pyrmont water contain 160, and, according to Westrumb, no less than 187 cubic inches of carbonic acid.

5. *Boracic acid* has been found in some of the lakes of Italy, though, in the waters in which it has been observed, it in general exists in a state of combination.

6. *Sulphureous acid* has been detected in some of the waters of Italy near volcanoes.

7. *Sulphuretted hydrogen* is a very common ingredient in mineral waters. It was first discovered in them by Scheele.

8. *Soda* is the only alkali which has been found, in its free state, in mineral waters. According to Dr. Black it exists in the waters of Geyser and Rykum, in Iceland.

9 *Lime* also, in its pure state, is said by some chemists to exist in mineral waters.

10. *Silica* exists in the waters of Geyser, and in many others. It was generally supposed that the earth was held in solution by soda; this however does not seem to be the case, as the quantity of alkali in the waters containing silica is so trifling.

Nitric, carbonic, sulphuric, and muriatic acids, and sulphuretted hydrogen, are frequently found in mineral waters, in union with potassa and soda, with lime and magnesia, and with the oxide of iron. Baryta, alumina, and the oxide of copper, have also been found in combination with some of the above-mentioned acids, though less frequently than the other bases. Subborate soda has likewise been detected in the lakes of Thibet and Persia; these waters, however, do not belong to those properly called mineral waters.

The *nitrates* are rarely found in mineral waters.

11. *Nitrate of potassa* has been detected in some of those in Hungary, and in the salt springs in Germany.

12. *Nitrate of lime* was first discovered to exist in water by Dr. Home. It is is found also in some springs in the Deserts of Arabia.

The *carbonates* are perhaps the most frequent of the compound salts contained in mineral waters.

13 *Carbonate of potassa* has sometimes, though rarely, been found. When present, it is in small quantity.

14. *Carbonate of soda* is a much more abundant production, being contained in a great many waters.

15. *Carbonate of ammonia* is seldom detected.

16. *Carbonate of lime*, in union with an excess of carbonic, is perhaps the most common ingredient in mineral waters, few waters existing without it. 1000 parts of water by weight, when they contain 2 of carbonic acid, can dissolve 2 of carbonate of lime. As the quantity of water increases, the carbonic acid necessary to hold the carbonate of lime in solution becomes smaller. Whatever be the quantity of carbonic acid in water, it is able to hold the carbonate of lime in solution, provided the carbonic acid exceed the weight of the lime.

17 *Carbonate of magnesia* is frequently found in mineral waters, also held in solution by an excess of acid.

18. *Carbonate of alumina*, according to Westrumb, exists in the waters of Weinberg and Pyrmont; it is doubtful, however, if this be the state of combination of the alumina.

19. *Carbonate of iron* is often contained in mineral waters. When iron is present in water, it is almost always in union with carbonic acid; the carbonate being held in solution by an excess of acid.

The *sulphates* are not so frequently found as the carbonates.

20. *Sulphate of soda*, however, often occurs.

21. *Sulphate of ammonia* has been detected in some springs near volcanoes.

22. *Sulphate of lime* is a common ingredient in mineral waters.

23. *Sulphate of magnesia* frequently exists. It is contained in the waters of Epsom; hence the name of the salt Epsom Salt.

24. *Sulphate of iron* is often found in waters in the neighbourhood of volcanoes. It has also been detected in other waters, as in those of Horley Green by Dr. Garnet, and in the waters of Denmark by Bergman.

25. *Sulphate of copper* is a very rare production in mineral waters. It is found only in those which issue from copper mines.

The *muriates* are very frequently observed in waters.

26. *Muriate of potassa*, however, rarely exists.

27. *Muriate of soda*, on the contrary, is found in almost all mineral waters.

28. *Muriate of ammonia* has been detected in some lakes in Italy.

29. *Muriate of lime* and *muriate of magnesia* are often found.

30. *Muriate of baryta* and *muriate of alumina*, it is said, exist in some waters, they are however very rare; the former has been detected by Withering, the latter by Bergman.

31. *Muriate of manganese* is found in some waters. According to Lambe it is contained in those of Lemington Priors, and Dr. Scudamore has found it in the water of Tunbridge wells.

32. *Hydro-sulphuret of soda* has been observed in some waters.

33 *Hydro-sulphuret of lime* also, though rarely, exists in them.

It mus ibe here remarked, that the salts mentioned above, as existing in mineral waters, are those which have been procured by the evaporation of the fluid, hence inferring, that those deposited by evaporation are the salts which the water contained. Other views are, however, entertained with respect to the state of combination of the acids and bases, which, if correct, will make the salts different from those stated.

Besides the substances enumerated, mineral waters contain animal and vegetable bodies; these, however, are probably accidental.

From the above statement, it would appear that a mineral water contains an immense variety of ingredients; this, however, is not the case. A mineral water seldom contains above 8 or 10 of these substances; indeed it rarely happens that the number is so great. In general it does not exceed 6. The substances most commonly found are, free carbonic acid and sulphuretted hydrogen, carbonates of soda, lime, magnesia and iron, sulphates and muriates of soda, lime and magnesia. Owing to the waters containing some of these ingredients, while the others are wanting, or in small quantity, they have been divided into different classes, and named according to the substance which imparts to them their particular properties.

Mineral waters are divided into four classes, the *acidulous*, the *sulphureous*, the *chalybeate*, and the *saline*.

Acidulous waters are those which contain carbonic acid in its free state, or in combination in excess with a base. These waters are easily distinguished by their slightly acid taste, and by their sparkling when poured from one vessel to another; both of which properties they lose, when exposed to the air for a length of time, or by boiling. Besides carbonic acid, they almost always contain muriate of soda, and some of the earthy carbonates; it is the free carbonic acid, however, that imparts to them their particular properties.

Sulphureous waters are those which contain sulphuretted hydrogen. These are very easily distinguished by their odour, and by their rendering a solution of a salt of lead black, or by causing a piece of silver, when immersed in them, to acquire a dark colour. Besides sulphuretted hydrogen, they in general contain alkaline and earthy sulphates and muriates. The sulphureous waters may be subdivided into two kinds; 1st, Those which have sulphuretted hydrogen in its free state: 2d, Those in which it exists in union with an alkali or an earth.

Chalybeate waters are those which have iron as an ingredient. These are known by their peculiar taste, and by their becoming black when mixed with an infusion of nutgalls. The chalybeate waters are of different kinds; sometimes the iron is combined with sulphuric acid, more frequently it is in union with carbonic acid; this may be just in sufficient quantity to hold the iron in solution, or it may be in excess, in which case, besides chalybeate, the water possesses acid properties, forming what is called an acidulous chalybeate water.

Saline waters are those which contain the saline ingredients generally found in mineral waters, but which have not carbonic acid in excess, and are free from sulphuretted hydrogen and iron, or contain them in very trifling quantity. Saline waters may be subdivided into four kinds.

(*a*) Alkaline waters, or those which contain alkali in its free state, or combined with carbonic acid, and which render the vegetable blues green.

(*b*) Hard waters, or those which contain carbonate or sulphate of lime.

(*c*) Salt waters, or those in which muriate of soda abounds.

(*d*) Purgative waters, or those which contain principally sulphate of magnesia.

The following Table shows the component parts of a Gallon of the principal Mineral Waters.

Of the Chemical Analysis of Mineral Waters.

In the analysis of mineral waters the first object is, to ascertain the different substances which they contain; the next is, to find out the quantity of each ingredient; and lastly, to ascertain in what state of combination

* And carbonate of soda.

† And sulphate of magnesia.

‡ This is given by Dr. Murray, according to the mode of analysis recommended by him, to be afterwards stated.

these substances exist, and what are the proportions of the different compounds which they form.

Of the Method of detecting the different Substances contained in Mineral Waters.

The substances employed in detecting the ingredients of mineral waters, are called *Tests*. By the addition of these to the waters, different appearances are produced, by which we are enabled to judge of the presence of those bodies which they contain. The tests required must be very delicate, as the quantity of matter to be indicated, is often very small. In many cases, it is necessary to evaporate the fluid to a certain extent, before some of the substances which are present can be detected.

34. *Carbonic acid*, in its free state, is easily detected. Water, when it contains this acid, sparkles when poured from one vessel to another. When it is added to an infusion of litmus, the blue is converted to red, and on boiling the fluid, or by exposing it for some time to the air, the original blue is restored. If the water be boiled, and then added to the litmus, no change in the colour takes place.

Water containing carbonic acid gives a white precipitate when added to lime water, which is soluble in nitric and muriatic acids. When also an excess of carbonic acid water is added to the precipitate formed with lime water, the precipitate is dissolved, and by boiling the fluid, the superabundant carbonic acid is expelled, and the carbonate of lime is again deposited.

35. *Sulphuretted hydrogen.* Water containing this acid reddens litmus, and when the fluid is exposed to the air for some time, or is boiled, the blue is restored. In this respect it resembles carbonic acid, and may therefore be mistaken for it. There is, however, little danger of this, as sulphuretted hydrogen is easily distinguished by other tests. Sulphuretted hydrogen is known by the odour which it emits. When water containing it is added to a solution of a salt of lead, as the acetate, it throws down a black precipitate. A piece of silver when immersed in it acquires a dark colour.

36. To ascertain the nature of any other gaseous fluids besides carbonic acid and sulphuretted hydrogen, a retort must be filled about two-thirds with the water, and the mouth of it made to terminate under a jar, filled with mercury and inverted in the mercurial trough. The water is then to be boiled for a quarter of an hour, by which the gaseous fluids will pass over into the jar. The elastic fluids which are given off, may be common air, oxygen, nitrogen, carbonic acid, sulphuretted hydrogen, and sulphurous acid; the two last, however, never exist in the same water.

37. If *sulphuretted hydrogen* be present, it must be removed by the addition of nitric acid to the water, which will absorb the elastic fluid.

38. If the gaseous fluid contain *sulphurous acid*, on the introduction of the peroxide of lead its volume will be diminished.

39. The presence of *carbonic acid* may be known by admitting a solution of potassa, which will absorb it.

40. *Oxygen* may be discovered by exposing the residual air to the action of the solution of sulphuretted hydro-sulphuret of potassa or of lime, which will absorb the *oxygen*; if what remains extinguish the flame of a candle, it is *nitrogen*.

41. The *fixed acids* rarely exist in their free state in mineral waters. If they do, the water gives a red colour to litmus, which does not disappear on boiling the fluid. The acids when in combination are easily detected.

42. *Sulphuric acid* is detected by the addition of baryta, which gives a white precipitate with any fluid containing a sulphate.

Other tests indicate the presence of sulphuric acid, as nitrate of lead. This, however, is fallacious, as it gives precipitates with other substances besides sulphuric acid.

In using baryta as the test of sulphuric acid, we must be aware that carbonic acid likewise gives a precipitate with baryta; but this is easily distinguished from that occasioned by sulphuric acid, the latter being insoluble, the former being soluble in muriatic and nitric acids.

Nitrate or muriate of baryta is, in general, preferred to the pure earth, as sulphuric acid is by them more easily separated from the substance with which it is in union, owing to the decomposition of the sulphate being effected by double elective attraction. The most powerful of the barytic salts is the muriate. According to Bergman this indicates the presence of sulphuric acid, though diluted with a million parts of water.

43. *Muriatic acid* is easily detected by nitrate of silver, which gives a white precipitate, with water containing a muriate. Nitrate of silver, however, gives a white precipitate, when added to water containing free alkali or sulphuric acid. If the former be present, it must be saturated with nitric acid; if the latter exist in the fluid, it must be precipitated by baryta or its nitrate. The salt of silver likewise gives a white precipitate with carbonic acid. This, however, is soluble in nitric acid, while that occasioned by the muriatic is not. If the water contain carbonic acid, previous to adding the nitrate of silver, it will be necessary to expel it by the addition of nitric acid and boiling.

44. *Boracic acid* is detected by means of a salt of lead, with which it forms a white precipitate; but as lead is precipitated by sulphuric and muriatic acids, it is necessary to remove these by means of the acetates of strontia and silver, having previously saturated the alkalies and earths with acetic acid.

45. The presence of an *alkali*, or an *alkaline earth*, in its free state, may be known by the green colour which it imparts to the vegetable blues, or by changing the colour of turmeric to brown. This test, however, does not point out the particular substance present. We must, therefore, have recourse to other means.

46. *Potassa* and *soda* may be distinguished from each other by two different tests, muriate of platinum and tartaric acid.

When the solution of muriate of platinum is added to water containing potassa, a yellowish precipitate falls, which is not the case when soda only is present.

47. When tartaric acid is added to a fluid containing potassa, at first there is no visible change; but when the acid is added in excess, a white precipitate is formed, provided the water be not in very large quantity compared to that of the alkali. The precipitate formed is soluble in nitric and muriatic acids; but tartaric acid, when added to a fluid containing soda, does not occasion any perceptible change.

In using tartaric acid as a test of potassa, the fluid must be concentrated by evaporation, otherwise the supertartrate of potassa is not deposited, being soluble in a large quantity of water. These tests also distinguish potassa from soda, when they are in combination with an acid.

48. *Lime*, in union with carbonic acid, is easily detected by boiling the fluid, by which means the superabundant carbonic acid is driven off, and the carbonate of lime is deposited, the precipitate being soluble in nitric and muriatic acids, and also by the addition of water containing carbonic acid. Lime, however, frequently exists combined with a fixed acid. When this is the case, no change takes place on boiling the fluid. The most delicate test of the presence of lime, when in this state, is oxalic acid. This, when added to water containing a salt of lime, gives a white precipitate, which is soluble in nitric and muriatic acids. In using oxalic acid as a test of lime, we may employ either the acid pure, or in combination with ammonia. The latter, though not the most delicate, is the best, as the alkali combines with the acid with which the lime is in union, and prevents it from acting on the precipitate. If any free acid be present in the water, it must be neutralised by ammonia, and, if we have reason to suspect the presence of baryta, it must be precipitated by sulphuric acid. Oxalic acid, it must be remarked, likewise occasions a precipitate with magnesia; but the precipitation of this earth does not take place for many hours, while that with lime occurs the moment that the oxalate is added.

49. *Baryta* may be detected by the addition of sulphuric acid, with which it gives a white precipitate, not soluble in nitric or muriatic acid. Previous to the addition of the acid, it is necessary to remove the lime, as it may, if present in considerable quantity, also occasion a white precipitate with it.

50. *Magnesia* is precipitated by the alkalies and by lime. These tests, however, are liable to fallacy. Thus, if carbonic acid be present, and we employ lime as the test, carbonate of lime will be precipitated. If the water contain sulphuric acid, sulphate of lime may likewise be formed and deposited. When ammonia is used as the test of magnesia, if carbonic acid be present, carbonate of ammonia will be generated, which, if the water contain a salt of lime, will be decomposed, and carbonate of lime will be precipitated. In detecting magnesia, then, if we suspect the presence of the other substances mentioned, nitric acid must be added, to decompose any carbonate, and the fluid boiled. The sulphuric acid must then be precipitated by baryta.

The alkalies and lime-water also precipitate alumina: this is another source of error, in using those bodies as a test of magnesia. Alumina, however, rarely occurs in mineral waters; if it does, and is precipitated along with the magnesia, it is easily separated from that earth. For this purpose, after washing the precipitate, it must be boiled in a solution of potassa, by which the alumina is dissolved, and the magnesia is left. Or, the precipitate may be dissolved in strong muriatic acid, and an alkaline carbonate added to the solution; the precipitate which is thrown down by this must be washed and dried at the temperature of about 100. Diluted muriatic acid is then to be poured on it, which will dissolve the magnesia, but will not act on the alumina.

51. *Alumina* is detected by the methods just described for discovering the presence of magnesia. Succinic acid, or its compound with ammonia, is another test of alumina, as it precipitates this earth, but does not affect magnesia; the former methods are, however, generally employed.

52. *Silica* may be discovered by evaporating the water to dryness, and adding muriatic acid to the residue. If silica be present, it will be left undissolved, and will, when mixed with a small quantity of soda, and subjected to a strong heat, form a glass; if the quantity of soda be greater, the substance formed will be soluble in water, and the solution on the addition of an acid will deposit the silica.

53 *Iron* is very easily detected in mineral waters. The triple prussiate (*ferro-cyanate*,) of potassa, when added to the solution of a salt of iron, gives a blue precipitate. This, however, does not take place, if the water contain any uncombined alkali. If this be present, therefore, it must be neutralized, before adding the prussiate. If the iron also be in the state of protoxid, which is seldom the case, the precipitate is white; it is necessary, therefore, in some instances, before using the prussiate, to add a small quantity of muriatic acid, by which the protoxide will be converted to peroxide, and will give the blue precipitate with the prussiate.

Some have objected to this test, as the prussiate itself contains iron, and, if not carefully prepared, will give a blue precipitate when added to a mineral water, which contains an uncombined acid, even though iron be not present. This source of fallacy may be obviated, by ascertaining if the prussiate gives a blue tinge to diluted muriatic acid. If it do, it must be successively crystallized, till it does not give the blue colour with the acid; it may then be employed as an accurate test of the presence of iron.

Infusion of nutgalls is another very delicate test of iron. When this is added to a mineral water, containing a salt of iron with the protoxid, the fluid acquires a dark colour. This test is so delicate, that if one grain of the sulphate be dissolved in fifteen gallons of water, the solution will acquire a dark tinge on the addition of the infusion. In this case, however, the blackness does not appear for some days.

The colour produced by nutgalls, and the delicacy of it as a test, are affected by the presence of other substances. An earthy carbonate makes the test much more delicate; thus the infusion will detect a minute quantity of iron when dissolved in common well-water, which contains carbonate of lime, but will not indicate its presence, when dissolved in the same quantity of distilled water. An alkaline carbonate makes the colour dark violet; and, if sulphate of lime be present, the precipitate is at first white, and afterwards becomes black

54. *Copper* may be detected by evaporating the fluid to dryness, dissolving the residue in nitric acid, and adding ammonia to the solution. If this metal be present, it will acquire a blue colour.

Of the Methods employed in ascertaining the quantity of the different ingredients in Mineral Waters.

55. To ascertain the quantity of the *oxygen*, *nitrogen*, and *carbonic acid*, which water contains, the method already mentioned for ascertaining the nature of the elastic fluids must be followed. (36) The quantity of *oxygen* will be known by the use of the solution of the sulphuretted hydro-sulphuret of potassa, that of the *carbonic acid* by means of potassa having previously re-

moved the sulphuretted hydrogen by the addition of nitric acid to the water in the jar. If the elastic fluid contain *sulphurous acid*, its quantity will be ascertained by introducing the peroxid of lead; the amount of the absorption occasioned by the test for each will indicate its proportion, following the usual precautions of bringing the elastic fluids to the mean temperature and pressure.

56. The quantity of *sulphuretted hydrogen* cannot be found out by boiling the fluid, as the whole of the gas is not in this way expelled. The method recommended by Kirwan, is to fill three-fourths of a jar with the water, and invert it in a water trough; then throw up nitric oxide as long as red fumes appear. By this the sulphuretted hydrogen is decomposed, and the sulphur is deposited. This must be collected, and dried with a gentle heat. Each grain of it indicates 3 cubic inches of sulphuretted hydrogen.

The quantity of the saline ingredients in a mineral water may be ascertained either by finding its specific gravity, or by evaporation.

Mr. Kirwan has given an easy rule, by which we can ascertain the proportion of the saline matter by the specific gravity of the fluid. The specific gravity of distilled water must be subtracted from that of the mineral water, and the remainder must be multiplied by 1.4. The product is the quantity of saline matter, in a quantity of the mineral matter, equivalent to the number denoting the specific gravity of the distilled water. Thus, suppose the specific gravity of distilled water 1000, and that of the mineral water 1100, then $1100 - 1000 \times 1.4 = 140.00$ and $1000 : 140.00 :: 100 : 14.000$; the fluid therefore contains 14 per cent. of saline matter, supposing this free of its water of crystallization.

58. The other method of ascertaining the quantity of saline matter, is to evaporate slowly by heat, a certain quantity of the fluid to dryness, and expose the residue to a temperature sufficient to drive off the whole of the water; the residue indicates the quantity of saline ingredients.

59. *Sulphuric acid*. The quantity of sulphuric acid present, is ascertained by exposing to a red heat the precipitate given by baryta, (42.); 100 gr. of it are equivalent to 34 of real sulphuric acid.

60. *Boracic acid*. To find the quantity of boracic acid, add sulphuric acid to the precipitate given with the acetate of lead (44.) filter the fluid, and evaporate it to dryness. Dissolve the residue in alcohol, and again evaporate. The residue is boracic acid.

61. *Muriatic acid*. The quantity of muriatic acid is known by igniting the precipitate afforded by the salt of silver, (43.) 100 gr. are equivalent to 19 of muriatic acid.

62. *Lime*. The proportion of lime is ascertained by drying by a gentle heat the precipitate thrown down by oxalic acid (48.) 100 gr. = 44 lime. Or, the precipitate may be exposed to a high temperature, and then converted to sulphate by the addition of sulphuric acid. 100 gr. of this, after ignition, are equivalent to 41.5 lime.

63. *Magnesia* and *alumina*. By boiling in potassa the precipitate of magnesia and alumina thrown down by potassa, (56.) the magnesia will be left, and, after being washed and dried, must be weighed. By adding muriatic acid to the solution of the alumina, and then subcarbonate of potassa, the earth will be precipitated. It must be washed, exposed to a red heat, and weighed.

64. *Iron*. Different methods are recommended for ascertaining the quantity of iron or its oxides.

Some chemists have objected to the prussiate of potassa, as an accurate method of indicating the quantity of iron, as this salt itself contains iron, which is thrown down, and forms part of the precipitate. This source of error may be avoided, by ascertaining the quantity of iron that a given weight of the prussiate, carefully prepared, (53.) contains. This is done by exposing 100 grains of it to heat, in an open vessel, by which the oxide of the metal is obtained. In using this test then, to find out the quantity of iron in the mineral water, the quantity of prussiate employed must be ascertained, and the weight of the oxide, which this is known to contain, must be subtracted from the weight of the precipitate. 100 grains of the blue precipitate, dried by a gentle heat, according to Porret = 34.23 per oxide of the metal.

Another method of ascertaining the quantity of iron, is to bring the metal to a high state of oxidation, by exposing it for some time, in an open vessel, to a strong heat, in which condition it is insoluble in nitric acid. By pouring this acid on the residue, the oxide of iron is left, while the other substances are dissolved.

Of the Methods followed for ascertaining the state of Combination in which the different ingredients exist in Mineral Waters.

Very different opinions are entertained with respect to the state of combination in which the different ingredients exist in mineral waters. Some chemists suppose that they form binary compounds; others, on the contrary, imagine, that they are all more or less united with each other. Thus, if there be an acid, an alkali, and an earth together, it is not supposed that these are in the state of binary compounds, forming a salt of the alkali and another of the earth, but that they are combined so as to form a triple salt. The former is the more prevalent opinion. Some chemists assert also, that the salts procured by the evaporation of the fluid are those which exist in solution, while others maintain, that during the evaporation, new compounds are formed, so that we do not by this means procure those which the water in its natural state contains. This assertion is strengthened by the fact, that some salts exist together in solution, when much diluted, which decompose each other when the solution is concentrated. During the evaporation of a mineral water, therefore, new affinities may exert their influence, and salts, different from those which exist in the water, may be obtained. The experiments of Dr. Murray, immediately to be stated, tend to confirm this opinion.

According to the different opinions which are entertained, with respect to the state of combination of the ingredients, different methods have been recommended for ascertaining the compounds which mineral waters contain. The first of these is by the slow evaporation of the fluid.

By slowly evaporating the water, the different saline substances may be obtained separately. For this purpose, the evaporation is continued till a pellicle appear on the surface; the liquid is then allowed to cool slowly; by this the earthy carbonates will be deposited. After these are removed, by a farther evaporation and cooling, the sulphate of lime will be separated. The alkaline neutral salts, and the sulphate of magnesia, will be deposited after the next evaporation. The muriates of lime and magnesia will remain, and will be obtained by evaporation to dryness.

If the water contain carbonate of iron, it must, after having been evaporated to a certain extent, be exposed to the air, by which the iron passes to a higher state of oxidation, and is no longer soluble in the acid; it is therefore precipitated. The earthy carbonates are likewise separated by this means. After these have been deposited, the fluid may be evaporated to dryness, and a small quantity of water poured on the residue, by which some of the salts will be dissolved, and the others will be left. Sometimes the water is evaporated to dryness, and the residue is exposed to the air, by which the deliquescent salts, as the muriates of lime and magnesia, absorb moisture, and are dissolved. What is left undissolved, may be afterwards subjected to the action of water. Occasionally, after evaporating the fluid to dryness, the residue is subjected to the action of successive portions of water, by which the salts are taken up in the order of their solubility.

The different quantities of saline substances, thus obtained by these various methods, must be dissolved in separate portions of water, that by slow evaporation the salts which are mixed may be separated.

Another method of ascertaining the nature of the salts in mineral waters, is by means of alcohol. Some of the salts contained in mineral waters are soluble, while others are insoluble in alcohol. By a particular management, the different saline substances may be obtained, either in solution, or by deposition from the water.

When alcohol is added to water, containing saline matter, the attraction between the two fluids is so strong, that those salts which are insoluble in alcohol are separated from the water, and are deposited; thus, if a mineral water be mixed with an equal quantity of alcohol, sulphate of lime, if present, will be precipitated; if more alcohol be added to the fluid, the sulphate of soda will be separated; by adding another quantity of alcohol, muriate of soda will be thrown down. This method of employing alcohol in the analysis of mineral waters, was first pointed out by Boulduc.

Lavoisier has recommended another way of using alcohol. For this purpose the mineral water is to be evaporated to dryness, and eight parts of alcohol poured on the residue, by which some of the salts only will be dissolved. By adding alcohol, diluted with a little water, to the undissolved matter, another portion of the saline substance is taken up. In this way, by using alcohol of different specific gravities successively, the different saline compounds may be obtained separately; thus, when strong alcohol is poured on the residue of the evaporation of a mineral water, muriates of lime and magnesia, if present, will be dissolved. By diluting the next portion of alcohol with a little water, muriate of soda will be taken up, the carbonates and sulphates being left.

Occasionally these two methods of employing alcohol are joined; thus the mineral water is evaporated to dryness, and alcohol is poured on the residue, by which the muriates of lime and magnesia are dissolved. When the solution is completed, the fluid is filtered, and a small quantity of cold water is added to the undissolved matter, by which more of the saline substance is taken up. What remains is then boiled in a large quantity of water; by the application of the tests to the alcoholic and watery solutions, the different substances which they contain will be discovered.

It is supposed that considerable information may be derived with respect to the composition of mineral waters, from the knowledge of what are called incompatible salts. When a certain class of salts have been procured from a mineral water, it is generally inferred that other salts of a peculiar nature do not exist in it. Thus it is known that the alkaline carbonates decompose the sulphates and muriates of the earths and metals; these, therefore, it is supposed, are not contained in the same water. The same is the case with the alkaline sulphates, and the muriates of the earths, and with sulphate of magnesia and muriate of lime; these decomposing each other. Much reliance cannot however be placed in this conclusion, because salts which are known to decompose each other, when their solutions are not much diluted, exist together in solution, if a large quantity of the solvent be present, as has been fully proved by the analysis of different mineral waters.

By the different methods which have been pointed out, the different saline compounds of a mineral water may be procured; of course the mode to be followed must differ according to the ingredients, which by the use of the tests we have discovered in it. When the water contains a great variety of ingredients, the methods recommended require to be varied considerably before we can with certainty infer the presence of the different compounds. In addition to the evaporation of the fluid, and the use of alcohol, other substances must be employed to separate the saline bodies from each other, so that there may be no doubt of their nature. The various modes followed have been particularly illustrated by Kirwan, in his *Essay on Mineral Waters*.

65. *Alkaline nitrates*. To procure the alkaline nitrates, the water must first be freed of the sulphuric and muriatic acids, by means of acetate of baryta and acetate of silver, and then, after filtration, evaporated to dryness. Alcohol must be poured on the residue, which will dissolve part of it, and leave the nitrates probably mixed with acetate of lime. If this be present, the lime may be precipitated by dissolving the residue in water, and adding carbonate of magnesia to the solution. After this the fluid must be filtered, evaporated to dryness, and the residue digested in alcohol, by which the nitrates will be left. The alkali present may be known by the use of the tests. (46, 47.)

66. *Nitrate of lime*. To procure the nitrate of lime, the fluid must be evaporated, but the evaporation must be stopped before any deposition takes place. Alcohol is then to be added, which precipitates the sulphates. The fluid, after filtration, must be boiled, and the muriatic acid precipitated by acetate of silver. The fluid must be again filtered, evaporated to dryness, and the residue treated with alcohol. The solution then contains the acetates, and probably nitrate of lime. If present, the lime may be precipitated by oxalate of ammonia.

67. *Nitrate of magnesia*. Remove the sulphuric and muriatic acids, (65.) and evaporate to dryness. Digest the residue in alcohol, evaporate the solution to dryness, and dissolve what is left in water; the solution contains the acetates, and perhaps nitrate of magnesia. To this potassa must be added; if magnesia be present, a precipitate will fall. After this the solution must be

filtered, evaporated to dryness, and digested in alcohol; if any of it remain undissolved, it is nitrate of potassa, the nitric acid of which must have been set free from the magnesia.

68. *Alkaline carbonates.* The presence of the carbonates of the alkalies may be known, by the change effected on the vegetable colours. Should these changes not be permanent, we conclude that they are produced by ammonia. If permanent, then they are occasioned by the fixed alkalies. Whether potassa or soda, may be known by the proper tests. (46, 47.)

69. *The super-carbonates of the earths and iron* are detected by boiling the fluid, by which the excess of acid is expelled, and the carbonate precipitated. The substance precipitated may be known by dissolving the residue in muriatic acid, and applying the tests. (48, 50, 53.)

70. *Sulphates of potassa and soda.* To procure the sulphate of soda, evaporate the fluid to about one half of its bulk, and add lime-water, till all precipitation cease; this will throw down the earths, except lime. After this evaporate the fluid a little, and add alcohol, and then oxalic acid. After filtration add nitrate of lime. If a precipitate fall, then the solution contains sulphate of soda or potassa. These may be distinguished from each other by the tests of potassa, (46, 47.) or by adding to the solution acetate of baryta, which will throw down the sulphuric acid. Evaporate the fluid to dryness, and dissolve the residue in alcohol. Again evaporate to dryness, and expose the residue to the air. If it be acetate of potassa it will deliquesce, if acetate of soda it will effloresce.

71. *Sulphate of lime* may be detected by evaporating the water till a deposit be formed. If this be soluble in a large quantity of water, and the solution give a precipitate with baryta, not soluble in nitric acid, and also with oxalic acid, then it is sulphate of lime.

72. *Sulphate of magnesia* may be procured by the addition of hydro-sulphuret of strontia, which, if there be no free acid or sulphate of alumina present, gives a precipitate only with sulphate of magnesia. If sulphate of lime be present, a precipitate will be formed, but not for twenty-four hours after the addition of the hydro-sulphuret.

73. *Sulphate of iron.* When iron is in union with sulphuric acid, it is known by the tests of this metal detecting it in the water after it has been boiled. (53.)

74. *Muriate of soda.* Precipitate the sulphates by alcohol and nitrate of baryta. After filtration, decompose the nitrates and muriates by sulphuric acid, and boil the fluid. Again add alcohol and baryta, to precipitate the sulphates formed. The fluid then contains only alkaline nitrates and muriates. If the last be present, they must be decomposed by the addition of acetate of silver, by which acetates of the alkalies will be formed. These may be known by the methods recommended. (46, 47.)

75. *Muriate of lime.* Deprive the water of sulphates, by evaporation, and the addition of alcohol and nitrate of baryta; after filtration evaporate to dryness, and digest the residue in alcohol. Evaporate the solution, and subject the residue to the action of water. If the solution afford precipitates with oxalic acid, and with acetate of silver, then it contains muriatic acid and lime. But these may not be in union with each other, as the solution may contain magnesia or alumina. To ascertain if this be the case, add ammonia; if a precipitate fall, it contains magnesia. If the fluid give a precipitate on the addition of carbonate of lime, then it contains alumina, either of which may perhaps be in union with the muriatic acid. If neither of these earths be present, then the fluid contains muriate of lime. Suppose one or both present, to find out if the acid be in union with the lime, precipitate the earth by oxalic acid, filter, and subject the fluid to distillation, collecting the product in a cool receiver containing a little water. If this give a precipitate with nitrate of silver, then it contains muriatic acid, which was set free from the lime by the addition of the oxalic acid: or the solution may be evaporated to dryness, and exposed to a red heat for an hour; if it contain muriate of lime and magnesia in union with nitric acid, the latter salt will be decomposed. On exposing the residue to the air, the presence of muriate of lime will be known by its attracting moisture.

76. *Muriate of Magnesia.* Separate the sulphuric acid by baryta, filter, evaporate to dryness, and dissolve the residue in alcohol. Again evaporate and dissolve in water. If muriate of magnesia be present, it will be dissolved, and if carbonate of lime cause no precipitation, and if no precipitate be formed by evaporation and the addition of sulphuric acid and alcohol, then the fluid contains only muriatic acid and magnesia, in union with each other. But, along with these, there may be nitric acid, and lime or alumina, or both. We must therefore determine if, in this case, the muriatic acid and magnesia be in combination with each other. For this purpose, precipitate the lime by evaporation, and by the addition of sulphuric acid and alcohol, and drive off the acid with which it was in union, by boiling; then add oxalic acid, and the magnesia will be thrown down in the course of 24 hours. Subject the fluid to distillation, and ascertain if it contain muriatic acid, (43); if it does, then the fluid contained muriate of magnesia.

77. *Muriate of alumina.* If any free alkali be present, saturate it with nitric acid; then separate the sulphuric acid by nitrate of baryta. If the fluid after this give a precipitate with carbonate of lime, it contains muriate of alumina, or muriate of iron. Whether it be alumina or iron, or perhaps both, may be known by dissolving the precipitate in muriatic acid, and applying the tests of these substances, (50, 53.)

Of the Methods followed for ascertaining the quantities of the different compounds contained in Mineral Waters.

In ascertaining the quantities of the different compounds in mineral waters, the steps to be followed must, of course, vary in every different case, according to the substances contained in the water. A few examples will suffice to illustrate the methods employed.

In fixing the quantities of the different compounds, we may state them either in their crystallized condition, in which case they generally contain water; but it is better, if possible, to reduce them to dryness. This is done by exposing them to a red heat for some time, by which the whole of the water is driven off. Some of the salts which we procure undergo decomposition when subjected to a strong heat; such is the case with the carbonates and some others. We cannot, therefore, in this way, ascertain their quantity in the dry, or, as it is called, real state. We may do this, however, by decomposing them, ascertaining the quantity of the product, and finding how much of the decomposed salts is necessary to form these products.

78. *Nitrate of Potassa.* To ascertain the quantity of nitrate of potassa, suppose it exists in water, along with sulphates, and muriates of the alkalies, decompose these by the acetates of baryta and silver. After filtration, evaporate to dryness, and digest the residue in alcohol, which will dissolve the acetates formed, and will leave the nitrate.

79. *Nitrate of lime.* Suppose this contained in the water along with muriates of soda and lime, evaporate to dryness, and digest the residue in alcohol, which will dissolve the earthy salts, and leave the muriate of soda. Evaporate the alcoholic solution to dryness, and weigh the residue, after being dried; then dissolve it in water, and ascertain the quantity of muriatic acid, by precipitation with nitrate of silver, (43.); this will give the quantity of the muriate of lime, which, subtracted from the weight of the residue, leaves that of the nitrate of lime.

80 *Carbonates.* By boiling the fluid after it has been deprived of its sulphuretted hydrogen, (56.) the carbonates are precipitated, probably mixed with sulphate of lime. The carbonates may be that of lime, magnesia, alumina, or iron; the precipitate must therefore be digested in diluted muriatic acid, which will dissolve them all, except the alumina and the sulphate of lime. If any thing be left undissolved, it must be exposed to a red heat, and weighed; it is then to be boiled in the solution of subcarbonate of soda, and muriatic acid added, to saturate the alkali. By boiling the fluid, carbonate of lime, and alumina, if present, will be precipitated. Digest the precipitate in acetic acid, by which the alumina will be left; this, after being dried, will give the weight of the earth, and its weight, subtracted from that of the residue, the quantity of the sulphate ol lime.

81. *Carbonate of iron.* The muriatic solution may contain lime, magnesia, and iron. By the addition of ammonia, the iron and part of the magnesia will be precipitated. By digesting the precipitate in acetic acid, the magnesia will be dissolved, and the iron will be left. It must be dissolved in muriatic acid, and precipitated by the addition of sub-carbonate of soda. The precipitate, after boiling the fluid, must be washed, dried, and weighed, which gives the weight of the carbonate of iron.

82. *Carbonate of Lime.* The acetic solution of the magnesia must be mixed with the muriatic solution; to this, sulphuric acid must be added, and the fluid evaporated, and the sulphate of lime will be deposited. After being dried, it must be weighed, and its equivalent of carbonate of lime ascertained.

83. *Carbonate of Magnesia.* By the addition of subcarbonate of soda to the solution, the carbonate of magnesia will be precipitated. It must be dried and weighed The solution, however, still contains sulphate of lime, and carbonate of magnesia. It must therefore be evaporated to dryness, and the residue washed with water, which will dissolve the sulphate, and leave the carbonate. The weight of the latter of these must be added to that of the carbonate formerly procured. The solution of the sulphate must be evaporated to dryness, and the residue ignited, and the equivalent of carbonate of lime added to that already mentioned.

84. *Alkaline Sulphates.* The quantity of the alkaline sulphates may be ascertained, by freeing the water of the other sulphates, (70.) and then adding the solution of acetate of baryta. 100 grains of the precipitate are equivalent to 74.8 of dry sulphate of potassa, and to 61.2 of dry sulphate of soda.

85. *Sulphate of Lime.* Add nitric acid, to decompose the carbonates, boil the fluid, and add weak alcohol, the sulphate of lime will be precipitated. It must be then ignited and weighed.

86. *Sulphate of Magnesia.* If this be the only sulphate present, its quantity may be known by precipitating the sulphuric acid, and ascertaining the weight of the sulphate of baryta, 100 grains of which = 51 of the sulphate of magnesia. If sulphate of lime be likewise in solution, precipitate the lime by carbonate of magnesia, and weigh the precipitate; then throw down the sulphuric acid, and ascertain its quantity; subtract from it that which belongs to the lime, obtained by the former precipitation; the remainder gives the quantity of sulphate of magnesia, 100 of acid uniting with 50 of magnesia. If the fluid contain sulphate of magnesia and sulphate of soda, add soda, and the magnesia will be precipitated. Dry it and weigh it. 100 = 300 grains of dry sulphate of magnesia. If the fluid contain these three sulphates, add soda, by which the lime and magnesia will be precipitated. Dissolve the precipitate in diluted sulphuric acid, and evaporate to dryness; wash the residue with a little cold water, which will dissolve the sulphate of magnesia, and leave the sulphate of lime. Evaporate the solution, and weigh the residue; this is the weight of the sulphate of magnesia, the weight of the undissolved matter is that of the sulphate of lime. Should the water also contain sulphate of alumina, the precipitate given by the soda must be treated with acetic acid, which will dissolve the magnesia; the magnesia may then be precipitated by soda. If sulphate of iron be present, expose the fluid to the air for some days, and add alumina, the oxide of iron, and the sulphate of alumina are precipitated, and the sulphate of magnesia is left, and may be procured as above.

87. *Sulphate of iron.* Having ascertained, by boiling, that the iron is not in union with carbonic acid, precipitate the iron, (53.) and infer the quantity of sulphate.

88. *Muriates.* Suppose that the carbonates are thrown down by boiling, and that muriates of lime, magnesia, and alumina are present, add baryta, by which the whole of the three earths will be precipitated. Dissolve the precipitate in muriatic acid, and then ascertain, by the tests, (48, 50. 51,) the quantity of each earth, and infer that of the muriate of each.

100 lime = 196 dried muriate of lime.
100 magnesia = 238.3 dried muriate of magnesia.
100 alumina = 317.6 dried muriate of alumina.

89. When the sulphates are present with the muriates, the latter must be separated by evaporation to dryness, and treating the residue with alcohol, which will dissolve the muriates; then proceed as above. If sulphate of lime only be present, throw down the sulphuric acid by baryta, and ascertain its quantity, filter the fluid, and proceed as (88.) subtracting the quantity of the sulphate of lime from the lime obtained by precipitation, the remainder belongs to the muriatic acid.

90. When sulphates of lime and magnesia, and the muriates of soda, magnesia, and alumina are present, throw down the lime and alumina by carbonate of mag-

nesia, and ascertain the quantity of lime which will give that of the sulphate, (62.) Find out the quantity of sulphuric acid by baryta; subtract the quantity which we know was in union with the lime; the remainder will belong to the magnesia, and will shew the quantity of the sulphate of that earth.

91. To another portion of the water, add lime-water, which will throw down the magnesia and alumina; ascertain the proportions of these, (63.) that of the alumina will shew the quantity of muriate of alumina. (88) Subtract from the weight of magnesia that which we know to belong to sulphuric acid, the remainder will indicate the quantity of muriate of magnesia. By adding baryta, and then carbonic acid, to the fluid, the sulphuric acid and lime wlll be thrown down, and the quantity of muriate of soda may be ascertained by evaporation.

Such are the various methods which have been recommended for ascertaining the nature and quantity of the different compounds contained in mineral waters. It is doubtful, however, if, by these means, we arrive at the exact quantity of the different substances, and it is still more doubtful, if we really procure them in the state of combination in which they exist in the mineral water.

It has been already remarked, that little reliance can be placed in the knowledge derived from incompatible salts, as some salts which decompose each other, when their solutions are concentrated, exist together in solution, if a large quantity of the solvent be present.

This subject has been lately particularly investigated by Dr. Murray. From numerous experiments he has found, that salts, different from those known to be in solution, can be obtained by the evaporation of the solvent. This has induced him to call in question the accuracy of the modes of analysis explained, and to propose another method of determining the state of combination of the ingredients of mineral waters. See *Transactions of the Royal Society of Edinburgh*, vol. vii.

According to Dr. Murray, two views may be entertained with respect to the state of combination of saline substances dissolved in water. When we have two acids and two bases contained in this fluid, these may be united by the pure force of the affinity, and those substances between which the most powerful attraction is exerted, will be combined. Thus, suppose muriatic and sulphuric acids, and soda and lime, be dissolved in the same fluid, if the pure force of the affinity operate, the compounds formed will be sulphate of lime and muriate of soda. We know, however, that affinity is much influenced by external circumstances; when, therefore, any of these operate, compounds may be formed, different from those which the pure force of the affinity would generate. When the above mentioned substances are dissolved in a small quantity of water, the compounds stated are formed, but if the quantity of fluid be great, it is possible that it may, by its quantity, influence the affinity, and other compounds will be the result. When the quantity of fluid is small, or when we evaporate the fluid by which the cohesion is allowed to operate, we find invariably that the compounds existing in the water are those, between the particles of which the strongest cohesion is exerted. The reverse, it is probable, is the case, when the quantity of water is great, the quantity of the fluid causing the formation of substances, between the particles of which there is little power of cohesion, so that the most soluble salts are formed. When the above-mentioned substances, then, are dissolved in a large quantity of water, instead of sulphate of lime, and muriate of soda, we will have muriate of lime and sulphate of soda. The same it is supposed is the case, when carbonate of lime and muriate of soda are procured by evaporation, these salts having been formed by the decomposition of the carbonate of soda and muriate of lime, which were the salts that existed in the water, when a large quantity of the solvent was present. If carbonate of magnesia and muriate of soda be procured, the salts in solution were probably carbonate of soda and muriate of magnesia. In all mineral waters, the quantity of fluid is large in proportion to the saline ingredients; these, therefore, are probably united, so as to form the most soluble salts.

This view of the state of combination of the substances in solution in a large quantity of fluid, is supported by several facts. Thus, by the evaporation of some mineral waters, a quantity of a substance sparingly soluble, as of sulphate of lime, is obtained in greater quantity than we know water can hold in solution. It must therefore have been formed during the evaporation by the operation of new affinities. It usually happens also, that when this is the case, the deposition of the substance commences at a certain stage of the evaporation, and that, after the fluid is farther evaporated, the deposition ceases. At this point, then, it would appear that the substance deposited begins to be formed.

Another strong argument in favour of the opinion of Dr. Murray is, that different products are obtained from a mineral water according to the mode of analysis. Sea-water, for instance, by slow evaporation, affords muriate of soda, muriate of magnesia, and sulphate of magnesia. When the fluid is evaporated to dryness, and the residue is subjected to the action of alcohol, the products are, muriate of soda, muriate of magnesia, and sulphate of soda. It is likely, then, that during the evaporation of the fluid new affinities may exert their influence, so that salts, different from those which exist in solution, may be obtained.

Many mineral waters possess active properties, for which, however, we cannot account, on the known properties of the compounds discovered in them. Thus the Bath waters, according to the analysis by evaporation, contains in an English pint about 9 grains of sulphate of lime, 3.3 muriate of soda, 3 sulphate of soda, $\frac{8}{10}$ths of carbonate of lime, $\frac{1}{5}$th silica, and $\frac{1}{70}$th oxide of iron. These are either so inert, or in so small quantity, as to be incapable of producing any effects on the living system. According to Dr. Murray, the true component parts of the Bath water are very different. It contains muriate of lime, a substance possessed of considerable power, along with muriate of iron. The quantity of muriate of lime, equivalent to 3.3 of muriate of soda, is 3.1. A pint, therefore, of the Bath water, if the views of Murray be correct, contains 3.1 gr. of this active agent. If this be the case, we can perhaps account for its medicinal properties.

The opinions entertained by Dr. Murray, as just explained, afford another method of analysing mineral waters.

In analysing a mineral water, according to the mode recommended by Murray, we must first, by the use of the various tests already described, ascertain the different substances which it contains. We then infer that these exist in it in a state of combination, so as to form the most soluble salts.

This method of ascertaining the quantity of saline compounds in water, was previously employed by Dr.

Marcet, in his analysis of the water of the Dead Sea, published in the *Philosophical Transactions* for 1807. Dr. Marcet does not, however, state, that he supposed the ingredients were so combined as to form the most soluble salts.

Dr. Murray has given the following formula, which is applicable to almost all mineral waters.

The four classes of mineral waters, the acidulous, the sulphureous, the chalybeate, and the saline, may all be reduced under the last. By the application of caloric, the gaseous fluids are driven off from the two first, and the iron may be precipitated from the third by its proper test. The substances left after this are the same as those contained in saline mineral waters.

The substances which usually exist in saline mineral waters, are carbonic, sulphuric, and muriatic acids, with soda, lime, and magnesia. Suppose that in the water to be analysed all of these have been detected, the fluid must be evaporated, stopping the evaporation before there is any deposition from it. Muriate of baryta is then to be added, as long as any precipitate falls, carefully avoiding adding an excess. If the precipitate be soluble with effervescence in muriatic acid, it is carbonate of baryta. The weight of this gives that of the carbonic acid 100 gr. = 22 of acid. If the precipitate do not effervesce with muriatic acid, it is sulphate of baryta, 100 gr. of which = 34 of sulphuric acid. If the precipitate be partially soluble in muriatic acid, it contains both carbonate and sulphate of baryta; the proportions of each of which may be known, by weighing the precipitate, washing it with muriatic acid, and drying the residue. The weight of this gives that of the sulphate, the loss that of the carbonate of baryta. By this means the carbonic and sulphuric acids are removed, and the whole of the salts are converted to muriates. Oxalate of ammonia is next to be added to the filtered fluid. Oxalate of lime is precipitated, which, after being exposed to a strong heat, must be converted into sulphate. (62.) 100 g. = 41.5 of lime.

The filtered fluid is afterwards to be heated to about 100°, and reduced a little by evaporation. A solution of carbonate of ammonia is then to be added to it, and immediately afterwards a solution of phosphate of ammonia, continuing the addition of both as long as there is any precipitation, taking care to leave an excess of ammonia. By the addition of these substances, one part of the ammonia neutralises the muriatic acid of the muriate of magnesia, the other portion combines with the phosphoric acid and the magnesia, and forms the triple phosphate of magnesia and ammonia which is precipitated. By exposing this to a red heat for an hour it is converted into phosphate of magnesia, 100 gr. of which = 40 magnesia. After this the fluid contains muriate of soda, perhaps with muriate of ammonia. To procure the former it must be evaporated to dryness, and the residue exposed to a high temperature, 100 = 53.3 soda.

The muriatic acid in the muriate of soda obtained may be either greater or less than what was contained originally in the fluid; part of the soda may have been disengaged from the other acids, and have combined with the muriatic acid of the muriate of baryta, used in the precipitation of the sulphuric and carbonic acids. If this be the case, the acid in the muriate of soda procured will be greater than what existed in the water; or the soda may be in less quantity than could neutralize the whole of the muriatic acid, part of this acid having been combined with the other bases. If this be the case, the acid set free during the addition of the ammoniacal salts would be contained in the residue of the evaporation in union with ammonia, but would be volatilized by the heat, the muriatic acid in the muriate of soda would therefore be less than the water originally contained. Though the quantity of muriate of soda procured, therefore, gives the real quantity of the soda, yet it does not afford the proportion of the muriatic acid. This may be discovered, by combining by calculation the bases with the acids, taking the quantity of muriatic acid in the muriate of soda, and thus we will find whether there be a deficiency or redundance of muriatic acid. By subtracting the surplus from what exists in the muriate of soda, or by adding the deficiency to it, we arrive at the quantity of the muriatic acid. This method is, however, liable to fallacy. It is better, therefore, to take a separate portion of the water, evaporated to the proper strength, and remove the carbonic and sulphuric acids by means of nitrate of baryta, and then add nitrate of silver to it, by which we ascertain the quantity of muriatic acid. (61).

By these different steps we ascertain the quantity of the different ingredients. We must next ascertain the state of combination in which they existed. This is done, by supposing that the ingredients were so united as to form the most soluble salts. Should other substances, besides these mentioned, be supposed to exist in the water, as potassa or alumina, they must be detected by their proper test, and their proportions ascertained. These, it is supposed, are likewise so combined, as to form with the acids the most soluble compounds. Thus, in his experiments on sea water, Dr. Murray found that a pint of this fluid contained,

Lime	2.9
Magnesia	14.8
Soda	96.3
Sulphuric acid . . .	14.4
Muriatic acid . . .	97.7
	226.1

These, he inferred, existed in the water in the state of muriate of soda, muriate of lime, muriate of magnesia, and sulphate of soda. The quantity of sulphate of soda equivalent to 14.4, of sulphuric acid is 25.6; the remainder of the soda 85.1 is united with 74.2 of muriatic acid, to form 159.3 of muriate of soda. The quantity of muriate of lime, equivalent to 2.9 of lime, is 5.7. The 14.8 of magnesia is combined with the remainder of the muriatic acid, to form 35.5 muriate of magnesia. The saline contents, then, according to this way of determining the compounds, are

Muriate of soda . .	159.3
Muriate of magnesia	95.5
Muriate of lime . .	5.7
Sulphate of soda . .	25.6
	226.1

In the same way, having ascertained the proportions of the different ingredients in any mineral water, the quantities of the compounds which they form may be ascertained.

If this view of the constitution of mineral waters be correct, the component parts of those analysed will be very different from what has been stated in the foregoing Table, these having been ascertained by the evaporation of the fluid, and by the other methods usually followed in the analysis of mineral waters. Thus those which have yielded sulphate of lime and muriate of soda, it is inferred, contain muriate of lime and sulphate of soda, the two former having been generated during the evaporation by the decomposition of the latter. The quantities of the substances contained in the water may be ascertained, by finding the equivalents of the different compounds. Thus 100 of sulphate of lime are equivalent to 81.5 of muriate of lime; and 100 muriate of soda are equivalent to 122 sulphate of soda.*

The mode of analysing mineral waters recommended by Dr. Murray, is one attended with much less labour, and, it is probable, leads to results at least as accurate, if not more so, than those obtained by any of the other methods of analysis. A strong argument in its favour, is its detecting in mineral waters substances which act powerfully on the animal system, and thus enabling us to account for the medicinal effects of some of them, which cannot be done by the other modes of analysis.

MINERALOGY.

Mineralogy is that branch of natural history which makes us acquainted with all the properties and relations of minerals. It is divided, by Werner, into several branches, or doctrines, viz.: Oryctognosy, geognosy, mineralogical chemistry, mineralogical geography, and economical mineralogy. Oryctognosy, (or mineralogy, commonly so called,) arranges and describes simple minerals, according to their external characters; geognosy makes us acquainted with the structure, relative position, materials, and mode of formation of mountain rocks, or those mineral masses of which the crust of the earth is composed; mineralogical chemistry enumerates the various chemical properties and relations of minerals; mineralogical geography delineates the geographical distribution of simple and compound minerals over the face of the earth; and economical mineralogy teaches us the various uses of minerals, whether simple or compound.

In the general view of mineralogy adapted to the nature of an Encyclopædia, we cannot use this arrangement of Werner's. We shall consider mineralogy under two heads; viz. Geognosy and Oryctognosy; and view them in such a manner as to include the most important details which belong to the doctrines of chemical, geographical, and economical mineralogy.

GEOGNOSY.

CHAP. I. *History.*

This important branch of natural history makes us acquainted with the structure, relative position, materials, and mode of formation of the mineral masses of which the crust of the earth is composed. The term *geognosy* is derived from the Greek words γη, *the earth*, and γνωσις, *knowledge*. It has been confounded with *orology*, which instructs us regarding the physiognomy of mountains; with *geogony*, which is purely hypothetical, consisting of very abstract speculations regarding the original formation of the earth; also with *geology*, which, however, has a more extensive signification, for the word λογος comprehends the whole science, or rationale of any subject; and therefore geognosy is only a branch of geology. Geology, indeed, according to Werner, comprehends not only *geognosy*, but also *geography*, *hydrography*, *meteorology*, and *geogony*.

The speculative part of geognosy engaged the attention of mankind at a very early period; for we find that the priests of Egypt maintained the aqueous origin of the globe. From Egypt science passed into Greece; and we learn that Thales, one of the most distinguished of the Grecian philosophers, taught the Neptunian view of the origin and formation of the earth, which he had become acquainted with during his residence in Egypt. Zeno, another learned Greek philosopher, maintained that fire was the *prima materia*, and that the earth was formed from the igneous element. But it would be vain to attempt an account of the various fanciful speculations on the formation of the earth, proposed by ancient authors. These afford us no satisfactory information, in regard to the materials and structure of the crust of the earth. Agricola, in Saxony, and that remarkable man Bernard de Palissy, in France, were the first observers who proposed rational opinions respecting the formation of minerals. But the universal devotion to idle, useless, and pernicious scholastic discussions, so prevalent at that time, and which continued for a long succeeding period, occasioned an almost total neglect of their observations and opinions. In the year 1740, De Maillet, who had resided long in Egypt, and who adopted the opinions of the ancient philosophers of that country, where he himself had witnessed how the waters, by the deposition of earthy matter, contributed to the magnitude of the earth, attempted a general explanation of the formation of the globe. In his curious work, entitled *Telliamed*, (his own name reversed,) he maintains, that our globe is composed of strata, which have been successively deposited over each other by the sea, which gradually retired and uncovered the present continents. This opinion was adopted by Linnæus, in his amusing tract, entitled *De Telluris habitabilis incremento;* and Buffon, in his splendid vision of the formation of the earth, inclines partially to this hypothesis; for he considers the superficial strata of the globe as having been formed from water. But all these speculations rested on a very insecure basis; because the mineralogy of no tract of country had hitherto been accurately and scientifically examined. It was therefore idle to attempt to speculate on the formation of the earth with any prospect of success, when we were ignorant of the materials of which it is composed, and of their structures and modes of arrangement.

Tilias, a Swede, was one of the first naturalists who was aware of the utility and importance of such descriptions; and, in the year 1750, he published several topographical descriptions, illustrative of districts in Sweden. This example was speedily followed, and, in the year 1756, Lehman, a German miner, published his celebrated work on secondary, or flœtz rocks, in which the distinction into primitive and secondary mountains is first proposed. Wallerius, professor of mineralogy at Upsal, by the publication of his system of mineralogy

* For finding these numbers, the scale of equivalents of Wollaston is admirably adapted, as by it a great deal of calculation is saved.

in 1778, and Gerhard, in his elementary work on minerals, made us acquainted with the geognostical situation of many minerals. But of all the works of that period, the most important was the physical geography of Bergman, in which we find collected and disposed, in a luminous order, all the facts and observations hitherto published, in regard to the strata of the earth, and to mineral veins. Travellers now made the investigation of the strata of countries an object of particular attention. Pallas, who was employed by the Russian government, in examining the natural productions of that vast empire, although the state of mineralogy at that period, and the rapidity of his journeys, prevented minute investigations, made many important geognostical observations, and was the first who investigated with care the numerous and striking fossil remains of elephants, rhinoceroses, and other genera of the torrid zone, found buried under the icy soil of Siberia.

Guettard and Monnet, in France, supported by public aid, and assisted by many naturalists, undertook the mineralogical description of France. Several parts of this work were published, but the facts were not well arranged or connected. Lavoisier, the celebrated chemist, co-operated in this mineralogical history of France, and published several beautiful descriptive memoirs. Other naturalists gave descriptions of districts in France; Gensane published that of Languedoc; Faujas that of Dauphiny, and made us acquainted with the volcanoes of Vivarais; Desmarest had already described the volcanoes of Auvergne; Palassou, in his essay on the Pyrenees, explained the structure of that great range of mountains, and was the first to state the important fact, that the direction of the strata is parallel with that of the chain. But, of all the works published at this period, (1779,) the most important, and that which contributed in the most eminent degree to the advancement of geognosy, was the first volume of the travels of the celebrated Saussure. It contains many interesting mineralogical facts, and numerous important geological observations. The succeeding volumes of this work of Saussure's abound in valuable facts and beautiful views of nature, and characterise him as one of the most profound and successful of geologists. J. A. Deluc, also a native of Geneva, and cotemporary of Saussure, was an active enquirer, who added several important facts and views to geology. Some years before the appearance of the works of Saussure and of Deluc, the celebrated Werner was appointed professor of mineralogy at Freyberg in Saxony. This remarkable man, by his numerous observations, and profound views of nature, created a new æra in mineralogy. He was the first to point out and explain the true *mode* of investigating geognostical phenomena; he first arranged and developed the principal structures that occur in the crust of the earth, and explained and enumerated the various relations of mountain-rocks, beds, and veins, and of the fossil organic remains contained in strata of different kinds.

Unfortunately for science, he published but little, so that his discoveries, arrangements, and views, were principally made known by the writings of his numerous pupils. These were of all countries, from the shores of the Black Sea to the extremity of Norway; and his fame and views were carried to the Americas, and principally by his own pupils. Indeed most of the distinguished mineralogists of the present age have proceeded from the celebrated school of Freyberg. Mohs, Charpentier, Buch, Raumer, Freisleben, Humboldt, Steffens, Engelhart, Esmark, d'Andrada, Brocchi, De la Rio, and many others, might be mentioned as pupils of this great and profound naturalist. Whilst Werner, by his prelections, and the activity, zeal, and skill of his pupils, was advancing geognosy in Germany, and in many other countries, we find that Patrin, Delametherie, Raymond, and others in France, were adding to our knowledge of the structure and composition of the earth. But of all French geologists, the most distinguished was Dolomieu. He was one of the first naturalists who examined, in a satisfactory manner, the nature of active volcanoes, and his writings and views, in this department of geognosy, may be considered as having led the way to the investigations and views of Spallanzani, Fortis, Faujas, Breislac, and Cordier. But he did not confine his attention solely to the study of volcanic districts, for he has left several interesting memoirs on mineral formations. In France, the study of petrifactions, or fossil organic remains, has materially contributed to the advancement of geognosy. The previous views of Werner, on this subject, the discoveries and observations of Hunter, Blumenbach, Schlottheim, and others, paved the way for the more extended and brilliant investigations of Cuvier.

Whilst geognosy was advancing in other countries, it was until lately but little attended to in Great Britain. The publication of the theory of Burnet, in 1681, and the speculations of Robinson, in 1699, amused, without communicating any real information. Woodward's Essay on the Natural History of the Earth, published in 1702, was the first which contained any facts of importance, and the lectures and discourses on earthquakes, by Robert Hooke, in 1705, the physico-theological discourses of Ray, in 1713, and the new theory of the earth of Whiston, in 1722, were principally of a speculative nature. The inquiry into the original state and formation of the earth, by John Whitehurst, published in 1778, although principally theoretical, contained good observations on the structure of some districts in England. James Douglass, in 1785, published a dissertation on the antiquity of the earth, in which certain fossil organic remains are particularly considered. About this time, Dr. Hutton, of Edinburgh, published, in the *Philosophical Transactions* of the Royal Society of Edinburgh, a striking essay on the theory of the earth. But this work, like all those of a merely speculative nature, did not afford any beneficial results to geognosy; indeed it remained nearly unnoticed, except in some controversial tracts, by Mr. Kirwan, until it was reproduced to the public by Professor Playfair, in his interesting work, entitled "*Illustrations of the Huttonian Theory*," published in 1806. In 1801, Professor Jameson published, in two volumes quarto, the results of his observations on the geognosy of the Hebrides, Orkney, and Shetland Islands, in a work entitled *Mineralogy of the Scottish Isles*. This was the first extensive topographical geognostical work that had appeared in Britain. In 1808, the same naturalist published his *Elements of Geognosy*, in which the structure and materials of the earth are scientifically considered. About this time the Wernerian Society of Edinburgh, and Geological Society of London, were established; two associations which have eminently contributed to the advancement of geognosy. Other geological societies have since been established in different parts of Great Britain; and the science is now extensively and actively cultivated in every civilized country in Europe.

CHAP. II.

Description of the Surface of the Earth.

When we take a very general view of the earth, it appears as a globular solid mass, whose surface is diversified by numerous eminences, of various magnitudes and forms.

2. Experience teaches us, that the great fossil masses, of which the solid body of the earth is composed, when viewed on the great scale, have a *tabular form*, and are consequently more extended in length and breadth than in thickness.

We also find that these masses or rocks are composed of different minerals, in various states of aggregation. Of these the earthy form the greater portion of the earth, while the saline, inflammable, and metallic minerals occur in very various and remarkable relations, in the greater and more prevalent masses, yet always in such a proportion, that when viewed on the great scale, they do not contribute to the formation of the figure of the earth or its surface.

3. When we examine the surface of the globe more particularly, a certain locality of its inequalities is to be observed. Thus the most considerable inequalities, those, namely, which present the most frequent and the deepest sections and fissures, are always found in the more elevated regions; while in the lower places we observe very few, and by no means such special elevations and depressions. We further observe, that the masses of which the higher and lower parts of the earth are composed, are by no means of the same nature. The elevated, rugged, and very uneven places, are mostly composed of rocky masses, which present to the eye rough, bare, and fissured cliffs, mural precipices, and even entire rocky valleys. On the other hand, in the lower parts of the earth, we find in general earthy masses, as clay, loam, sand, and rolled stones; but neither cliffs nor rocky valleys, and only single blocks of the materials of the more elevated places.

4. There is still another general and very interesting observation to be made, namely, that the remains of organic beings more or less changed, (what are denominated *petrifactions*,) are found embedded in these rocks. These remarkable bodies are generally found in the middle and lower heights of the earth. In the middle heights they are still very rare; but they increase in variety and number, as we approach the lower places, and are at length accumulated in immense quantities in the lowest parts. We also observe, that the organic remains found in the middle heights are totally changed into stone; but the lower the situation, the more these bodies appear unaltered, or approach to their original state. It is also observed, that the higher places afford different genera and species of petrifactions from those found in the lower; and although we are able to show the originals of some of those petrifactions which are found in lower places, as proofs of their origin, those found in the middle heights belong to species that are unknown to us. Lastly, we may remark, that in all the situations already mentioned, that is, from the middle to the lowest heights, but particularly in the latter, there are some rocks in which few or no traces of such organic remains have ever been found; although, from the local situation of the rocks, we might as readily expect to find petrifactions in them, as in other rocks of the same relative height.

5. When we examine the surface of the earth more particularly, we find that the special inequalities are included in others more general; that these general inequalities are again contained in others still more general; and that at length the whole are included in the most general. These inequalities may be divided into five classes or degrees. The first contains the most general inequalities; these are *the bottom of the sea*, and *the dry land*. The second comprehends what may be termed *low country* and *high country*. The third, which is more special, comprehends *mountain groups*. The fourth, which is still more particular, comprehends *mountain chains* and *valleys*. The fifth and last, which is the most special, comprehends *single mountains*, and the *ravines* or valleys between them. We have thus a most beautiful series, from the single mountain and the ravine to the great fabric of the high country; and still further to the most general division of the inequalities of the earth's surface, the dry land, and the bottom of the sea.

First Degree.

Dry Land. Bottom of the Sea.

Second Degree.

High Land. Low Land.

Third Degree.

Alpine Land. Plain.

The mountainous and hilly land make the transition from the Alpine land to the plain.

Fourth Degree.

Mountain Range. Valley.

Fifth Degree.

Mountain. Ravine.

We shall now consider each of these inequalities in detail.

6. In regard to the *bottom of the sea*, we may at present remark, that it is diversified by many inequalities; which, however, are not so special as those on the surface of the dry land.

The ocean covers about three-fifths of the whole earth, so that there is but a comparatively small portion of it elevated above the surface of the water. Even this does not form a connected whole; on the contrary, it is divided into a number of detached masses, to which geographers have given different names: the larger are denominated *continents*, the smaller, *islands*.

The geographic division of the earth into continents is not quite correct. Thus Europe and Asia, which form but one continent, are by geographers divided into two; whereas America, which forms two very distinct continents, having their natural boundary at the Isthmus of Darien, is considered as one. Europe and Asia should therefore be considered as forming one continent, and America two. Africa, on the contrary, is well characterised as a distinct continent.

The great inequality of the distribution of the land, which rises above the surface of the ocean, deserves attention. If we conceive the earth divided into two equal parts by the equator, we shall find a most striking difference in the proportion of land on its north and south sides: the southern half is almost entirely composed of water; but in the northern, the greater portion is land. The proportion of land on the north and south sides of the equator, is as $\frac{2}{3}$ to $\frac{1}{3}$. It has been also observed, that if the earth be divided by a meridian line, the proportion of land and water on opposite sides is strikingly different; there being always a preponderance of water in the one side, and land on the other.

This great accumulation of land in the northern half of the globe, suggested to some speculators the idea of the existence of a southern continent; as they conceived it to be impossible that the equipoise of the earth could otherwise remain undisturbed. The illustrious Cook, however, has shown, that even beyond 71° S. latitude, there is no appearance of a continent; and that these dreary regions of water and ice are only diversified by a few islands.*

7. The most general inequalities observable on the surface of the *dry land* are, as we have already observed, *high land* and *low land*. By the first, we understand a lofty, uneven, and widely extended mass of land: by the second, a great and widely extended low and flat country.

In Europe, we find but two high lands and one low land. The one is the great European or Southern; the other the Scandinavian or Northern. The one has its middle point in Switzerland, in the Tyrol, and the Alps of Savoy. Hence it passes through three-fourths of France; traverses the whole of Portugal and Spain; includes nearly two-thirds of Germany; passes through the greater part of Italy; and also part of Hungary and Turkey; and terminates on the borders of the Black Sea. The course of this high land determines that of the great low land. Saxony lies nearly on the border of this low land or plain. It passes through the north part of Saxony, to the East or Baltic Sea. It also passes by the foot of the Hartz Mountains; through the upper part of Westphalia; and further, through the whole of Holland, the Netherlands, and a small part of France; it even reaches the east coast of this island. It extends very considerably towards the north, including in its course, Prussia, Poland, and nearly all Russia in Europe; and reaches to the Uralian Mountains, including the greater part of Moldavia.

The other high land rises in Norway and Sweden; comprehends a portion of Russia; and extends, with some interruption, to the Uralian mountains.

High and low lands might also be pointed out in the other continents.

8. Every high land is composed of what may be termed *alpine*, *mountainous*, and *hilly* land; and sometimes of small plains. The low land, on the contrary, consists principally of *plains*; but we find in it, also, sometimes mountainous and hilly land, and, very rarely, small mountain groups. Here the constituent parts are directly reversed; in high land, the alpine country forms the predominating feature, but in low land the plain is the characteristic appearance.

9. *Alpine land* is composed of *mountain groups*, or groups of mountains. Each mountain group consists of a number of inequalities, which are denominated *mountains*; and these are arranged into series, forming what are called *mountain chains*, or chains of mountains. A number of these chains, when joined together in a determinate manner, form a *mountain group*. Mountain groups are thus excellently distinguished from the other constituent parts of the high land.

It is of much importance to be able to discriminate a mountain group from others on which it may border, or with which it may be surrounded. For facilitating this discrimination it may be remarked, that mountain groups are highest in the middle, and usually become gradually lower and smaller towards the extremities; and that each individual group has a particular direction.

Mountain groups are sometimes separated from each other by plains; sometimes by valleys; frequently by mountainous or hilly country.

10. *Mountainous land* is composed of mountains that

* The *dry land*, according to some French geographers, is divided into *three worlds*, the *Old World*, *New World*, and *Maritime World*; and these are subdivided into eight divisions or parts.

The *old world*, in the eastern hemisphere, extends from south-west to north-east, and comprehends two continents, viz. Africa and Asia, and Europe.

The *new world*, in the western hemisphere, extends from north to south, and is composed of *two* continents, North and South America.

To the south-east of Asia, there is a mass of land nearly as large as Europe. It is Notasia, or New Holland. It is surrounded with many islands of great extent, and with smaller groups of islands, that extend to the vicinity of the New World. This is named the *maritime world*.

The maritime world is composed of three distinct parts: 1. *Australasia*, which includes New Holland, and the great islands that lie to the east of it. 2. The great archipelago of islands to the south of Asia, named the *Archipelago of Notasia*. The third, which is named *Polynesia*, includes the islands scattered through the great Pacific Ocean.

Those islands situated near continents, are considered as belonging to them. Thus the British Isles belong to Europe; those of Japan, to Asia; the West India Islands to America; Madagascar to Africa. But there are other small islands situated in the middle of the Great Ocean, and which cannot be referred to any of the preceding divisions. These may be named *Pelagien*, and belong to the oceans in which they are situated.

Great islands, like continents, have their high chains of mountains, rivers, lakes, forests, deserts, and large animals.

In the island of Sumatra, which is only a secondary one in point of magnitude in the *Archipelago of Notasia*, we meet with the elephant, rhinoceros, and hippopotamus; but the species of animals are often different from those of the neighbouring continents. Thus the rhinoceros of Sumatra is different from that of Asia and Africa. Madagascar produces that singular species of sloth named *ai*, and the different species of makis, which we do not meet with in Africa or elsewhere. The inhabitants of Van Dieman's Land are very different from those of New Holland; and the greater number of mammiferous animals and reptiles are specifically different from those met with on the neighbouring continent. The dog, which is so much prized, and so generally distributed, is a stranger to them, while it is met with very generally in New Holland. Islands of a moderate extent have no great animals, and their rivers are smaller than those of the first magnitude.

The smallest isles are simply rocks, without rivulets, or even springs. Their precipitous cliffs and caves are sometimes beautifully ornamented with madrepores, and with fuci of various beautiful colours and elegant forms. Their summits are inhabited by pelicans, cormorants, albatrosses, frigate birds, and a host of other marine birds; and during tempests, they are lashed by a furious and highly phosphoric ocean.

As these three worlds are narrow towards the south, and broad towards the north, it follows, that the *northern hemisphere* contains the larger portion of land, and may be called the *terrestrial hemisphere*. The *southern hemisphere*, which is very much covered with the waters of the ocean, may be named the *maritime hemisphere*.

are aggravated into chains; but these chains not connected together by a central or high mountain chain. Hence it never forms groups. It is lower than alpine land; and is often intersected, which is never the case with alpine land.

11. The third constituent part of high land, namely, *Hilly land*, is much lower than mountainous country, and consists of gentle, rounded, waved-like elevations. These are sometimes arranged into groups.

We have thus a complete series, from the most elevated and complete alpine country, through the mountainous and hilly, to the low country.

12. In regard to the local situation of the constituent parts of high land, we may remark, that alpine land forms its principal constituent part, and that this is distinguished from mountainous and hilly land, not only by its frequency, but also by height, and its usually occupying the middle part of the high land; whereas its borders are marked by mountainous and hilly land; thus forming the transition to what is termed low land.

13. The fourth constituent part of high land is *plains*. These are small, isolated, and rare; and hence form but unimportant features in the general aspect of high land.

14. *Low land* differs very much in its characters from high land. It is principally composed of plains, and sometimes contains flat hilly country, chiefly where it borders on alpine country. Very rarely small mountain groups occur in it, and these always occupy its middle part.

15. As alpine land is very varied in its aspect, it will be proper now to consider its different parts somewhat in detail. When a mountain group, or alpine land, is viewed as a whole, it appears highest in the middle; and this highest part extends through the whole group without being intersected. This elevated portion is by geographers denominated the *high mountain chain*, and is one of the most remarkable parts of a mountain group, because nature appears to have arranged all the other parts as subordinate to it. It is the water-shed for the whole of the neighbouring country, and is parallel to the length of the group; hence the extremities of the group are at the same time that of the high mountain chain.

All the other parts of the mountain group decline on both sides from the high mountain chain; and the inclined plains thus formed, are denominated the *fall* or *acclivity* of the group. The inclination of the acclivity varies from 2° to 6°; that of the northern declivity of the Pyrenees is from 3° to 4°; that of the southern acclivity of the Alps, from the line formed by the colossal summits of Mont Blanc, Mont Cerven, and Mont Rose, and of which the general height is 3500 metres, to the plains of Piedmont and Lombardy, is 3¾°. But as such a general inclination is made up of many particular inclinations, on account of the inequalities of the acclivity, we must, before we reach the summit, ascend and descend acclivities much more considerable than that we have just mentioned. The two acclivities of a group have rarely the same degree of inclination; on the contrary, one is generally shorter and steeper than the other. Thus, the northern acclivity of the Erzgeberge is long and gentle, while the southern is rapid and short. In the Pyrenees, the northern acclivity is more extensive and steeper than the southern. The western acclivity of the Andes is shorter and steeper than the eastern. The lower part of the group, that which borders on mountainous and hilly country, is denominated its *foot*. When a portion of it extends far into low country, it is denominated a *mountain arm*. We sometimes meet with small plains on the acclivity of the group, and these may be denominated *mountain plains*, to distinguish them from those observed in low country. Very considerable heights sometimes occur in the acclivity of the group, but these seldom reach the height of the high mountain chain.

The concavities, or hollows, in a mountain group, are denominated *valleys*. The valleys shoot from the high mountain chain, intersect the acclivity of the mountain group, and terminate at its foot. The valleys divide the mountain chains from each other; and by this division nature has formed all the varieties of structure observed in mountain groups.

The lateral chains shoot on both sides from the high mountain chain towards the foot of the group. Of these lateral chains some are more considerable than others: the most considerable, that which rises from the middle of the high mountain chain, and reaches to the foot of the group, is denominated the *principal mountain chain*; the other chains either shoot from the foot of the group towards the principal mountain chain, but never reach the high mountain chain; or they proceed from the high mountain chain, but never reach the foot of the group. The principal mountain chain of one group cannot join with the principal mountain chain of another, nor can the high mountain chain of one group join with that of another. The summit of a mountain chain is denominated its *ridge*, and that of the highest mountain chain the *highest mountain ridge*.

We have nearly the same circumstances to attend to in regard to valleys as to mountain chains; only there is here nothing analogous to the high or middle mountain chain. There are two chief kinds of valleys, namely, the *principal*, and *lateral* or *subordinate*. The *principal* valleys stretch uninterrupted from the high mountain chain to the foot of the mountain group, and those only are the principal valleys that reach this point; all the others are *subordinate* or *lateral* valleys. These either extend from a mountain chain to a principal valley, or begin from a lateral chain, or the principal mountain chain, and terminate at the foot of the mountain group. Mountain chains are divided into *mountains* by small valleys or ravines. In the valleys of mountain groups, we have always rivers or streams, but in those of mountain chains, there are either none, or small rivulets. The bottom of such valleys has usually a very rapid ascent; they are not deep, and are neither so wide nor so extensive as true valleys, or those formed of ranges of mountains.

16. The different parts of individual mountains must also be described. Almost every mountain has a *foot*, *acclivity*, and *summit*. By the first, we understand the lowest and flattest part of a mountain. It sometimes extends to a considerable distance, and then rises under an angle of 8° or 10°; when it is less extensive, or has a smaller base, it rises under a somewhat greater angle, but never greatly exceeds 10°. The mountains in wide valleys have generally a considerable foot, but those in narrow valleys are less in extent. Sometimes, as in mountains having a *mural ascent*, there is no foot.

The Acclivity or Ascent.—By this we understand the space contained between the foot and the summit of a mountain. It is usually the steepest and most considerable part of it. Its inclination is less or more than 30°, and on this depends the greater or less covering of soil. Upon an acclivity of 30° and upwards, we find a good cover of soil; at 45°, however, the acclivity is too great to admit the growth of trees. Sometimes the acclivity is perpendicular, forming mural precipices; and it is either mural on one, two, or all sides, or in single spots. Granite, porphyry, and sandstone, afford examples of such acclivities. Humboldt remarks, in regard to acclivities in general, that they are to be reckoned considerable when their angle is 7° or 8°, which is the maximum for carriages; that they are very rapid when 15°, which is the maximum for loaded beasts of burden; that an inclination of 35° is so great, that we cannot ascend it without cutting steps in the rock; and that, even with the aid of steps, an inclination of more than 44° is very difficult of ascent.

The Summit.—This is usually the smallest part of a mountain, and its inclination is generally less considerable than that of the acclivity. There occur, however, exceptions to this: thus there are summits that rise more rapidly than the acclivity; and these are usually very high, almost of equal length with the acclivity, and completely naked. Such lofty and precipitous summits are, in Switzerland, denominated *Peaks*. The summit varies considerably in its shape: it is tabular, or round-backed, or obtuse, or acute, or short conical. Generally the shape of the mountain is characteristic of the rock of which it is composed. Thus gneiss and transition rocks form flat or round-backed summits; clay-slate, conical summits; and basalt and some other rocks, short and obtuse conical summits: granite and limestone often present extremely sharp pointed summits or peaks.

The summits of mountains are sometimes divided by means of ravines, and these are to be considered as the smallest kind of valley. They form one extremity of the series of which the principal valleys in mountain groups form the other. The inequalities formed on the summits of mountains by these ravines or very small valleys, are denominated *Caps*. A mountain may have many caps, and the highest of these will be the *top* of the mountain.

17. Mountain groups may be considered under five different points of view, namely, according to their *length*, *height*, *breadth*, *shape of the mountains*, and *their connection*.

18. Mountain groups, in regard to their length, may be divided into *principal*, *middle*, and *small*.

A principal mountain group or Alpine country must be at least 130 miles long. They occur but seldom. The Alps of Switzerland, the Pyrenees, and the Carpathians, afford examples of this kind.

A middle-sized mountain group is from 40 to 130 miles in length. The greater number of European mountain groups belong to this class; as examples, we may mention the Grampians, Hartz, the Reisen or Giant Mount ins, &c.

A small mountain group is from 10 to 40 miles in length, as examples of it, we may mention the Forest of Turingia, and the Bohemian Mittelgebirge.

19. Mountain groups, in regard to their height, are by [illegible]graphers divided into *high*, *of a middle height*, and *low*

A high mountain group is above 1000 toises or fathoms in height. In Europe, almost the only examples of this class are, the Alps of Switzerland, Savoy, the Tyrol, and the Pyrenees. In the Alps of Switzerland, the highest point is Mont Blanc, which is about 15,646 feet above the level of the sea. The Jungfrau-horn is 13,730 feet above the level of the sea. In the Tyrolean Alps, the Gross Glockner reaches the height of 12,780 above the sea; and the Ortler 15,430. In the Pyrenees, the highest point is Mont Perdu, which is 11,283 feet above the sea.

The elevations in South America are much more considerable. Thus Antisana is 19,150; Tonguragua 16,579; Cotopaxi, according to Condamine, 18,890. Chimborazo, the most elevated summit in the new world, is 21,440 feet above the level of the sea.

The Himalya mountain in Asia is still higher, having, in some instances, an elevation of 27,000 feet.

In Asia, Africa, and America, there appear to be many mountain groups that belong to this division.

20. Mountain groups of a *middle* height are from 500 to 1000 toises high. These are not uncommon. In Germany, the Erzgebirge, Fichtelgebirge, Riesengebirge, and Hartz, are of this magnitude. The highest point of the Fichtelgebirge is 3600 feet; of the Hartz nearly the same. The Schneekoppe in the Riesengebirge is 4949 feet above the sea.

21. *Low* mountain groups are from 600 to 3000 feet high. These are the most numerous. The Schwarz-Wald or Black Forest, the mountains between Moravia and Bohemia, the Thuringer-Wald, &c. belong to this class.

22. Mountain groups, in regard to the breadth of their base, are divided into *massive* and *longish* groups.

In *massive* mountain groups, the length and breadth of the base are nearly alike. The Swiss and Tyrolian Alps, and the Hartz, are of this kind.

In the *longish* mountain group, the length of the base is very considerable in comparison of the breadth. Of this kind are the Riesengebirge, Erzgebirge, &c. The greater number of groups have this shape.

23. Mountain groups, in regard to the form of the mountains of which they are composed, are divided into *common*, *conical* and *alpine* groups.

In the *common* mountain group, the individual mountains of which the chains are composed are singly aggregated, and are joined nearly to their summits.

In the *conical* mountain group, the individual mountains of which the chains are composed, are also singly aggregated, but not joined together higher up than the declivity; so that they appear conical.

In the *alpine* mountain group, the mountain chains are composed, not of single mountains joined together, but of groups of pyramidal-shaped mountains, in which groups a large pyramidal mountain has arranged around it a number of smaller mountains of the same figure.

24. Mountain groups, in regard to their connection, are either *isolated*, or several are joined together, forming a *chain* of mountain groups. A chain of mountain groups extends from the Alps of Switzerland to Servia and Bulgaria: a similar range is formed by the Fichtelgebirge, which is connected with the Carpathians by the Alpine land or mountain groups of the Erzgebirge, Riesenbirge, Silesian and Moravian groups.

25 *Plains*, as we have already mentioned, form the principal constituent part of *low land*; yet there frequently occurs in it flat hilly land, more rarely low and isolated groups; and the hills are often isolated, and at a considerable distance from each other.

The plains of the low land are characterized by particular hollows or concavities, which are denominated *river valleys*, or *river courses*. In these there are to be distinguished the *bed of the river*, and the *holm* or *haugh* land: Further, there are to be observed the *high* and *low bank* of the river, and the ravines or small valleys that traverse the high bank, and terminate in the low bank.

There is still another kind of hollow to be observed in *low* land; it is that formed by shallow and wide-extended lakes. Numerous instances of this are to be observed in the great European low land. The Marc Brandenburg affords many instances of these latter. We further observe, that the plains of the low land are not perfectly level, but are frequently marked with rising grounds, which can scarcely be entitled to the name of hills. They often extend for many miles. They are denominated by German geognosts *Landhöhen*, when they are nearly of equal length and breadth; and *Landrücken*, when they have a lengthened form.

Humboldt, in his valuable book of travels, gives an interesting account of the great plains of South America, which we shall here lay before our readers.

In the Mesa de Paja, in the 9th degree of South latitude, says Humboldt, we entered the basin of the Llanos. The sun was almost at the zenith; the earth, wherever it appeared, sterile and destitute of vegetation, was at the temperature of 48° or 50° centigrade. Not a breath of air was felt at the height we were on the mules; yet, in the midst of this apparent calm, whirls of dust incessantly arose, driven on by the small currents of air that glide only over the surface of the ground, and are occasioned by the difference of temperature, which the naked sand and the spots covered with herbs acquire. These *sand winds* augment the suffocating heat of the air. Every grain of quartz, hotter than the surrounding air, radiates heat in every direction; and it is difficult to observe the temperature of the atmosphere, without these particles of sand striking against the bulb of the thermometer. All around us, the plains seemed to ascend towards the sky, and that vast and profound solitude appeared to our eyes like an ocean covered with sea weeds. According to the unequal mass of vapours diffused through the atmosphere, and the variable decrement in the temperature of the different strata of the atmosphere, the horizon in some parts was clear and distinct; in other parts it appeared undulating, sinuous, and as if striped. The earth was there confounded with the sky. Through the dry fog and strata of vapour, the trunks of palm-trees were seen from afar. Stripped of their foliage, and their verdant summits, these trunks appeared like masts of a ship discovered at the horizon.

There is something awful, but sad and gloomy, in the uniform aspect of these steppes. Every thing seems motionless; scarcely does a small cloud, as it passes across the zenith, and announces the approach of the rainy season, sometimes cast its shadow on the savannah. I know not whether the first aspect of the llanos excite less astonishment than that of the chain of the Andes. Mountainous countries, whatever may be the highest elevation of the highest summits, have an analogous physiognomy; but we accustom ourselves with difficulty to the view of the llanos of Venezuela and Casanary, to that of the *Pampas* of Buenos-Ayres and of Chaco, which recal to the mind incessantly, and during journeys of twenty or thirty days, the smooth surface of the ocean. I had seen the plains or llanos of La Mancha in Spain, and the heath-lands that extend from the extremity of Jutland, through Luneburg and Westphalia, to Belgium. These last are real steppes, of which man, during several ages, has been able to subject only small portions to cultivation; but the plains of the west and north of Europe present a feeble image of the immense llanos of South America. It is in the south-east of our Continent, in Hungary, between the Danube and the Theiss; in Russia, between the Borysthenes, and the Don, and the Wolga, that we find those vast pastures, which seem to have been levelled by a long abode of the waters, and terminate the horizon on every side. The plains of Hungary, when I traversed them, on the frontiers of Germany, between Presburg and Oldinburg, strike the imagination of the traveller by the constant display of the *miràge*, or extraordinary refractions; but their greatest extent is more to the east, between Czegled, Debreczen, and Tittel, which has only two outlets, one near Grau and Waitzen; the other between Belgrade and Widdin.

The different parts of the world have been supposed to be characterized by saying, that Europe has it *heath lands*, Asia its *steppes*, Africa its *deserts*, and America its *savannahs;* but by this distinction contrasts are established, that are not founded either in the nature of things, or the genius of languages. The existence of a heath always supposes an association of plants of the family of *ericæ;* the steppes of Asia are not every where covered with saline plants; the savannahs of Venezuela furnish not only the gramina, but with these small herbaceous mimosas, leguinina, and other dicotyledonous plants. The plains of Songaria, those which extend between the Don and the Wolga, and the *Puszta* of Hungary, are real savannahs, pasturages abounding in grasses; while the savannahs to the east and west of the Stony mountains, and of New Mexico, produce chenopodiums, containing muriate and carbonate of soda. Asia has its real deserts, destitute of vegetation, in Arabia, in Gobi, and in Persia. Since we have become better acquainted with the deserts in the interior of Africa, so long and so vaguely confounded together under the name of Desert of Sahara (Zahra,) it has been observed, that in this continent, toward the east, savannahs and pastures are found, as in Arabia, set in the midst of naked and barren tracts. It is these last, these deserts covered with gravel, and destitute of plants, that are almost entirely awanting in the New World. I saw them only in the low part of Peru, between Amotape and Coguimbo, on the borders of the South Sea. These are called by the Spaniards, not Llanos, but the *Desiertos* of Sechura and Atacamez. This solitary tract is not broad, but 440 leagues long. The rock pierces every where through the quicksands. No drop of rain ever falls on it; and, like the desert of Sahara, to the north of Tombuctoo, the Peruvian desert affords, near Huara, a rich mine of rock-salt. Every where else, in the New World, there are plains, desert because not inhabited, but no real deserts.

The same phenomena are repeated in the most distant regions; and, instead of designating those vast plains, destitute of trees, by the nature of the plants they produce, it seems natural to distinguish them into *deserts*, and *steppes* or *savannahs;* into bare lands without any appearance of vegetation, and lands covered with gramina, or small plants of the dicotyledonous tribe. The savannahs of America, especially those of the temperate regions, have, in many works, been designated by the name *prairies;* but this term appears to me little applicable to pastures that are often very dry, though covered with grass of four or five feet in height. The *llanos* and the *Pampas* of South America are real steppes. They display a beautiful verdure in the rainy season, but in the time of great drought assume the aspect of a desert. The grass is then reduced to powder; the earth cracks; the alligator and the great serpents remain buried in the dried mud till awakened from their long lethargy by the first showers of spring. These phenomena are observed in barren tracts of fifty or sixty leagues in length, wherever the savannahs are not traversed by rivers; for on the borders of rivulets, and around little pools of stagnant water, the traveller finds, at certain distances, even during the period of the great droughts, thickets of mauritia, a palm, the leaves of which, spread out like a fan, preserve a brilliant verdure.

The steppes of Asia are all beyond the tropics, and form very elevated table-lands. America, also, displays savannahs of considerable extent on the backs of the mountains of Mexico, Peru, and Quito; but its most extensive steppes, the Llanos of Cumana, Caraccas and Meta, are little raised above the level of the ocean, and all belong to the equinoctial zone. These circumstances give them a peculiar character. They have not, like the steppes of southern Asia, and the deserts of Persia, those lakes without issue, those small systems of rivers, that lose themselves either in the sands, or by subterraneous filtrations. The Llanos of America are inclined towards the east and south, and their running waters are branches of the Oroonoko.

The course of these rivers had once led me to believe that the plains formed table-lands, raised at least from one hundred to one hundred and fifty toises above the level of the ocean. I supposed that the deserts of interior Africa were also at a considerable height; and that they rose one above another, like stages, from the coast to the interior of the continent. No barometer has yet been carried into the Sahara. With respect to the llanos of America, I found by barometric heights, observed at Calabozo, at the Villa del Pao, and at the mouth of the Meta, that their height is only 40 or 50 toises above the level of the sea. The fall of the river is extremely gentle, often nearly imperceptible; and, therefore, the least wind, or the swelling of the Oroonoko, causes a reflux in those rivers that flow into it. The Indians believe they descend during a whole day in navigating from their mouths towards their sources. The waters that descend are separated from those that flow back by a great body of stagnant water, in which the equilibrium being disturbed, whirlpools are formed that are dangerous for boats.

The chief characteristic of the savannahs, or steppes of South America, is the absolute want of hills and inequalities, the perfect level of every part of the soil. Often in a space of thirty leagues there is not an eminence of a foot high. This resemblance to the surface of the ocean strikes the imagination most powerfully, where the plains are altogether destitute of palm-trees; and where the mountains of the shore, and of the Oronooko are so far distant, that they cannot be seen, as in the *Mesa de Pavones*. The equality of surface is still more perfect in the meridian of Calabozo than towards the east, between the Cari, La Villa del Pao, and Nueva Barcelona; but it reigns without interruption from the mouths of the Oronooko to Lavella de Araure and Ospinos, under a parallel of an hundred and eighty leagues in length; and from San Carlos to the savannahs of Caqueta, on a meridian of two hundred leagues. It particularly characterises the new continent, as it does the low steppes of Asia, between the Borysthenes and the Wolga, between the Irtisch and the Obi. The deserts of central Africa, of Arabia, Syria, and Persia, Cobi, and Casna, present, on the contrary, many inequalities, ranges of hills, ravines without water, and rocks that pierce the sands.

The llanos, however, notwithstanding the apparent uniformity of their surface, furnish two kinds of inequalities, that do not escape the observation of an attentive observer. The first is known by the name *Bancos;* they are real shoals in the basin of the steppes, fractured strata of sand-stone, or compact lime-stone standing four or five feet higher than the rest of the plain. These *banks* are sometimes three or four leagues in length; they are entirely smooth, with a horizontal surface; their existence is only perceived by examining their borders. The second species of inequality can be recognised only by geodesical or barometric levellings, or by the course of rivers. It is called *Mesa*, and is composed of small flats, or rather convex eminences, that rise insensibly to the height of a few toises.

The uniform landscape of the llanos; the extreme rarity of inhabitants; the fatigue of travelling beneath a burning sky, and an atmosphere darkened by dust; the view of that horizon, which seems for ever to fly from before us; those lonely trunks of palm-trees, which have all the same aspect, and which we despair of reaching, because they are confounded with other trunks that rise by degrees in the visual horizon; all these causes combined, make the steppes appear far greater than they are in reality. The planters who inhabit the southern declivity of the chain of the coast, see the steppes extend toward the south, as far as the eye can reach, like an ocean of verdure. They know that from the Delta of the Oronooko to the province of Varinas, and thence, by traversing the banks of the Mela and the Guaviare, and the Caguan, they can advance three hundred and eighty leagues in the plains, first from east to west, and then from north-east to south-west, beyond the equator, to the foot of the Andes of Pasto. They know, by the accounts of travellers, the Pampas of Buenos Ayres, which are also llanos covered with fine grass, destitute of trees, and filled with oxen and horses become wild.

26. In mountainous and hilly country, funnel-shaped hollows of different sizes are sometimes to be observed. The smallest kind have been formed by the sinking of rocks, and are peculiar to certain formations. The others are circular valleys: a stream or river usually traverses them, and disappears by a subterranean canal. Hence it happens that these hollows are sometimes filled with water, and at other times dry. The Lake of Cirknitz is an example of this kind of valley.

27. We obtain a very distinct conception of the surface of the earth, by comparing together the different inequalities that have been described, and we are much assisted in forming this conception, by attending to the course of the water over the earth's surface. We can, by means of the course of rivers, distinguish great portions of the surface of the earth, which are termed *river districts* by geographers. These districts are generally very wide and flat troughs or concavities, in which the main river occupies the lower, and its exit from the concavity the lowest point of the district. In good maps we can trace out these districts, by drawing lines along the points where the small rivers and rivulets of

the district took their rise; and thus we obtain the boundary of the river district.

In the *high land*, river districts form peculiar basins or concavities; and these sometimes form connected series. They are often contained in the mountain group, but more frequently without them; but still in the high land. Thus the Vallais, which is a concavity of this kind, lies between the Alps of Switzerland and Savoy; and the vicinity of Geneva affords another similar example. The river district of the Rhine forms many basins of this kind, in its course towards the ocean. As long as it continues in the Alps, these basins are inconsiderable; but they increase in magnitude as soon as it leaves those elevated regions. The basin in which the Lake of Constance is situated, may serve as an example. A second basin of the Rhine occurs in Baden, where it is increased by many lateral streams. It extends from Upper Alsace to Hundsruck, and the vicinity of Mayence; where the Rhine forces its way through a narrow rocky passage. The river district of the Danube forms a basin in Swabia, several in Bavaria, and one in Lower Austria, but is nearly shut up at Presburg, which forms the entrance into the great valley of Hungary. At the lower extremity of Hungary, the river is again forced to seek its way through a narrow rocky channel at Orosova, which is the only opening from Hungary into Wallachia. It now continues its course through Wallachia, and at length falls into the Black Sea. We have a continuation of these valleys or basins, although still filled with water, in the Black Sea, Sea of Marmora, and Mediterranean. This latter fact is particularly interesting, as it leads to interesting considerations in regard to the former state of such basins or valleys. Bohemia affords another example of this kind. That extensive country is a great circular valley, whose bottom inclines towards the only opening of the valley, above Konigstein, through which the river Elbe issues, carrying with it nearly all the water that falls on Bohemia. Immediately below this narrow rocky outlet, there is another small circular valley, which extends from Konigstein to Pirna. At Pirna it is nearly closed up, the river forcing its way through a narrow rocky opening, and at length it enters a very beautiful valley, in which the city of Dresden is situated. This valley, as we approach Meissen, which is further down the Elbe, becomes narrow, and the river again flows through a rocky channel, until it escapes into the low country, through which it winds and traverses the flats of Lower Saxony, and is at length poured into the North Sea at Cuxhaven. The river Don, in Aberdeenshire, also passes through several circular or inclosed valleys, in its course to the ocean. At its estuary, the rocks confine it to a narrow channel; but on ascending on it for about a mile, the hills recede from it, so as to form a considerable extent of country on each side. About Inverury it again appears to flow through a channel; and still farther up it flows through another spacious valley. This valley continues for a considerable extent; it at length contracts, and the river flows through another rocky channel. It continues in this channel for a considerable distance, until it again flows through another wide valley.

In the county of Dumfries there are appearances of the same kind, as in the course of the Nith, in which we have the valleys of Sanquhar, Closeburn, and Dumfries; also in other parts of Scotland.

Similar appearances are to be observed in almost every quarter of the globe; and many of the lakes we see so abundantly distributed over the surface of the globe are to be considered as similar basins, but filled with water.

28. Having in the preceding sections described the various inequalities observable on that portion of the surface of the globe which is elevated above the level of the sea, we may now give a short description of the inequalities discoverable on the *bottom of the sea*, or that part of the globe which is still covered with water.

From the observations of mariners, we learn that the bottom of the sea has very considerable inequalities, and that these correspond, in many respects, to those observed on the surface of the land. Indeed this must be the case, when we consider that the present dry land was formerly the bottom of the sea. In paragraph 6. we mentioned, that it does not present so great a variety, or so beautiful a system of elevations and depressions, as the dry land; and this difference is also easily explained. The submarine land must be exposed, for many ages, to the action of the waves of the ocean, and of rain, rivers, and lakes, before its surface can agree, in all its features, with that of the dry land.

When the ground at the bottom of the sea approaches near to the surface of the water, and is pretty level, it is denominated a *shoal*. The Dogger Bank, in the North Sea, is an example of the shoal surface. It resembles the plains on the dry land; it makes the transition from the dry land to the submarine, and will no doubt one day be changed into a plain. *Deep submarine plains* also often occur. Sometimes the bottom of the sea has a very uneven surface, and is composed of *hills*, either of sand and gravel, particularly near the coast, (as is the case on the coast of Holland), or of rocky hills, or of cliffs and other irregularities. The summits of these submarine hills form islands, and these sometimes appear as continuations of the high country on the dry land. We sometimes also meet with great hollows, which are unfathomable.

The coral reefs that surround the islands in the South Sea and Indian Ocean are to be viewed as a variety of the shoal surface already mentioned. These are the work of very minute animals. They occur in vast abundance along the east coast of New Holland, and in the South Sea, particularly to the eastward of the Friendly Islands, from the 10° to 15° South Latitude. A reef of this kind surrounds the island of Otaheite, and rises like a wall from unfathomable depths. Many of the other islands are encompassed with similar reefs, in particular New Holland, New Caledonia, &c. Captain Flinders says, the quantity of coral reefs between New Holland and New Caledonia and New Guinea is such, that this might be called the coral sea. Thus for 350 miles, in a straight line from south-east to north-west, in the east coast of New Holland, is a coral reef uninterrupted by any large opening into the sea, and this reef is probably connected with others, so as altogether to form an extent of upwards of 1000 miles, and having a mean breadth of from 20 to 50 miles. These reefs sometimes give rise to islands. The coral rises above the surface of the water, disintegrates, becomes mixed with seeds of different kinds, carried by birds, floated by the waves, or wafted by the winds. These grow and decay, and thus afford a more or less deep covering of soil, on which the cocoa nut and other large trees take root and grow. Palmerston island, the island of Tanea, the island of Middleburg, the island of Tongataboo, the island of Mangea, and others in the South Sea, have a base of coral.

The following details in regard to the formation of coral reefs and islands, as given by Dr. Forster and Captain Flinders, will increase the interest of the preceding account. Dr. Forster remarks, "All the low isles seem to me to be a production of the sea, or rather its inhabitants, the polype-like animals forming the lithophytes. These animalcules raise their habitation gradually from a small base, always spreading more and more, in proportion as the structure grows higher. The materials are a kind of lime mixed with some animal substance. I have seen these large structures in all stages, and of various extent. Near Turtle Island, we found, at a few miles distance, and to leeward of it, a considerable large circular reef, over which the sea broke every where, and no part of it was above water; it included a large deep lagoon. To the east and north-east of the Society Isles, are a great many isles, which, in some parts, are above water; in others, the elevated parts are connected by reefs, some of which are dry at low water, and others are constantly under water. The elevated parts consist of a soil formed by a sand of shells and coral rocks, mixed with a light black mould, produced from putrified vegetables, and the dung of sea-fowls; and are commonly covered by cocoa-nut trees and other shrubs, and a few anti-scorbutic plants. The lower parts have only a few shrubs, and the above plants; others, still lower, are washed by the sea at high water. All these isles are connected, and include a lagoon in the middle, which is full of the finest fish; and sometimes there is an opening, admitting a boat or canoe in the reef, but I never saw or heard of an opening that would admit a ship.

"The reef, or the first origin of these isles, is formed by the animalcules inhabiting the lithophytes. They raise their habitation within a little of the surface of the sea, which gradually throws shells, weeds, sand, small bits of corals, and other things, on the tops of these coral rocks, and at last fairly raises them above water; where the above things continue to be accumulated by the sea, till by a bird, or by the sea, a few seeds of plânts, that commonly grow on the sea shore, are thrown up and begin to vegetate; and by their annual decay and reproduction from seeds, create a little mould, yearly accumulated by the mixture with sand, increasing the dry spot on every side; till another sea happens to carry a cocoa-nut hither, which preserves its vegetative power a long time in the sea, and therefore will soon begin to grow on this soil, especially as it thrives equally in all kinds of soil; and thus may all these low isles have become covered with the finest cocoa-nut trees.

"The animalcules forming these reefs, want to shelter their habitation from the impetuosity of the winds, and the power and rage of the ocean; but as, within the tropics, the winds blow commonly from one quarter, they, by instinct, endeavour to stretch only a ledge, within which is a lagoon, which is certainly entirely screened against the power of both; this therefore might account for the method employed by the animalcules in building only narrow ledges of coral rocks, to secure in their middle a calm and sheltered place; and this seems to me to be the most probable cause of THE ORIGIN of all THE TROPICAL LOW ISLES, over the whole South Sea."

Captain Flinders, gives the following interesting account of the formation of Coral Islands, particularly of Half-way Island on the north coast of Terra Australis. Vol. ii. p. 114, 115, 116.

"This little island, or rather the surrounding reef, which is three or four miles long, affords shelter from the south-east winds; and being at a moderate day's run from Murray's Isles, it forms a convenient anchorage for the night to a ship passing through Torres' Strait; I named it *Half-way Island*. It is scarcely more than a mile in circumference, but appears to be increasing both in elevation and extent. At no very distant period of time, it was one of those banks produced by the washing up of sand and broken coral, of which most reefs afford instances, and those of Torres' Strait, a great many. These banks are in different stages of progress; some, like this, are become islands, but not yet habitable; some are above high-water mark, but destitute of vegetation; whilst others are overflowed with every returning tide.

"It seems to me, that when the animalcules which form the corals at the bottom of the ocean, cease to live, their structures adhere to each other, by virtue either of the glutinous remains within, or of some property in salt water; and the interstices being gradually filled up with sand and broken pieces of coral washed by the sea, which also adhere, a mass of rock is at length formed. Future races of these animalcules erect their habitations upon the rising bank, and die in their turn, to increase, but principally to elevate, this monument of their wonderful labours. The care taken to work perpendicularly in the early stages, would mark a surprising instinct in these diminutive creatures. Their wall of coral for the most part, in situations where the winds are constant, being arrived at the surface, affords a shelter, to leeward of which their infant colonies may be safely sent forth; and to this their instinctive foresight it seems to be owing, that the windward side of a reef exposed to the open sea, is generally, if not always, the highest part, and rises almost perpendicular, sometimes from the depth of 200, and perhaps many more fathoms. To be constantly covered with water, seems necessary to the existence of the animalcules, for they do not work, except in holes upon the reef, beyond low-water mark; but the coral sand and other broken remnants thrown up by the sea, adhere to the rock, and form a solid mass with it, as high as the common tides reach. That elevation surpassed, the future remnants, being rarely covered, lose their cohesive property; and remaining in a loose state, form what is usually called a *key*, upon the top of the reef. The new bank is not long in being visited by sea birds; salt plants take root upon it, and a soil begins to be formed; a cocoa-nut, or the drupe of a pandanus, is thrown on shore; land birds visit it, and deposit the seeds of shrubs and trees; every high tide, and still more every gale, adds something to the bank; the form of an island is gradually assumed, and last of all comes man to take possession.

"Half-way Island is well advanced in the above progressive state; having been many years, probably some ages, above the reach of the highest spring tides, or the wash of the surf in the heaviest gales. I distinguished, however, in the rock which forms its basis, the sand, coral, and shells, formerly thrown up, in a more or less perfect state of cohesion. Small pieces of wood, pumice stone, and other extraneous bodies, which chance had mixed with the calcareous substances when the cohesion began, were inclosed in the rock; and in some cases were still separable from it without much force. The upper part of the island is a mixture of the same substances in a loose state, with a little vegetable soil; and is covered with the *casuarina* and a variety of other trees and shrubs, which give food to parroquets, pigeons, and some other birds; to whose ancestors, it is probable, the island was originally indebted for this vegetation.

CHAP. II.

EFFECTS OF WATER AND VOLCANOES ON THE SURFACE OF THE EARTH.

29. Having now described all the varieties of inequality observed on the surface of the dry land, it will be interesting to endeavour to discover how these have been formed.

Many of the elevations and hollows appear to be original formations, while others seem to be more particularly the effects of water and of volcanic fire. We shall consider each of these in particular.

30. Water acts either *chemically* or *mechanically* on the surface of the earth: and it may further be considered, according to its destroying and forming effects.

Destroying Effects of Water.

We shall first consider the *mechanical destroying effects of water.*

Every long continued rain convinces us of the powerful mechanical effects of water on the surface of the earth. The precipitated water penetrates the surface, then flows along mixed with the matter of the soil, and in its course forms small water-courses, and occasions considerable changes in the flat country and the declivities of mountains. As it rains a very considerable portion of the year, and as every rain carries along with it a quantity of the soil, very obvious changes must in this manner be induced on the surface of the globe. Thunder storms and water-spouts, although more uncommon phenomena, produce more considerable changes, and this either alone, or when their waters join or flow into rivers. These deprive whole districts of their soil to the bare rock; they sometimes even form small ravines, and break down and carry away great masses of rock, that were either formerly much rent, or of such a form as to be easily overpowered by water. If such changes take place in the low land, they must be vastly more considerable in the high land.

The thaw-floods that take place in low countries towards the end of winter and beginning of spring, and in mountainous districts during summer, occasion still greater changes on the surface of the earth. Their effects are truly frightful, particularly when accompanied with rain. The declivities in low countries, over which water flows, are less considerable than in high countries; and besides, the water can extend itself farther in low and flat countries; hence its destroying effects are diminished in intensity. In mountainous countries, on the contrary, the fall is much greater than in flat countries, and the water is compressed into narrow rocky valleys; hence it follows, that rain-floods must be more destructive, the more considerable the quantity of water, and the more mountainous the country. These floods are still more destructive, when the mountain rocks are of such a nature, as to afford little resistance to the impetuosity of the water; that is, when they are decomposed, loose in their texture, or have such a shape as to allow the water to act more easily on them. If we compare together all these circumstances, we shall find that mountainous countries are more liable to suffer from the effects of floods, than low and flat countries. To this, indeed, there are exceptions, as in the case in some granites, and other rocks that long resist the effects of the most powerful and violent floods.

The water of these floods, in its progress towards the lower parts of the earth, flows either into ravines, and from these into valleys and beds of rivers; or when it meets with no ravine, scoops out a bed for itself, wherever it meets with a soft yielding rock or a slight hollow. The junction of these mountain streams with the river of the district, not only increases its power by the addition of a considerable quantity of water, but also causes it to overflow its banks, and deluge the neighbouring country, and thus to occasion great changes on its surface. The different loose materials are carried towards the sea, and are deposited at different distances from the mouth of the river; and these are proportioned to the magnitude of the masses. The finest or loamy parts reach the sea; the sand, gravel, and larger rolled masses being left on the surface at greater or less distance from the sea, according to the relative magnitude of their parts.

This mechanical action of water appears in many cases to have contributed in an eminent degree to the hollowing out of valleys; but all valleys have not been formed in this manner; for many and very extensive valleys are formed by mountain groups disposed in a circular form, as is the case in Bohemia, Hungary, Transylvania, &c.; others by the original inequalities of the crust of the earth; some by the unequal deposition of formations, and others by the widening of great rents.

It is also observed, that numerous rents and fissures, and the fall of great masses of mountains, take place during floods or wet seasons. These falls are occasioned either by the weight of the masses being increased by the great quantity of absorbed water, or by the diminished cohesion of the parts of the rock effected by the same cause, or by the splitting of great masses by freezing of water, or any other power that interrupts the continuity of the rock, and favours its separation into different masses. The fall of rocks is also occasioned by the softening and removal of subjacent strata or beds by means of water.

These masses sometimes interrupt the course of rivers, and thus form lakes. These lakes in their turn again force a passage through this inclosing barrier, and sometimes so suddenly as to deluge and desolate the lower country.

In the year 1618, the once considerable town of Plurs, in Graubunden, with the neighbouring village of Schilano, were overwhelmed by an immense mountain mass, which separated with a frightful noise from the south side of the mountain of Corto. In 1678, the sinking of several great masses of rocks in the Pyrenees caused very violent overflowings in Gascony. In 1714, the west side of the Diableret, in the Vallais, fell down, and covered the neighbouring country with its ruins for two miles in length and breadth, and the immense blocks of stone interrupted the course of the rivers; and lakes were thus formed. Many similar instances are on record in France, Italy, England, Scotland, &c. When the barriers of lakes, in high and mountainous countries, burst during great thaws or uncommon floods of rain, tremendous overflowings of the lower country that almost exceed conception are the consequence. Immense masses of rock are torn away and carried to an inconceivable distance, and whole countries are desolated. Many of the deluges mentioned by ancient writers appear to have been caused by the bursting of lakes.

The Waller Lake, in the Tyrol, rose so much, owing to the melting of the ice of the neighbouring glaciers, that it broke through its natural barrier; and its water was precipitated with so much velocity and violence into the lower country, that whole valleys and plains were desolated. The bursting of a lake in the valley of Bagne occasioned great devastation. There are many other instances of lakes having emptied themselves in other parts of Switzerland, as also in the Fichtelgebirge, &c.

The waters of the ocean also act very powerfully in breaking down the land. Its waves and currents are particularly active in these destroying operations. They either hollow out the rocks on the coast into caves of greater or less magnitude, or, by washing away softer subjacent strata, cause sinkings and fallings of great masses of rock. The caves in the islands of Arran and Jura have been partly formed in this manner.

If many streams act in different directions on the same coast, or in conjunction with land-floods, as is often the case, the destroying effect is very great. Frequently also the power of the flood is increased by ebb and flood tide. In this manner many maritime countries have been overwhelmed by the sea.

The Baltic Sea affords examples of these destroying effects; thus the island of Rugen was formerly joined to the Continent, but, by the violent action of the sea, has been much diminished in magnitude, and separated from it. The effects it has produced on the coasts of Carniola, Dalmatia and Egypt, are well known. The Zuyder-zee, which is contained between the provinces of Holland, Utrecht, Gelders, Overyssel, and Friesland, was formerly a lake, through which an arm of the Rhine, named the Flevo, flowed towards the ocean. In the 13th century the sea broke in, covered the whole country, and left only detached portions of the land, which now form the islands denominated Texel, Vlieland, Schelling, Newland, and others, that now serve to defend this sea from the power of the waves of the ocean. This remarkable change is supposed to have been occasioned by a violent land-flood, in conjunction with high tides, and a high wind blowing in an opposite direction to the course of the river.

In the year 1164, a violent storm of wind caused a deluge in Friesland, which occasioned the death of many thousand persons. In 1218, another inundation in Friesland occurred, by which 100,000 persons were drowned; and another equally destructive took place in 1530. Florus speaks of a rising of the water in the year of Rome 644, which forced the Teutonians, Cimbrians, and Tigurians, back from the countries they inhabited. This was occasioned by a violent north wind, which raised the ocean along the coast of the countries they inhabited.

Water in the state of ice, also produces considerable changes on the surface of the earth. Thus we often observe masses from a hundred weight to many tons floated by rivers during thaw-floods, and these frequently break up the banks of the rivers, and even tear away immense masses of solid rock. Sea-ice also produces similar effects on coasts, but on a greater scale.

It sometimes happens, that great fields of ice rise from the bottom, and bring with them masses of rock several hundred tons weight. These masses of stone are embedded in the ice. They are carried along with the ice, and deposited on shores at a great distance from their original situation. This fact will serve to explain the appearance of loose blocks of particular kinds, in situations far removed from their original repository.

Similar changes are occasioned by the fall of ice from the heights of mountains. When the glacier, or mountain ice, rests on inclined planes, dreadful devastation is caused by it, during the time of floods, as it then splits, and is hurled down to the lower country with irresistible impetuosity. The inhabitants of the Alps of Switzerland and Savoy, of Iceland and Greenland, often experience the terrible effects of the fall of these tremendous masses.

In like manner, the fall of snow produces striking effects. The consolidated snow is often precipitated with great velocity, accompanied with terrible noises, carrying along with it rocks of vast size, and often burying villages under it.

The freezing of water contained in the fissures of rocks also occasions considerable alterations on the surface of the earth. This is observed most particularly in those rocks that have perpendicular fissures, because these allow the water to enter more easily, and favour the separation of the masses when the water expands during the process of freezing. Hence we find no species of rock more changed by the effects of frost than basalt and porphyry-slate.

The *Chemical effects* of water, particularly the destroying effects, depend on the kind of rock over which it flows; for some allow water to act on them chemically, others do not. Limestone, gypsum, and rock-salt, are more particularly acted on by water than most other rocks.

By this agency of water, the height of limestone and gypsum mountains is gradually diminished, caves are excavated in them, and the water of such countries is much impregnated with gypseous and calcareous matters. The rock-salt which occurs in hills of gypsum is often dissolved by the water, and thus cavities of considerable magnitude are formed; and by the continued action of the water on the gypsum, the cavities increase in size, until the superincumbent pressure becomes too great, and then the roof falls in and forms those remarkable funnel-shaped hollows so often observed in gypsum countries.

Sometimes, as in felspar rocks, the percolating water washes away the alkaline ingredient; in other cases, the moisture combines with iron, and forms hydrate, or by its decomposition oxidates the metallic substances in a greater or less degree. By its action on sulphurous compounds, as on pyrites, it gives rise to sulphates or vitriols. As iron is the most general and abundant metal in the mineral kingdom, and is easily acted on by air and moisture, it follows that it must be one of the most active agents in the disintegration of mineral substances.

Forming Effects of Water.

We shall next consider the *forming* effects of water, which are, as already mentioned, either *mechanical* or *chemical.*

It is evident, that every mechanical destruction will be followed by a mechanical formation; for the masses which are separated by the water will be again deposited on the surface of the land, in lakes, rivers, on coasts, or on the bottom of the sea. During land floods, the water does not always convey its mechanically mixed parts to rivers; on the contrary, it often deposites them in hollow places. Those particles that reach rivers form sand-banks, particularly in slow-flowing rivers. Very extensive mechanical formations are daily taking place on the coasts, and even in some places at a considerable distance from them, by the waters of the ocean. In the Baltic or East Sea, many appearances of this kind are to be observed. Thus the Bay of Fulbaka, which was navigated with boats within the memory of man, is now filled up, and covered with grass. Several harbours in Lapland that formerly admitted vessels, are now three or four thousand paces from the sea; and at Helsingor there are iron-works in places which were covered by the sea about eighty years ago. The whole of the ancient kingdom of Prussia appears to have been formed in this manner; it is said that the sea reached as far as Culm within the period of human history. The city of Dantzic, several hundred years ago, was close on the sea-shore.

Similar appearances occur on other coasts. Between the coasts of Norfolk and Zealand in Holland, there is a great sand-bank, where opposite currents meet, and it is probable that this bank will in time form an island, and probably even an isthmus. Much of the country of the United Provinces has been produced by the forming action of the sea.

A great portion of the flat country from the mouth of the Rhone to the Pyrenees is said to be the work of the ocean; and the whole tract of country from Pisa to Leghorn is a formation of the same nature.

In those parts of the sea where its waters are but little agitated, similar forming effects are to be observed.

Where marine currents flow rapidly, and near the coast, they exert a destroying power, but when they act at a distance, a forming power.

The effects produced by the sea alone, without the aid of rivers, are far less beneficial. When the sea-coast is low, and the bottom consists of sand, the waves push this sand towards the shore, where, at every reflux of the tide, it becomes partially dried; and the winds, which almost always blow from the sea, drift up some portion of it upon the beach. By this means *downs*, or ranges of low sand hills, are formed along the coast. These, if not fixed by the growth of suitable plants, either denominated by nature, or propagated by human industry, would be gradually, but certainly, carried towards the interior, covering up the fertile plains with their sterile particles, and rendering them unfit for the habitation of mankind, because the same winds which carried the loose dry sand from the shore, to form the downs, would necessarily continue to drift that which is at the summit further towards the land. On the east coast of Scotland, and in many of the islands, there are striking effects of this kind. De Luc, the brother, in the *Mercure de France*, communicates the following interesting statement in regard to the progress of the blowing sand, termed the *sand flood* in Egypt:

"The *sands* of the Lybian desert," he says, "driven by the west winds, have left no lands capable of tillage on any parts of the western banks of the Nile not sheltered by mountains. The encroachment of these *sands* on soils which were formerly habited and cultivated is evidently seen. M Denon informs us, in the account of his *Travels in Lower and Upper Egypt*, that summits of the ruins of ancient cities, buried under these *sands*, still appear externally; and that, but for a ridge of mountains called the *Lybian chain*, which borders the left bank of the Nile, and forms, in the parts where it rises, a barrier against the invasion of these *sands*, the shores of the river, on that side, would long since have ceased to be habitable. Nothing can be more melancholy," says this traveller, "than to walk over villages swallowed up by the sand of the desert, to trample under foot their roofs, to strike against the summits of their minarets, to reflect that yonder were cultivated fields, that there grew trees, that here were even the dwellings of men, and that all has vanished.

"If then our continents were as ancient as has been pretended, no traces of the habitation of men would appear on any part of the western bank of the Nile, which is exposed to this scourge of the *sands* of the desert. The existence, therefore, of such monuments attests the successive progress of the encroachments of the sand; and these parts of the bank, formerly inhabited, will for ever remain arid and waste. Thus the great population of Egypt, announced by the vast and numerous ruins of its cities, was in great part due to a cause of fertility which no longer exists, and to which sufficient attention has not been given. The *sands* of the desert were formerly remote from Egypt; the Oases, or habitable spots, still appearing in the midst of the sands, being the remains of the soils formerly extending the whole way to the Nile; but these *sands*, transported hither by the western winds, have overwhelmed and buried this extensive tract, and doomed to sterility a land which was once remarkable for its fruitfulness.

"It is therefore not solely to her revolutions and changes of sovereigns that Egypt owes the loss of her ancient splendour; it is also to her having been thus irrecoverably deprived of a tract of land, by which, before the sands of the desert had covered it and caused it to disappear, her wants had been abundantly supplied. Now, if we fix our attention on this fact, and reflect on the consequences which would have attended it if thousands, or only some hundreds of centuries had elapsed since our continents first existed above the level of the sea, does it not evidently appear that all the country on the west of the Nile would have been buried under this *sand* before the erection of the cities of ancient Egypt, how remote soever that period may be supposed; and that, in a country so long afflicted with sterility, no idea would even have been formed of constructing such vast and numerous edifices? When these cities indeed were built, another cause concurred in favouring their prosperity. The navigation of the Red Sea was not then attended with any danger on the coasts; all its ports, now nearly blocked up with reefs of coral, had a safe and easy access; the vessels laden with merchandize and provisions could enter them and depart without risk of being wrecked on these shoals, which have risen since that time, and are still increasing in extent.

"The defects of the present government of Egypt, and the discovery of the passage from Europe to India round the Cape of Good Hope, are therefore not the only causes of the present state of decline of this country. If the *sands* of the desert had not invaded the bordering lands on the west, if the work of the *sea polypi* in the Red Sea had not rendered dangerous the access to its coasts and to its ports, and even filled up some of the latter, the population of Egypt and the adjacent countries, together with their product, would alone have sufficed to maintain them in a state of prosperity and abundance. But now, though the passage to India by the Cape of Good Hope should cease to exist, though the political advantages which Egypt enjoyed during the brilliant period of Thebes and Memphis should be re-established, she could never again attain the same degree of splendour.

"Thus the reefs of coral which had been raised in the Red Sea on the east of Egypt, and the *sands* of the desert which invade it on the west, concur in attesting this truth: That our continents are not of a more remote antiquity than has been assigned to them by the sacred historian in the book of Genesis, from the great era of the Deluge."

Sea-salt affords us examples of *the chemical forming* effect of water, as is exemplified in the lakes of the Tauride, in Southern Africa, and many other places. We there observe beds of salt formed by precipitation from the waters of the lakes; and sometimes these beds alternate with others of clay and loam, and vary much in their degree of inclination. Bog iron-ore, which is forming daily, is another example of the same kind of formation. Morass-ore sometimes alternates in beds with peat; and swamp-oar sometimes occurs in thin beds, covering the more compact kinds of peat. Peat itself may be ranked as one of the substances formed by chemical agency.

The vast accumulations of calc-sinter found in limestone caves, as in those of Derbyshire, the Hartz, the Fichtelgebirge, Antiparos, Gibraltar, &c. belong also to the chemical formations. Calc-sinter is found usually in inclosed spaces, whereas calc-tuff is formed in open spaces. This substance is deposited sometimes in caves, and frequently in fissures, forming veins, which are in this manner filled with very compact calc-sinter, and sometimes even with crystallized calc-spar. Calc-tuff is formed by calcareous brooks emptying themselves into hollows, and thus affording an opportunity for the deposition of their calcareous contents. Near Canstadt in Wurtemberg, streams of this kind incrust every thing in their vicinity with calc-tuff, which approaches more or less to calc-sinter. If such streams flow into situations where the water has repose and time to deposite its calcareous contents, calcareous beds or strata are formed, which are more or less porous. This porosity is increased on the land, by the tuff mixing with reeds and grass. In beds of this substance skeletons of extinct quadrupeds are met with.

Destroying and forming effects of Volcanoes.

The operation of volcanoes is still more limited and local than that of water. Although we are entirely ignorant of the means employed by nature in producing volcanic fire, we can judge by its effects of the changes it is capable of producing upon the surface of the earth. When a volcano announces itself after some shocks of an earthquake, it forms for itself an opening. Stones and ashes are thrown to a great distance, and lava is vomited forth. The more fluid part of the lava runs in long streams, while the less fluid portion stops at the edge of the opening, raises it all round, and forms a line terminated by a crater. Thus volcanoes accumulate substances on the surface that were formerly buried deep in the bowels of the earth, after having changed or modified their nature or appearances, and raise them into mountains. By these means, they have formerly covered some parts of the continents, and have suddenly produced mountains in the middle of the sea. But these mountains and islands have always been composed of lava, and the whole of their materials have undergone the action of fire. Volcanoes have never raised up or overturned the strata, through which their apertures pass, and have in no degree contributed to the elevation of the great mountains which are not volcanic.*

CHAP. III.

INTERNAL STRUCTURE OF THE EARTH.

Having in the preceding Chapters described the various inequalities observable on the earth's surface, and stated the means which nature appears to have employed in forming them, we come now to the consideration of the second branch of Geognosy, which makes us acquainted with the *internal structure* of the earth.

At first sight the solid mass of the earth appears to be a confused assemblage of rocky masses piled on each other without order or regularity: to the superficial observer, nature appears, in the apparently rude matter of the inorganic kingdom, to present us as only with a picture of chaos, where none of those admirable displays of skill and contrivance, which, in the structure of animals and vegetables, so powerfully excite our attention, and claim our admiration, are to be observed. It is not surprising that this unfavourable opinion should have long continued to be prevalent, when we consider the experience, skill and judgment, which are necessary for enabling us to unravel all the variety of apparently unconnected relations, which are observable in the internal structure of the earth. In ancient writers we find nothing on this important subject; and it is only by the light of modern discoveries, that we have been enabled to trace out those beautiful arrangements that prevail in the mineral kingdom. Of these, we shall now give a concise and accurate description, and at the same time state some of those inferences that appear to be deducible from these various relations and appearances. But these descriptions and inferences can only be fully understood, and the gratification derived from them completely enjoyed, by an intimate acquaintance with nature herself, not in cabinets alone, but in mines and among mountains. On descending into mines, we are not only gratified by displays of human ingenuity and skill, but we also receive much information respecting the structure of the earth, and the changes it has experienced during the different periods of its formation. Our researches on the surface of the earth, on the other hand, often leads us among the grandest and most sublime

* Cuvier's *Theory of the Earth.*

works of nature; and amid alpine groups, the geologist is, as it were, conducted nearer to the scene of those great operations, which it is his business to explore. In the midst of such scenes, he feels his mind invigorated; the magnitude of the appearances before him extinguishes all the little and contracted notions he may have formed in the closet; and he learns, that it is only by visiting and studying these stupendous works, that he can form an adequate conception of the great relations of the crust of the globe, and of its mode of formation.

Nature appears, in her formations, frequently to proceed from the most special to the most general; or, we observe the most general, including a series of gradually diminishing subordinate differences. In simple minerals, many instances of this occur, as in the distinct concretions, fracture, and external surface. But it is more strikingly the case in the structure of the crust of the earth, for here there is a series from that of the simple mountain rock to those grand and extensive arrangements in the formations that form whole mountains and chains of mountains.

Four different kinds of structure are observable in the crust of the earth.—The *first* is, that which is to be observed in hand specimens; it is the smallest kind of structure, and occurs in what are termed *Mountain Rocks* or *Stones*.—The *second* kind of structure, or that of *Mountain Masses*, is more on the great scale, and is not to be observed in hand specimens, but only in single masses of rock. To this structure belongs stratification, and the seams of distinct concretions.—The *third* kind of structure is that of *Rock Formations*, or those great masses of which the crust of the earth is composed. To examine this kind of structure, we must traverse considerable tracts of country.—The *fourth* kind of structure is that of the *Earth* itself, which is formed by the junction of various formations. To examine this structure, we must travel through many countries.

We have thus a geognostic series of structure from hand specimens, which can be examined in the closet, to that which can only be known by travelling through many countries.

We shall now describe the different kinds of structure, in the order already mentioned.

Structure of Mountain Rocks.

Mountain Rocks or Stones, are those mineral masses of which the greater portion of the crust of the earth is composed. Minerals, or mineral aggregates, to have the true characters of mountain rocks, must occur not only in great masses, but frequently, and present in their structure and composition such characters as will serve to distinguish them, and make them known in whatever situation they may be found.

They are either simple, or aggregations of simple minerals. In the one case, they are denominated *Simple mountain rocks*; in the other, *Compound mountain rocks*.

Simple mountain rocks are either compact, slaty, or granular. Clay-slate, limestone, and serpentine are examples of simple mountain rocks.

When minerals occur disseminated through simple mountain rocks, they are to be considered as accidental, and do not entitle us to consider such varieties as distinct species of rock. Thus garnets, imbedded in granite or mica-slate, are accidental mixed parts.

Compound mountain rocks are either *conglomerated* or *aggregated*. This distinction is founded on the mode of their formation. The grains or masses in the conglomerated mass, according to some naturalists, have not been formed on the spot where they are now found, but have been carried thither, and connected together by a cement. To this class belongs sandstone, puddingstone, and different kinds of fragmented or brecciated stones.*

In *aggregated mountain rocks* or stones, their present structure is their original one, and the parts of which they are composed have been formed on the spot where we now find them. Their parts are immediately connected together; hence this structure is termed *aggregated*.

Aggregated mountain rocks are either *determinately* or *indeterminately* aggregated. The parts in the *indeterminately aggregated*, are irregularly and confusedly joined together. This kind of structure occurs in those varieties of serpentine, where limestone and serpentine are so conjoined that it is difficult to say which predominates, and where the one sometimes encloses the other. The Campan marble, which is an irregular mixture of limestone and steatite, and many Cipolin marbles, which contain veins and patches of green talc, are of the same description.

The *determinately aggregated structure*, presents a number of subordinate differences. It is either *simple* or *double* aggregated. The *simple aggregated* contains two subordinate kinds. In the *first*, the minerals are connected together in such a manner that one serves as a basis for the other, which is included in it; and it also contains two subordinate kinds. These are denominated the *porphyritic* and *amygdaloidal*. In the *second*, all the parts are immediately connected, or joined together; and here we have also two subordinate kinds, the *granular* and *slaty*.

The *double aggregated* includes five subordinate kinds: These are, 1. *Granular slaty*. 2. *Slaty granular*. 3. *Granular porphyritic*. 4. *Slaty porphyritic; and*, 5, *Porphyritic and amygdaloidal*. The first four kinds of double aggregated structure comprehend one structure in another, so that, as the denominations intimate, a smaller structure is contained in a greater. In the fifth, or last kind, one does not include the other; but, as the denomination expresses it, they are placed near or beside each other.

We shall now describe each kind in particular.

Simple Aggregated Structure.

1. *Porphyritic structure.*—When one of the constituent parts of the mountain rock is disseminated through a basis, in the form of grains or crystals, the rock presenting this appearance is said to be *porphyritic*. Common porphyry, porphyry slate, and gypsum containing crystals of quartz, may be mentioned as examples of this kind of structure. The crystals or grains are here of cotemporaneous formation with the basis, and not mechanically mixed, as some have maintained.

2. *Amygdaloidal structure.*—When vesicular cavities are dispersed through a basis or ground, and appear

* We shall afterwards examine particularly the above, which is the general opinion, in regard to the formation of conglomerated rocks.

empty, encrusted, half filled, or completely filled, such a structure is denominated *amygdaloidal*.

The rock named amygdaloid, is a principal example of this kind of structure. Its basis approaches more or less to basalt or greenstone; when it is much iron-shot, it becomes harder and more solid. It is alleged, that while the amygdaloidal rock was still soft, bubbles of air were disengaged, which being prevented escaping by the viscosity of the mass, various shaped cavities, often however of an amygdaloidal shape, were formed. Water holding in solution the various minerals met with in these amygdaloids, is alleged to have traversed the rock, penetrated into the empty vesicular cavities, and to have deposited on their walls its mineral contents. Hence it is maintained, that the amygdaloidal portions are of posterior origin to the basis in which they are contained. It cannot be questioned, that some amygdaloidal structures have originated in this manner, but many others are certainly of cotemporaneous formation with the rock in which they are contained. The minerals that usually occur in these vesicles, are lithomarge, zeolite, steatite, chalcedony, agate, heavy spar, and calc-spar. Those filled with agate and chalcedony, present many interesting phenomena.

3. *Granular structure.* In aggregated rocks, some kinds are formed by the immediate aggregation of different minerals, which are intimately joined together, either by the power of cohesion, or by mutual penetration or interlacement. These minerals are generally in grains, and may be regarded as imperfect crystals. Granite affords an example of this kind of structure.

4. *Slaty structure.*—The slaty structure in rocks composed of different minerals differs from the granular in this circumstance, that the constituent parts are flat, having considerable length and breadth, but inconsiderable thickness. Mica slate, which consists of small plates of quartz and small plates of mica placed upon each other, is an example of this kind of structure.

Double Aggregated Structure.

Under this head we include those varieties where two structures occur together. The following are the different kinds.

1. *Granular-slaty structure.*—Gneiss affords a good example of this kind of structure; the granite and felspar are in grains, and immediately aggregated together, which forms the granular structure; and these aggregations are generally disposed in plates, which are interposed between the plates of mica, and hence the slaty structure.

2. *Slaty-granular structure*—Is slaty in the small, and granular in the great. The only example of this kind of structure is the topaz-rock of Schneckenstein, in Voightland, in the electorate of Saxony. It is composed of large granular masses, which have a slaty structure; the slates consist of fine granular quartz, thin columnar schorl, and small granular topaz. In the drusy cavities that occur between the large granular concretions, lithomarge, crystals of topaz, and schorl, sometimes occur; the schorl, however, is but rarely crystallized.

3. *Granular-porphyritic structure.*—This kind of structure is granular in the small, and porphyritic in the great. When large and distinct crystals of felspar appear dispersed through a granular base, as is often the case with granite, sienite, and greenstone, this kind of structure is formed.

4. *Slaty porphyritic.*—This kind of structure is slaty in the small, and porphyritic in the great. The basis is slaty, and the porphyritic structure is formed by interspersed crystals or grains of minerals different from the basis. Mica-slate, when it contains grains or crystals of garnet is said to have a slaty-porphyritic structure.

5. *Porphyritic and Amagdaloidal.*—Here two kinds of structure are placed together, not included in each other, as in the preceding kinds. It occurs in many amygdaloidal and porphyritic stones. When amygdaloid contains, besides the elliptical-shaped masses, also crystals of hornblende and mica, it is then said to have an amygdaloidal and porphyritic structure; the amygdaloidal being the predominant. In Basalt, on the contrary, where the two kinds of structure sometimes occur, the porphyritic is the predominating. Green Porphyry, although rarely, sometimes possesses this kind of double structure.

Table of the Structure of Mountain Rocks.

Structure of Mountain Stones or Rocks.

- A. Compound,
  - a. Conglomerated, — Sandstone. Puddingstone. Different fragmented stones.
  - b. Aggregated,
    - α. Determinate,
      - a. Double,
        - I. Granular-slaty, — Gneiss.
        - II. Slaty-granular, — Topaz-Rock.
        - III. Granular-porphyritic, — Granite. Sienite. Greenstone.
        - IV. Slaty-porphyritic. — Mica-slate.
        - V. Porphyritic and Amygdaloidal, — Amygdaloid. Basalt. Green-Porphyry.
      - b. Single.
        - I. With a basis,
          - 1. Porphyritic, — True Porphyry. Green Porphyry. Porphyry Slate. Porphyritic Basalt. Gypsum.
          - 2. Amygdaloidal, — Different kinds of Amygdaloid.
        - II Aggregated,
          - 1. Granula, — Granite. Senite. Greenstone.
          - 2. Slaty, — Mica-Slate.
    - β. Indeterminate, — Serpentine with Limestone.
- B. Simple. — Limestone. Gypsum. Serpentine. Clay Slate. Quartz-Rock. Flinty-Slate.

Structure of Mountain-masses and of Strata.

We understand by the structure of mountain masses, those regular divisions which many of them exhibit through a considerable extent of rock. There are two kinds of this structure; the stratified structure, or that of strata; and the seamed structure, or that of distinct concretions.

Stratified structure.—When a mountain, mountain-mass, or bed composed of one species of rock, is divided by means of parallel seams into masses, whose length and breadth are greater than their thickness, or into what may be denominated Tabular Masses, which extend generally through the whole mountain, it is said to be stratified, and the individual masses are termed strata. Of this kind of structure we have instances in Granite. Limestone, Clay-slate, and Mica-slate. The seams that separate the strata are named strata-seams, or seams of stratification. On a general view, we say the globe is composed of formations; formations of beds; beds of strata; and such strata as are slaty, of layers, or slates.

Strata vary very much in their position. The examination of this appearance of strata is of great importance to the geognost and mineralogical geographer.

In determining the stratification of a rock, we have to observe, 1. The direction of the strata. 2. Their inclination. 3. Their thickness. 4. The differences in their direction and inclination.

The direction is the angle which the stratum makes with the meridian, and is determined by the compass; or viewing the strata as planes, the direction is that of a horizontal line, drawn on the surface of the plane; therefore, to determine the direction, is to indicate the point of the compass towards which this line is directed. It is always at right angles to the dip.

The inclination is the angle which the stratum forms with the horizon, and is determined by the quadrant.

The dip is the point of the compass towards which the stratum inclines. If we know the dip, the direction is given, because it is always at right angles to it. Thus, if a stratum dip to the east, its direction must be north and south; if it dip to the north, its direction must be east and west. But we cannot infer the dip from the direction; because a stratum, whose direction continues the same, may dip in opposite directions; thus, a stratum ranging from north to south may dip either to the east or to the west.

Strata are frequently variously waved, thus producing changes in their direction; but these changes in direction are, in general, subordinate to the general direction. It is therefore of importance, in making observations with regard to the position of strata, to distinguish the *general direction* and inclination, from the *partial*. To effect this, we must take the results of a number of particular observations, and compare them together; and those similar angles, which are the most numerous, are to be considered as expressive of the general inclination and direction. It sometimes happens, that this general position has also its variations; these must also be attended to and noted. An acquaintance with the shape of a mountain group will assist us very much in such investigations, as it is intimately connected with the general disposition of the stratification of the masses of which it is composed. It is also of importance to know the fall or declivity of a mountain group, as its direction and inclination are frequently conformable, particularly in the older formations, with that of the superimposed masses.

It is often very difficult to determine, whether the rock we are examining be stratified or not, and when the seams of stratification are hid, to know the direction of the strata. The following observations will be useful in removing some of the difficulties attending such investitions.

1. Strata are almost always parallel with the slaty structure of the stone. In certain porphyritic granites, the crystals of felspar appear to lie parallel with the strata; the latter character, however, is by no means so decisive as the former.

2. Strata can only be formed by parallel seams, which have the same direction and extent through the mountain-mass. Where parallel rents occur in different directions in the same species of rock, as in granite, sandstone, lime-stone, &c. it is evident that they are to be considered as accidental.

3. The seams of tabular distinct concretions, which are often of considerable extent, should not be confounded with strata seams, because their extent is not so considerable; and in each group of concretions the direction is different.

4. Where parallel rents have a different direction from the slaty structure of the stone, they are certainly accidental. Inattention to this circumstance has led mineralogists into error. I observed a striking instance of these rents in a quarry of gneiss, in the forest of Tharand, in Upper Saxony. The gneiss, at first sight, appeared to be disposed in vertical strata, and as such it was viewed by De Luc: on a closer examination, however, the apparent vertical seams proved to be merely accidental parallel rents, perpendicular to the slaty structure of the stone; therefore the strata were horizontal, not vertical.

5. Beds are generally parallel with the strata; these, therefore, point out the direction of the strata.

6. Although the slaty structure points out to us the direction which the strata must have, it does not follow, that a rock having a slaty structure is stratified.

7. In sand-stone, lime-stone, and rock-salt, regular and very extensive stripes are sometimes observed, which have been confounded with true seams of stratification. An attentive examination, however, always discovers them traversing the real strata seams. Von Buch, in his description of Landeck, and geognostical observations made in Italy and Germany; and Friesleben, in his observations on Thuringia, describes striking instances of stripes resembling strata-seams.

Strata vary very considerably in the angle which they form with the horizon; they occur from horizontal to vertical, but the general inclination is between horizontal and 45°. The differences are either original, or have been produced by subsequent changes.

Certain species of rock are constantly stratified, while others either are not stratified, or only in an imperfect manner. All the secondary rocks, such as lime-stone, sand-stone, coal, &c. are very distinctly stratified. In the most modern of the secondary rocks, the strata are often horizontal, and frequently extend to a great distance of the same thickness. In more ancient rocks of this class, as in certain lime-stones and in gypsum, the stratification is less distinct, and the position of the strata is not so horizontal. In the coal formation, which is of a still older date, the stratification is very distinct, but the beds are frequently variously waved and convoluted, and often highly inclined. In the transition and primitive classes, many rocks, such as gneiss, mica-slate, and clay-slate, are distinctly stratified, while others, as granite, porphyry, trap, limestone, gypsum, serpentine, and quartz, are in general but imperfectly stratified, and the strata of these two classes more often incline to the vertical than to the horizontal position.

Rocks which appear to have been mere deposites of mud, gravel, sand, &c. have been formed by successive depositions, while others, such as gypsum, limestone, quartz, gneiss, mica-slate, clay-slate, granite, &c. owe their stratified structure to crystallization, from a more or less perfect state of solution. This latter opinion is illustrated by the uninterrupted transitions of the beds into each other, and by the position of the embedded crystals and masses to the surrounding rock.

On examining the structure of a mountain or tract of country, we must be careful to avoid all unnecessary minuteness, otherwise we shall fail in acquiring a distinct conception of it. This observation is founded on a knowledge of the geognostical features of nature, which are all on the great scale.

By not attending to this mode of examination, geologists have fallen into errors, and given to extensive tracts of country a most irregular and confused structure. Speculators, building on these errors, have represented the whole crust of the globe as an irregular and unseemly mass. It is indeed surprising, that men possessed of any knowledge of the beautiful harmony that prevails in the structure of organic beings, could for a moment believe it possible, that the great fabric of the globe itself,—that magnificent display of Omnipotence,—should be destitute of all regularity in its structure, and be nothing more than a heap of ruins.

Seamed Structure.—Those rocks in which parallel seams occur, that do not extend throughout the whole bed, are said to have the *seamed structure*. The following are the different kinds of this structure: 1. Polyedral. 2. Lamellar. 3. Globular.

1 *Polyedral.*—In this kind of structure, the rock is divided into columns. The columns are sometimes regular, sometimes approach to the globular form, and occur even curvated. They are from a few inches to many fathoms in length. In the islands of Staffa and Eigg, and on the Craig of Ailsa, there are admirable examples of this kind of structure. These columns are sometimes collected into groups, and such groups are often separated from each other by seams, or rather rents, which render them more distinct. Such groups may be considered as immense distinct concretions. The columns of such a group often tend towards a centre; others are parallel or perpendicular; some are horizontal; and all this variety sometimes occurs in the same hill. The columns are sometimes jointed, so that the convex extremity of the one column is fitted to the concave extremity of the other; and these columns are usually composed of globular distinct concretions. These globular concretions are composed of curved lamellar concretions. The spaces between the different globular concretions are composed of a looser matter than the concretions themselves; and it is by the falling out of this less compact substance that the structure of such columns is first developed.

No rock shows this kind of structure more distinctly than basalt: in it we have all the varieties of the seamed structure, from the smallest, which is the lamellar distinct concretion, to the largest, which is formed by the grouping of columns.

This kind of structure occurs also in porphyry, greenstone, and lava.

2. *Tabular.*—In this kind of structure, the rock is divided into tables a few inches thick, and of small extent. These tables frequently change their direction, and then the bed of rock is divided into many groups or systems of tables, having in each group a different direction.

Their inconsiderable length, frequent change of direction, and the even surface of the planes, distinguish them from strata. Basalt, in the lower parts of an individual deposition, has often this kind of structure. At first sight it is not unlike stratification. It also occurs in columnar porphyry.

3. *Globular.*—In this kind of structure the rock is either wholly or partially disposed, or arranged into globes or balls of various magnitudes. These balls are either simply granular, as in granite, syenite, greenstone, or sand-stone; granular, and lamellar, as in the syenite of Corsica; compact, as in basalt; porphyritic, as in porphyry; or radiated, as in limestone. Globular formations are sometimes met with in rocks and minerals having a less crystalline aspect. As examples, we may mention balls of hornstone in limestone, and masses of flint in chalk.

The roundish balls of granite found dispersed over low countries have been considered as bowlder or rolled stones, and many theories formed to account for their transportation. The granite of the island of Arran presents this kind of structure.

Structure of Formations.

By a *Rock formation*, we understand a determinate assemblage of similar or dissimilar beds or rock masses, which are characterised by external and internal relations as an independent whole; that is, as an unity in the series of rock formations. These masses are either *simple* or *compound*. When the mass is uniform throughout, as is the case with limestone or sandstone, it constitutes what may be denominated a *simple formation*. Granite, gneiss, and mica-slate, are also of this kind. When dissimilar masses occur in a formation, as in the case of coal and secondary trap, it is said to be a *compound formation*.

Similar rocks are often repeated in very different periods. Each of these individual depositions is a particular formation, and the whole is denominated a *series* or *suit of formations*. Thus there is a limestone, a porphyry, a granite suit, &c.

It is, Werner remarks, a determinate character of certain formations, to constitute the principal mass of the mountain in which they occur: this is the case with gneiss, clay-slate, porphyry, and others. With other formations, on the contrary, it is as essential a character to occur only in single beds in the others, and these are said to be imbedded. Primitive porphyry, limestone, and many others, are of this kind. When such individual beds occur in different principal formations, (that is, are not confined to a single one,) as primitive limestone and primitive trap in gneiss, mica-slate, and clay-slate, and always continue the same, notwithstanding the difference of the rocks in which they are embedded, they are to be considered as *independent formations*. If, on the contrary, they are confined to one formation, and are connected with no series or suite of formations, they are said to be *subordinate* to it. Alum, slate and Lydian stone n clay-slate, are examples of this kind. Beds comp sed of various minerals sometimes occur in different rocks. These minerals are usually those of which the rock is principally composed, irregularly mixed, or are simple minerals. Such beds are usually very irregular, do not extend through the whole rock, and in general exhibit apparently great irregularity in all their relations. They have been, but rather improperly, denominated *foreign beds*. When single beds are well distinguished by the kind of stone of which they are composed, and if their composition shows certain peculiarities, (as, for example, the determinate presence of metallic fossils, &c.) they are referred to the *particular repositories*. Beds of iron-pyrites and magnetic ironstone are of this kind.

Structure of the Crust of the Globe.

The fourth and last kind of structure we have to describe is by far the most extensive and important. It is the structure of the crust of the globe itself, in so far as it is composed of rock-formations of different magnitudes, laid over each other in certain directions.

Under the five following heads, Werner comprehends every relation respecting the extent and relative position of formations in general.

1. The original extent of formations.
2. Their present extent and continuity.
3. The position and direction of the strata of formations, in respect to the fundamental rock.
4. The direction of the strata themselves, without reference to the fundamental rock.
5. The relation of the outgoings of the strata to the exterior of the mountain.

It may be previously remarked, that when one formation lies on another, it is said to *rest* on it, and the rock on which it rests is termed the *fundamental* rock; and the plane which separates the fundamental rock from the formation that covers it, is denominated the *plane of separation*, which is always parallel with the seams of the strata. See Plate CCCXCV. Fig. 1.

1. *The Original Extent of Formations.*

Werner observes, that the greater number of formations appear to have been very widely deposited; and these he denominates *Universal Formations*. Some others he considers as having been partially deposited, and these he terms *partial* or *anomalous formations*.

Universal Formations extend around the whole globe, (not, however, without interruption.) and constitute by far the greater part of the mass of which its crust is composed. Almost all the primitive transition, and secondary formations, are universal depositions; of these, we may mention granite, gneiss, porphyry, and limestone.

Partial formations occur only in particular places, and appear to owe their existence to particular and local causes, for example, to depositions in lakes. Lamanon is of opinion, that the gypsum formation around Paris was formed from the waters of a lake which formerly occupied that part of France; and the extensive local formation in the Isle of Wight, and the opposite coast of England, appears also to be a lake formation. At Wehraw, in Lusatia, there is an example of a partial formation. It consists of sandstone, limestone, bituminous-shale, and iron-clay; and these rest on loose sand. The sandstone resembles, in many respects, that found in other sandstone formations; yet it does not belong to any of them, as is evident from its position, and the rocks with which it is associated. Werner conjectures that it may have been formed by a small and partial flood.

The examination of these partial appearances is of much importance, not only in extending our knowledge of the variety of formations, but in connecting the history of the earth more nearly with that of man.

2. *The Present Extent and Continuity of Formations.*

The present extent and continuity of formations is very different from what it was originally. We find them either extended uninterruptedly over great tracks of country, or they appear isolated, of little extent, and frequently resembling partial formations. In the one case, they are said to be *unbroken*, in the other *broken*. The broken formations occur in small detached masses; and these have peculiar denominations, according to their position and shape.

When detached portions occur on the summits of hills, these are called *caps*, Fig. 2. *a*. When portions occur, filling up hollow spaces between mountains, they are denominated *upfillings*, Fig. 2. *b*. And when a portion occurs only on one side of a mountain, it is said to be *shield formed*, Fig. 2. *c*. or to have the shape of a shield.

3. *The Position and Direction of Strata in regard to the Fundamental Rock.*

When strata have the same direction as the fundamental rock, they are said to be *conformable* with it, Fig. 3. *a*. if the direction is different, they are said to be *unconformable*. If they differ only in direction, we say that they are *simply unconformable*, Fig. 3. *b.*; but if they differ not only in direction, but lie over the ends of the strata of the fundamental rock, they are said to be *unconformable and overlying*, Fig. 3. *c*. Overlying strata occur more frequently than simply unconformable, and have far greater extent.

4. *Direction of the Strata themselves, without reference to the Fundamental Rock.*

Strata are either *straight*, that is, disposed in one direction on the fundamental rock, Fig. 4. or they turn around it, and inclose it; in this latter case they are said to be *mantle formed*, or *mantle-shaped*, Fig. 5. *b*. If the strata are not only wrapped around the fundamental rock, but also cover its extremities, they are said to be *saddle-shaped*, Fig. 6.

When the upper part of the saddle-shape is carried away, the *mantle-shape* is formed.

Strata are sometimes concave, and they are then said to be *basin-shaped*, Fig. 7. *a.*; Fig. 10. but if the concavity be oblong, they are named *trough shaped*, Fig. 8 *b*. In the concave, that is, the basin and trough-shaped, and in the convex, that is, the saddle and mantle-shaped strata, the *outgoings** form circles: in the concave, the outer and greatest circle, according to Werner, is

* By the *outgoings* of the strata are understood their upper extremities, as they appear at the surface of the earth. Fig. 59.

the oldest; in the convex, on the contrary, the outer and largest circle is considered to be the newest.

5. *The Relation of the Outgoings of the Strata to the Exterior of the Mountain.*

We have to consider first, the relation of the outgoings of strata to mountain-masses of considerable extent; and, secondly, to mountain caps.

In mountain-masses, the strata either cover each other completely, or the outgoings are open and exposed. When the outgoings are exposed, the newer strata have a *rising* or *sinking level*, Fig. 9.

There are three different kinds of *mountain-caps*: In the *first*, the cap rests on a fundamental rock, the seams of the strata are parallel with the plane on which the strata rest, and these are unconformable and overlying, Fig. 10. *a*. The *second* kind of cap is formed by a rock rising through the surrounding strata, Fig. 11. *b.*: and the *third* kind of cap is formed by portions of harder beds remaining after the superincumbent and adjacent and softer strata have been carried away, Fig. 12. *c*.

In the *first*, the rock is unconformable and overlying. The secondary-trap and porphyry formations afford numerous examples of this kind of mountain-cap.

In the *second*, the newer strata are mantle-shaped. Granite often occurs in caps of this kind.

In the *third*, all the strata are conformable, so that the subjacent and superincumbent strata have the same direction with the bed which forms the cap. Primitive greenstone in clay-slate, sometimes forms caps of this kind.

CHAP. IV.

ON THE FORMATION OF ROCKS, AND ON FORMATIONS.

Having now described the different kinds of structure which occur in the crust of the earth, we shall next treat of the formation of mountain rocks, and of the revolutions which the earth is alleged to have experienced during its formation. But those revolutions are of a different nature from the effects now produced on the surface of the earth; and therefore the speculations in regard to them are to be considered more interesting on account of the facts they bring to light, than from any intrinsic merit they themselves possess. The most ingenious of these speculations respecting the formation of the earth, hitherto proposed, is that of Werner; and the following statement will, we think, convey to our readers a distinct account of it.

The spheroidal figure of the earth, its crystalline and stratified structures, and its numerous petrifactions, are proofs of its original fluidity. The fluidity, according to Werner, was aqueous; and he conjectures that the various rocks were originally suspended or dissolved in water, and gradually deposited from it.

In chapter second, when mentioning the effects of water on the surface of the globe, we described several mechanical and chemical depositions which are daily taking place, as it were, under our eye; and as these present the same kind of structure that occurs in mountain rocks, Werner infers these also to have been formed by the same agent. As the highest mountains are composed of rocks, possessing a structure resembling those fossils which have been formed by water, we naturally conclude, that the ocean must have formerly stood very high over these mountains. Further, as the most elevated mountains are composed of rocks, such as granite, gneiss, mica-slate, clay-slate, and others, which extend around the whole globe, and have been formed during the same period of time, it follows, that the ocean must have *formerly covered the whole earth at the same time*.—The former great height, and the present low level of the waters of the globe, is so remarkable a phenomenon, that it gave rise to many very opposite hypotheses, as soon as it attracted the attention of observers. We shall notice a few of these speculations.

It has been supposed, that the water has suffered a translocation, by a complete alteration of the terrestrial poles and equator. This hypothesis, however, is unsupported by fact, as no traces are to be found of so vast a change. The difference between the equatorial and polar diameters, the accumulation of high land around the equator, are proofs that the present poles and equator are the original ones. Even allowing that such a change had taken place, it is evident that the greatest possible alteration of the earth's axis could cause no uncovering of it, as the water stood high over the whole globe.

Another opinion was proposed by De Luc, La Metherie, and others; namely, that the water had retired into immense caverns, situated towards the centre of the earth. From the description already given of the internal structure of the earth, it is evident that the existence of such caverns is imaginary, and totally irreconcileable with the notion of precipitation from a state of solution. Allowing, for a moment, the possibility of their existence, is it not evident, not only that the water would have rushed into them with such violence as to leave the most marked traces of its effects on the surface of the earth, but that the places where the water entered would still be discoverable?

The most probable explanation is that of the gradual diminution of the water from the surface of the earth. It was first obscurely hinted at by Herodotus, Strabo, and other ancient writers. Maillet, French consul at Alexandria, in a work entitled *Telliamed*, published in 1740, was the first in modern times who directed the attention of philosophers to the theory of the diminution of the waters of the globe. This opinion was eagerly adopted, and keenly supported by Linnæus, Celsius, and other Swedish naturalists. They collected many facts, to show that the waters of the Baltic are diminishing; and the scholars of Linnæus observed many similar appearances in other countries. Of these, many interesting instances are detailed in the writings of Pallas, Gmelin, Ferber, Niebuhr, Vancouver, Peron, and others. Even although all these proofs were wanting, it is evident that, if the water remained unaltered in quantity, it would rise and overflow its boundary, owing to the great quantity of earthy matter which is daily carried into it by rivers and streams. This opinion, as supported by Linnæus and several others, met with considerable opposition. Many facts were brought forward, to show, that while the land is left by the sea in one place, it is invaded in an equal proportion in another; and consequently that there is no diminution of the water. The invasion of the land by the sea is, however, a comparatively rare occurrence; and besides, these partial elevations of the water depend on particular circumstances, which can in general be pointed out. Thus, the change in the direction of currents, produced by the accumulation of water by winds, the alteration of the shape of coasts, and many other causes, produce alterations in the level of the ocean.

Werner, with his usual acutenes, soon discovered that the documents for the illustration of this supposed phenomenon were not to be sought for in the formations that have taken place within the limits of human history, but in the *solid strata* of which the crust of the earth is composed. His investigations led him to the following observations: 1*st*, That the outgoings of the newer strata are generally lower than the outgoings of the older, from granite downwards to the alluvial depositions, and this not in particular spots, but around the whole globe. 2*d*, That the primitive part of the earth is entirely composed of chemical precipitations, and that mechanical depositions do not appear until a later period, that is, in the Transition class; and that from this point they continue increasing, through all the succeding classes of rocks, to the newest or the alluvial, which are almost entirely mechanical deposits. These observations, in his opinion, illustrate the universal diminution of the waters of the globe. The sinking of the level of the outgoings of the newer and newer strata, he continues, shows that the solution from which they were formed must have experienced a similar change; that is, it must have diminished in height, and that not in one spot, but around the whole globe. Hence the water which once covered the whole globe to a great height must have diminished universally.

The period of the occurrence of mechanical depositions is a further proof of the diminution of the water. We find, that in the earliest periods chemical productions only were formed, owing to the high and universal submergence. It is evident, that when the earth was covered to a great height with water, no mechanical deposits could be formed; for it is well known, that the motion communicated to water does not reach to a great depth. Mechanical deposits would, therefore, be first formed, as soon as part of the solid mass of the earth appeared above the level of the water, or when the surface of the water approached so near to that of the earth, that it could act on it mechanically. Hence, as soon as the higher parts of the earth rose above the surface of the water, mechanical depositions would increase; and we find, accordingly, an increase of mechanical deposition, corresponding to the diminishing level of the ocean, from the transition to the newest period. It follows, that as these alterations have been universal, extending around the whole globe, the level of the water has changed uniformly and universally, and that it has sunk by degrees to its present level.

Several other interesting phenomena, which we have already mentioned in part, strengthen and illustrate more fully the preceding conclusions. Petrifactions, we know, first occur in formations of a middle age; but none have ever been observed in the older and completely chemical formations. In the transition rocks, where they first occur, they are but rare, yet in the newer transition rocks they increase considerably in quantity. In the flœtz formations, they also continue increasing in quantity, to the newer formations.

In respect to the nature of these remains, Werner remarks, that those which occur in the earliest periods belong to the lowest and most imperfect class of animals, the zoophytes. In the newer and newer formations, we meet with quantities of shells and fish, and these are accompanied by a variety of marine plants. But these organic remains are completely different from any of the animals or vegetables of the present state of the earth. The organic creation during that period, appears to have had a totally different aspect from what it assumed in the succeeding. In the newer formations, we find the remains of known genera, and in the newest of all the remains of organic species, resembling those found in the present seas. Land plants appear later, and land animals still later. At first, they appear to have been but few, and very different from those of the present time. In the oldest of the transition rocks, which appear to have been formed while the earth was still covered with water, we find the remains only of marine plants and animals, but no traces of terrestrial organization. We first meet with such relics in the newer rocks of this class, which were formed after a portion of the land was uncovered, and capable of supporting terrestrial vegetation. From this period to the newest or alluvial, as we have already remarked, the quantity and variety of vegetable remains increase; and this is further confirmed by a correspondent increase of coal.

All the appearances we have now detailed are, in Werner's opinion, distinctly connected with the diminution of the water, and are to be considered as effects and proofs of its reality. It it evident that, during the period when the earth was still covered to a great height with water, neither plants nor animals had been created. When the water diminished in height, and the dry land began to appear, marine plants, and the lowest and most imperfect animals, were created. As the water diminished, it appears to have become gradually more fitted for the support of animals and vegetables, as we find them increasing in number, variety, and perfection, and approaching more to the nature of those in the present seas, the lower the level of the outgoings of the strata, or, what is the same thing, the lower the level of the water. The same gradual increase of organic beings appears to have taken place on the dry land.

The facts we have just detailed lead us to distinguish two grand epochas in the formation of rocks; the first anterior, and the second posterior, to the formation of organic beings. The rocks of the first division are named *primitive;* they contain no fossil organic remains, are situated below the others, and are wholly of chemical formation. The rocks posterior to the creation of organized beings are denominated *secondary.* Several of these resemble those of the primitive class in composition and structure; but differ from them in containing petrifactions. These Werner dénominated *transition,* and other geologists, *intermediate.* They partake partly of the primitive, partly of the secondary character, hence are named intermediate or transition. These transition rocks become intermixed with sandstones, and other rocks of the same description, and at length disappear; when a series of sandstone and limestone rocks, remarkable for their abundance of vegetable and animal remains, make their appearance, and form the *secondary, or flœtz rocks* of geologists. The newer, or upper rocks of the secondary class, are covered with an alternating series of limestone, gypsum, clay, sandstone, and sand, which abounds in fossil organic remains, and particularly of quadrupeds. The name *tertiary* has been given to these.

The great beds of gravel, sand, clay, marl, &c. which rest on the rocks of the preceding classes, form a class named *alluvial*. They contain abundance of organic remains, and even of animals, at the top of the zoological scale. Those rocks, which are undoubted productions of fire, are named *volcanic*, and form the fifth and last class of the series of mountain rocks. They are often posterior to secondary rocks, and sometimes even to substances of the alluvial class.

Werner, as indeed appears from what has been already stated, seems to consider all the mineral formations as formed by one and the same solution, which has gradually changed in height and in nature. But he saw that this explanation would not apply to every case: for example, if every rock, or bed, should occur at a height corresponding to its age, that is, at a higher level in old than in new rocks, how does it happen that porphyry, resembling those in primitive regions, rests upon secondary rocks, and attains a great elevation? A simple oscillatory movement, Werner remarks, would not explain this arrangement. It follows, therefore, according to Werner's principles, that a new solution must have invaded the district already abandoned by the old solution, and deposited the newer formations. Werner admitted these new inundations, and attributed to them some particular formations, such as the secondary trap rocks, and certain primitive porphyries.

Werner remarks, that when we view the various depositions from the earliest discoverable period to the newest, we find in them such differences, as show that the contents of the water of the globe must have changed by degrees, and that all its depositions form beautiful and connected series. The oldest rocks, which are pure chemical precipitates, are composed principally of siliceous, argillaceous, and magnesian earths. The rocks, as granite, gneiss, and mica-slate, contain metals that are of cotemporaneous formation with them, and that scarcely occur in newer periods; these are tin, molybdena, and tungsten.

This state of the water of the globe, however, alters gradually and remarkably, as we approach the newer periods, by the appearance of limestone in quantity, coal, and salt, and the disappearance of old and the appearance of new metals. Besides this general succession, (which will afterwards be particularly considered,) discoverable in the productions of different periods, we have instances of the repetition of certain products at considerable intervals, and in formations of different æras and kinds. In a series of this kind, all the members have general characters of agreement, and the individual members bear characters expressive, not only of the period of their formation, but also of the circumstances under which they were formed. Such a series, as we have already mentioned, is denominated a *Principal Formation Suite*, or *Series of Formations*. By contrasting the old and new members of such a series, the difference will be found so great, that we can with difficulty recognize them as members of the same formation suite: on the contrary, the immediately preceding or following members are so much alike, that it is equally difficult to distinguish the one from the other. This shews how much the prevailing circumstances that existed during the time of their formation, were alike in the members of the same age, and differed in those of a different date.

We shall now illustrate this subject by a short abstract of Werner's descriptions of several of these series of formations.

1. *Limestone Formation-Suite.*

The first member of this series is the white granular limestone, which occurs in primitive rocks, as gneiss, mica-slate, and clay slate. This limestone has large granular distinct concretions; but in the newest clay-slate, the concretions become more minute, and it even approaches to compact. The transition rocks contain the second member of this series, the variegated limestone, which has less translucidity than the preceding, but more than the following members of the series, and shews the first traces of petrifactions. The following, or flœtz rocks, contain the third member of the series, the grey flœtz-limestone, which is scarcely translucent on the edges, and is full of petrifactions. It has some resemblance to the limestone of the transition period, but only a very remote one to that of the primitive. How great is the difference between the granular translucent primitive limestone, and the dull earthy and nearly opaque flœtz limestone; and yet both are members of a series of chemical formations, which are still not the most distant. Chalk is a still newer formation, and the limestone and marls of the Paris formation connect the foregoing members, which have been deposited from the ocean, with the calc-tuff, the lowest link of this series of formations, (if we do not include the coral-rocks that are daily forming) which has been formed on the land. We have thus a complete series from the earliest to the latest period, in which we observe a gradual disappearance of the crystalline, and increase of the earthy aspect, corresponding with the relative age of the different members of the series, and the state of the solvent from which they were precipitated, and all serving as proofs of the immensely great, but gradual alteration of the state of the universal waters. If we even examine the individual members of this series, we find these gradations still more minute, but always very characteristic. Thus the limestone of the primitive period, (that which occurs in gneiss,) has the largest granular distinct concretions, and possesses the highest degree of translucidity and lustre, and has therefore the most highly crystalline structure of the whole series. Does not the highly crystalline structure correspond most intimately with a calm state of the solution? The next member of the series, which is still crystalline, but with smaller distinct concretions, occurs in mica-slate; and, still less crystalline, or with smaller distinct concretions, in the oldest clay-slate. In the newer clay-slate, on the contrary, the distinct concretions are so small, as only to be discoverable by their glimmering and translucidity. The white colour, which hitherto characterised the older limestone, is now intermixed with black, red, &c; and the newest members of this formation form the transition to the products of the next period. In the transition period, the limestone is compact, translucent, glimmering, and variegated or marbled.

The secondary or floetz-limestone contains several formations that resemble each other very much, and differ principally by the newer being more earthy than the older. To these succeed, as we have already mentioned, chalk and calc-tuff, which are in general still more earthy in their external appearance.

It is not enough, Werner continues, to detail the differences and agreements of this great series; we must also endeavour to discover how these have been produced. The whole series, as has been already observed, is completely chemical, yet the different members have distinct characters of difference. In the first and second periods, the productions are almost entirely chemical, but the crystallization becomes more imperfect, the newer the formation. Lastly, in the third period, the members of the series become mixed with small portions of mechanical matter, as is shown by the earthy aspect of many flœtz-limestones. We know the conditions necessary for the formation of a crystalline structure, and that rest and motion are the agents which assist or prevent its regular formation. Hence we may fairly infer, that the solution, or ocean, when it stood high over the earth, was calm and undisturbed. During succeeding periods, the solution appears to have become more and more agitated; yet at first it only prevented the perfection of the crystallization. As the water diminished in height, its motions increased; its destroying powers reached to the surface of the earth, and the crystalline shoots were destroyed, and thus the first mechanical productions were formed. The water still continuing to diminish, the dry land began to appear; of course the mechanical action of the water would be much increased, as also the formation of mechanical productions. How admirably does this agree with the appearances presented by this series of formations!

The connection and import of all these appearances will be more apparent, if we take a view of the characteristic position of the strata in the different members of this series of formations, and of their relations to the exterior of the earth. This will be considered particularly afterwards. At present we shall only mention the highly elevated level of the limestone in gneiss, contrasted with the low situation of chalk and calc-tuff.

2. *Slate Formation-Suite.*

This is a very extensive series of formations.* The limestone series is composed only of limestone, and a single earth, as its principal constituent part. In the series of clay-slate formations, on the contrary, different earths have united together, to form the rocks we shall now mention. Silica, alumina, and magnesia, but particularly the two latter, are the most characteristic earths belonging to this suite of formations. We shall begin the description with that member of the series which may be considered as a central point from which the others diverge, and which gives the name to the whole series. This is clay-slate. It is evident, that the oldest clay-slate must border on the newest Mica-slate; and the newest, on transition-slate. The oldest clay-slate has more lustre than the newer, and is even slightly micaceous, so that it resembles the fine slaty mica slate on which it rests. The newer clay-slate has a darker grey colour, less lustre, and contains finely disseminated scales of mica, which brings it nearer to the transition-slate. Mica-slate is an aggregate rock, composed of quartz and mica: but in the older, it becomes gradually intermixed with felspar, which, in the oldest varieties, increases, and shows itself more and more as an essential constituent part, until the mica-slate passes into gneiss. The texture of the newest gneiss which lies nearest to mica-slate is still thin slaty; but it becomes gradually coarser, more crystalline, thick slaty, and very nearly granular, when it passes into granite. In granite, the texture is completely granular, and this rock stands as the first and oldest member of the series.

The same clue will conduct us back to the transition-slate, which occurs in mountains of grey-wacke. Here distinct mechanical matter is mixed with the chemical. Grey-wacke is a complete sandstone; we have a gradation of its grains from those the size of a pebble, until, from their smallness, they are no longer distinguishable; and this constitutes a transition to grey-wacke-slate.

Sandstone, and sandstone-slate, are the next members of this series. The sandstone-slate resembles mica-slate so much, that it has been sometimes confounded with it. To the sandstone succeeds the coal formation, which contains friable sandstone and slate-clay. Lastly, the series is terminated by bituminous wood and earth-coal, accompanied with sand and clay; which latter correspond to the sandstone and slate-clay of the immediately preceding formations.

A material division of this beautiful series takes place with grey-wacke. From it, upwards, all the members are completely chemical. On the contrary, in the lower, the chemical is combined with mechanical, and only the lowest links of the series are completely mechanical productions.

3. *Trap Formation-Suite.*

In this series, all the formations have a great resemblance to each other; yet all of them bear very distinct marks of the period of their formation. The oldest or primitive greenstone is highly crystalline; the newer or transition is less crystalline; and in the newest or flœtz-trap, it approaches to earthy, as appears in basalt, and more particularly wacke, as the lowest links or farthest removed from the highly-crystalline primitive greenstone.

4. *Porphyry Formation-Suite.*

The first member of this series, or which is denominated the *Old Porphyry Formation*, occurs in great unbroken beds, in gneiss, and its basis is hornstone. The second member, or what is denominated the *Newer Porphyry Formation*, occurs in unconformable, over-lying, and broken stratification. Its basis is clay-stone, pitchstone, &c. The third and last member of this suite is probably the clay-stone, and porphyritic-stone which occurs in the coal-formation.

5. *Gypsum Formation-Suite.*

The oldest member of this formation occurs in mica-slate and clay-slate. The second member is that which accompanies salt, and with which salt-springs are connected. It lies over the old flœtz-limestone, and is covered by the second flœtz-sandstone. The third and last member is what is denominated the second gypsum formation of the flœtz period. It lies over the second sandstone formation, and under the second limestone of the flœtz period.

6. *Salt Formation-Suite.*

This series contains only two members. The first

* If we would judge of the propriety of the name given to this series, from its extreme members, it would appear very unappropriate. To judge rightly, we must consider it in the whole, or on the great scale.

and oldest occurs along with the oldest flœtz, gypsum, and the newer is that which is still forming at the bottom of the lakes.

7. *Coal Formation-Suite.*

This is a very interesting series. Inflammable matter occurs in considerable quantity only in the newer formations. The small portion that occurs in primitive mountains, is carbon, uncombined with bitumen. In the newer formations, bitumen makes its appearance; and in the newest formations, as in the flœtz-trap, we find immense accumulations of bituminous inflammable matter.

It was only after the deposition of these immense repositories of inflammable matter in the flœtz-trap, that volcanoes could take place: they are, therefore, to be considered as new occurrences in the history of nature, although they may extend far beyond historical record. The volcanic state appears to be foreign to the earth—a circumstance that points out its great antiquity.

8. *Serpentine Formation-Suite*

Contains but two members; the older, that which occurs in a conformable position with the primitive rocks; and the newer, that which overlies the primitive rocks.

The phenomena presented by all these formations, Werner remarks, coincides with the hypothesis of the gradual and universal diminution of the waters of the globe. We shall conclude what relates to that subject, by a general observation respecting the effects which would be produced on the surface of the earth by the diminution of the water; and then state the arrangement of the different formations, founded on the preceding observations respecting their order of succession.

It is evident, that as the water diminished, and the dry land appeared, the motion of the water would be altered, and its currents receive new directions, or be divided. These changes must have had a very powerful effect on the former surface of the dry land, and, by destroying a part of the earlier formations, would afford matter for newer formations.

FORMATIONS, *according to* WERNER.

PERIOD.	*Slate.*	*Limestone.*	*Trap.*	*Porphyry.*	*Gypsum.*	*Coal.*	*Serpentine.*
PRIMITIVE. *Stratification conformable*, with sinking levels of the out-goings of the newer and newer strata.	Granite.						
	Gneiss.	Limestone.	Hornblende-slate.	Oldest Porphyry.	- -	Slaty glance-coal.	Oldest Serpentine.
	Mica-slate.	Limestone.	Hornblende-rock.	Oldest Porphyry.	Oldest Gypsum.	Slaty glance-coal.	Oldest Serpentine.
	Clay-slate.	Limestone.	Primitive greenstone. Greenstone-slate.	Oldest Porphyry.	- -	Slaty glance-coal. Also Graphite.	Oldest Serpentine.
Stratification overlying.	Newest Granite.		-	Newer Porphyry, including Clay-Porphyry. Pitchstone-P. Obsidian-P. Pearlstone-P.–Also Sienite.			Newer Serpentine.
TRANSITION.	Grey-wacke. Grey-wacke-slate	Transition-Limestone.	Greenstone. Amygdaloid.		Transition-Gypsum.	Slaty glance-coal. Graphite.	
FLŒTZ. *Stratification conformable*, with sinking levels of the out-goings of the newer and newer strata.	1st Flœtz-Sandstone. 2d Flœtz-Sandstone. 3d Flœtz-Sandstone. Sandstone in the coal formation.	1st Flœtz-limestone. 2d Flœtz-limestone. Chalk. Limestone and Marl in the Coal formation.	Amygdaloid. Greenstone and Amygdaloid in the Coal-formation.	Porphyritic-Stone in the independent Coal-formation. It may be considered as the 3d Porphyry-formation.	1st Flœtz-gypsum. Rock-Salt Formation. 2d Flœtz-Gypsum.	In the independent Coal formation: Coarse-Coal. Foliated-Coal. Slate-Coal. Cannel-Coal. Pitch-Coal. Slaty glance-Coal Graphite.	
Stratification overlying.	Quartzy-sandstone, in the Newest Flœtz-trap formation.	Limestone in the Newest Flœtz-trap formation.	Greenstone. *Greystone.* *Porphyry-slate.* *Basalt.* *Wacke.* *Trap-Tuff.* Amygdaloid. Iron-clay.	Clay-stone? Compact-felspar? Pitchstone-Porphyry. Obsidian-Porphyry. Pearlstone-Porphyry.		In the Flœtz-trap formation: Pitch-Coal. Columnar-Coal. Conchoidal-glance-coal.—Also Bituminous Wood. Alum-earth. Common Brown Coal. Moor-Coal.	
ALLUVIAL.	Clay. Loam. Sand. Gravel. Rolled masses.	Calc-spar. Calc-tuff. Calc-sinter.				Earth Coal. Bituminous Wood. Also Moor Coal. Common Brown-coal.—And Alum-earth.	

CHAP. V.

We have already, in Chap. IV. established five classes of rocks, distinguished by the names *primitive*, *transition*, *secondary*, *alluvial*, and *volcanic*. We shall now describe these in the order just mentioned, beginning therefore with those of the primitive class.

Class I. Primitive Rocks.

Urgebirge.—*Werner.*
Terrains Primitifs.—*Daubuisson.*

Primitive rocks are those whose period of formation is considered as antecedent to that of the creation of organic beings. Hence we arrange in this class all those formations which have not been found to contain petrifactions or fossil organic remains. Should future observations, however, prove that these rocks do occasionally inclose animal or vegetable remains, still it would be well to consider them as a distinct class, and retain the name primitive, because, from their lying under the rocks of the other classes, they are to be considered as having been formed before them, and may, therefore, be said to be primitive, or first formed.

They are of chemical formation; and if mechanical deposites do occur associated with them, the quantity is inconsiderable. All those kinds which abound in mica are distinctly stratified, while the others that do not contain it are less distinctly stratified. The direction of the strata is frequently parallel with that of the mountain range in which they are contained.

All the different rocks of the class alternate with and pass into each other.

The constituent parts are quartz, felspar, mica, limestone, and hornblende, minerals indeed of which nearly the whole mass of the upper coat of the earth is composed. Of these minerals, the felspar, quartz, mica and hornblende occur together, and in various forms of aggregation, while the limestone forms beds of greater or less extent, which are but slightly intermixed or connected with the boundary strata.

The following are the rocks of this class:

1. Granite, with sienite, protogine, and topaz-rock.
2. Gneiss, with some varieties of white stone.
3. Mica-slate, with different varieties of talc-slate.
4. Clay-slate, with alum-slate, flinty slate, &c.
5. Granular limestone, and primitive gypsum.
6. Primitive trap.
7. Serpentine and euphotide.
8. Porphyry.
9. Quartz-rock.

I. *Granite.*

Granite. *Werner.*

Saxum, quartzo spato scintillante et mica, in diversa proportione mixtis compositum.—Granites. *Wallerius.*

Granite of the Germans, French, &c.—Moorstone of Cornwall. Whinstone and sandstone in some parts of Scotland.

1. The name *granite* is a corruption of the Latin word *geranites*, used by Pliny to designate a particular species of stone. The first modern writer who uses this word is Torneforte, the celebrated naturalist. It occurs in the *Account of his Voyage to the Levant*, published in 1699. Antiquarians appear to have named every granular stone capable of being used in architecture or statuary, granite, and it continued to be used in this vague sense by mineralogists until about fifty years ago, when true granite was distinguished as a particular mountain-rock.

2. It is a rock composed of grains or concretions of felspar, quartz, and mica, intimately joined together, but without any basis or ground. These parts vary in quantity, so that sometimes one, sometimes the other, and frequently two of them, predominate. Felspar is generally the predominating, as mica is the least considerable, ingredient of the rock. In some varieties, the quartz is wanting, in others the mica, and these have received particular names. Such distinctions, however, are useless, as these masses are to be considered as mere varieties, not distinct species.

The constituent parts differ also considerably in their magnitude: they alternate from large to small, and even very fine granular. In some varieties, the concretions of felspar and quartz are several inches in size, and the mica is in plates upwards of a foot square; while in others, the grains are so small that the granite appears nearly compact.

It differs also considerably as to colour; and this depends principally on the predominating ingredient, the felspar, the quartz and mica having usually a grey colour. The felspar is usually white, and most commonly greyish and yellowish white; also reddish or milk-white; sometimes also flesh-red. It is seldom grey, yellow, or green. The quartz is usually grey, seldom milk-white, and always translucent. The mica is usually grey, and sometimes nearly black.

The felspar in granite has usually a vitreous lustre, and perfect foliated fracture, yet in some varieties it passes into earthy, with the loss of its lustre and hardness; in short, it has passed into porcelain earth. This appearance is sometimes produced by the weathering of the felspar; sometimes it appears to be its original state. When veins containing pyrites traverse granite, the felspar and mica in their vicinity are converted into a kind of steatitical matter, by the action of the sulphuric acid formed during the decomposition of the pyrites. The mica sometimes also decomposes by exposure to the atmosphere; but the quartz is never altered. Granite, with earthy felspar, is found in Cornwall.

Sometimes the constituent parts of granite are regularly crystallized; principally, however, the felspar and quartz. The mica sometimes occurs in nests, unmixed with the other constituent parts, and these have been confounded with fragments. Sometimes the constituent parts are so arranged, that when the specimen is cut, its surface has a kind of resemblance to written characters: hence this variety has been denominated *graphic stone.* This particular variety is found at Portsoy, and in the island of Arran; also in the forest of Thuringia in Germany, in Corsica, in the mountain of Odontschelong, in the Uralian range, and also in France. Granite, with regular crystallized felspar, occurs in the island of Arran, in many places on the continent of Europe, and also in South America. At Mount St. Gothard, all the three constituent parts are found crystallized together. In the island of Arran and the Saxon Erzgebirge, there is a remarkable variety of granite, in which the felspar, quartz, and mica, have a diverging radiated structure.

Several other *varieties* of granite have been described by geognosts. Of these, the two most important are *protogine* and *sienite.* We shall now describe them.

Protogine.

In this variety, talc, either in the lamellar compact, or steatitic form, or as chlorite, takes the place of the mica. Mont Blanc, and the surrounding mountains, are formed of protogine. It is named protogine, (primævi,) because Jurine, the author of the name, considers it as of very old formation. Daubuisson proposes to name it simply talcose, or steatitic granite.

Sienite.

Sienite is a granite, in which the mica is generally replaced by hornblende; not always, as some varieties contain also mica. Werner says it is a granular aggregated rock, composed of felspar and hornblende, with occasional grains of quartz and scales of mica. It is named from Syene, in Upper Egypt, where the ancients quarried it in blocks of great magnitude.

Werner having remarked, that this rock was associated with the porphyries of Saxony, arranged it along with them, separated it from granite, and described it as a distinct species. On the Wernerian view, therefore, it is distinguished from granite by its hornblende and its situation. Our observations in Scotland oblige us to consider sienite as a variety of granite, as it occurs in the same beds with that rock, and exhibits every variety of geognostical position hitherto observed in granite.

Accidental mixed parts.—Besides felspar, quartz, and mica, the essential constituent parts of granite, and those minerals that take the place of the mica, viz. hornblende and chlorite, others sometimes occur in it. These, however, are to be viewed as accidental. Of these schorl is the most frequent, and the next are garnet and tinstone. The following also occasionally occur, either imbedded in the rock, or in veins that traverse it, viz. rock-crystal, adularia, chlorite, pinite, actynolite, common opal, topaz, corundum, fluor-spar, beryl, diallage, epidote, apatite, magnetical iron ore, and iron pyrites.

Granite, besides the granular, exhibit various other kinds of structure, such as *porphyritic*, *globular*, *tabular*, *columnar*, and *stratified*.

1. *Porphyritic.*—When large crystals of felspar occur imbedded in a basis of smaller granular granite, the porphyritic variety is formed. These imbedded crystals are sometimes upwards of a foot in magnitude, as is the case with some granites in Saxony, and in other countries.

2. *Globular.*—Some granites are disposed in roundish balls or concretions, which are from a foot to several fathoms in diameter. These balls are sometimes composed of curved lamellar concretions, which always include a harder central mass or nucleus. The spaces between the concretions are filled with granite of a softer nature, which decays readily, and thus leaves the harder central masses heaped on each other, or strewed about. Such heaps, or tumuli, have been erroneously described as rolled masses brought from a distance to their present situation, by the agency of currents that formerly swept the surface of the earth. Examples of this kind of structure occur in the island of Arran, Bohemia, the Hartz, the Fichtelgebirge, and in other countries.

3. *Tabular.*—Some granites, when they are traversed by parallel seams, appear divided into tables. These tables vary in extent from a few inches to several fathoms. They appear in some cases to be mere varieties of the stratified structure.

4. *Columnar.*—When the seams are arranged in directions parallel to several planes, the granite is divided into columnar masses, which resemble the columnar structure of trap and porphyry rocks. We many years ago, as mentioned in our account of the Hebrides, observed this columnar structure in the granite of Mull; and since that time Humboldt has described it as occurring in the granite of Caraccas, as it does in the granite rocks of Carlsbad.

5. *Stratified structure*, or *Stratification.*—Granite is sometimes disposed in great beds in gneiss and other rocks, and occasionally these beds appear divided into strata. In other instances, in granite mountains, we observe, besides the tabular, globular, and other structures, also the stratified; but this latter is, in general, less perfect than what is observed in gneiss, and other similar rocks.

6. *Beds in Granite.*—Granite does not afford so many different beds and veins as occur in gneiss, mica-slate, and other similar rocks. In Scotland, it sometimes contains beds of quartz and of felspar. In Switzerland, beds of quartz in granite have large drusy cavities, the walls of which are lined with magnificent crystals, and groups of rock-crystal. At Zinnwald, in Bohemia, the tin is worked in a quartz bed, situated in the middle of the granite. Beds of limestone are also met with in granite mountains, as in the Pyrenees; and some of them of great extent, having been traced by that excellent observer, Charpentier the younger, for four leagues, and with a thickness of ninety feet. We need not speak of the beds of gneiss, mica-slate, clay-slate, porphyry, trap, &c. upon which it often rests, and with which it frequently alternates.

7. *Metals in Granite.*—On a general view this rock contains fewer and less extensive metalliferous veins and beds than the slaty rocks of the primitive class. Tin, of all the metals, is that which is most peculiar to granite. Tin-stone occurs in the granite of Cornwall, Saxony, Limoges, and in these countries is generally associated with walfram.

Iron is frequent in granite. The mines of Traversella, in Piedmont, are situated in a granite which is subordinate to mica-slate. The mines of brown iron ore at Tauryniâ, and of Fillolo in the eastern Pyrennees, are in granite. Iron pyrites is frequently found disseminated through granite; and galena, or lead-glance, graphite, molybdena, bismuth, gold, silver, copper, zinc, manganese, cobalt, are among the metals sometimes met with in this rock.

8. *Formations of Granite.*—Granite occurs in masses, often many miles in extent, surrounded by gneiss, mica-slate, and clay-slate, and so connected with these rocks, that the whole may be considered as the result of one grand process of crystallization; that is, the granite is of cotemporaneous formation with the gneiss, as the gneiss is with the superimposed mica-slate; and the mica-slate, again, with the clay-slate which rests upon it. In other instances, the granite alternates in beds, often of enormous magnitude, with gneiss, mica-slate, clay-slate, and other primitive rocks, or it traverses these in the form of veins.

9. *Decomposition of Granite.*—Some granites resist, for ages, the destroying effects of the weather; while others are resolved into sand or clay in a comparatively short period. The obelisk which is at present in the

place of Saint Jean de Latran, at Rome, and which was quarried at Syena, under the reign of Zetus, King of Thebes, thirteen hundred years before the Christian era; and that which is in the place of Saint Pierre, also at Rome, and which a son of Sesostris consecrated to the sun, have resisted the effects of the weather for three thousand years.

On the other hand, there are granites, as those in some districts in Scotland, which are speedily disintegrated into gravel or sand. But between these two extremes, of extreme durability and rapid decay, there are numerous intermediate degrees. In the same mountain, or even in the same hillock, granites of different qualities will sometimes be met with. One portion will be excessively obdurate, and resist long the gnawing effects of the weather; another variety, immediately beside it, will be of a very decomposable nature; and while a third, associated with the two former, will possess an intermediate degree of durability. Granites vary in their mode of decomposition. Some assume the globular form; others that of rhomboidal or irregular masses. These are further disintegrated, and then the constituent parts fall asunder; when a kind of gravel, or sand, depending on the size of the grains, is formed. The felspar in this gravel is further altered, and easily changed into a clay, which is carried into hollows or plains, and forms beds of clay; the quartz grains, by attrition, are reduced in size, rounded in form, and give rise to beds of sand; and, when mixed with the matter of felspar, to sandy clays. The mica is further broken down, and becomes mixed with the clays and sands formed from the felspar and quartz.

The soil formed from decomposed granites, is in general comparatively unproductive.

10. *Shape of Granite Mountains.*—In those granite districts, in which the granite is of a loose texture, and easily acted on by the weather, the hills have a roundish form, and the lower granite tracts have a waved, or rather a mamillary outline.

But if very hard and indestructible granite rises through softer and more easily disintegrated, the harder portions appear in the form of peaks, needles, or in deeply dentated ridges, or cristæ, and thus give rise to the bristled and denticulated aspect so peculiar to many granite districts. The valleys, in granite countries, are in general very deep, narrow, and their sides often resemble immense perpendicular walls.

Granite rocks are frequently much traversed by rents or fissures. When these rents widen by the action of the weather, the mass separates into fragments of greater or lesser magnitude, which remain long piled on each other in a most fantastic manner, often appearing like vast artificial tumuli, or masses brought together by a flood. The upper parts of the granite mountains in Arran present very striking appearances of this kind, and I have observed the same in many places of the high granite ridges of the Riesengebirge. Travellers have described similar appearances in the mountains of Switzerland; those of Siberia; the Hartz; the Bohmerwald-gebirge, and the Carpathians.

11. *Geographical distribution of Granite.*—It is one of the most frequent and widely extended rocks. It occurs in almost every mountain group, and there it frequently juts out, forming its central and highest part, having the newer primitive rocks resting on it, or placed beside it. It forms mountains in this country, as in the island of Arran, and the central part of the Grampians. The same is the case in the Hartz, the Riesengebirge, the Bohmerwald-gebirge, the Fichtelgebirge, and the Alps, particularly those of Savoy; also in Bavaria, Bohemia, Franconia, Lusatia, Moravia, Upper Saxony, Thuringia, Austria, Stiria, and the Tirol. As granite is the basis on which the other primitive rocks sometimes rest, it may also appear in low mountainous situations, owing to the newer primitive rocks either not having been deposited, or having been washed away since deposition. Instances of this we have in the Island of Arran, near Carlsbad in Bohemia, and many other places.

The following list of localities shows the known extent of granite in the different quarters of the globe, without, however, any reference to its forming the centre and highest, or the lowest part of mountains or mountain-groups.

In Europe, it forms the range of Sewoga in Scandinavia; the rocks of Finland; occurs also in Cornwall in England, in the Hartz, the Forest of Thuringia, Erzgebirge in the Electorate of Saxony, the Fichtelgebirge, Lusatia, the Riesengebirge, the Bohmerwald-gebirge, the Schwarzwald (Black Forest,) the Alps of Switzerland, and Savoy; also in the Tyrol, Salzburg, Stiria, Archduchy of Austria, the Carpathian Mountains, Auvergne, Dauphiny, Elsass, and the Pyrenean Mountains.

In Asia, it forms the centre of Caucasus; occurs at Kolywan, and other places in Siberia; forms a very considerable portion of the Uralian, Altain, and Himalya chains of mountain-groups.

In Africa, it is said to form a principal constituent part of the mountains in Upper Egypt, the Atlas Mountains, and the country about the Cape of Good Hope.

America.—It occurs but in comparatively small quantity in the United States; and in Mexico, owing to the deep and high cover of porphyry, it is found only low down, as at Acapulco. In the Andes of South America, it is usually covered with gneiss, mica-slate, and trachyte, and in general is not observed higher than 6000 feet: but it abounds in the low mountains and regions of Venezuela, and of Parima, and descends even to the plains and to the level of the sea, as is the case on the sides of the Oroonoco, and the coasts of Peru.

In North America, it is said to occur in New York, Pennsylvania, and Virginia. In South America, it forms De los Mariches, near Caraccas, the whole Cordillera of Parima, Sierra Nevada de Merida, Torrito between South Carlos and Valencia, the country between Valencia and Portocabello, and Cape Horn, the southern extremity of America.

Uses.—It forms an excellent building and paving stone, and has been extensively employed in ornamental architecture.

Topaz-Rock.

This rock, which appears to be intimately connected with granite, has the following characters. Its constituent minerals are quartz, tourmaline, topaz, and lithomarge. It is composed of many small masses, which have the appearance of fragments, although they are true granular concretions. Each of these masses is composed of thin layers of quartz, tourmaline, and topaz; and these layers have different directions in the different masses or concretions. The quartz appears in granular concretions; the topaz is also granular; but is distinguished by its foliated aspect and hardness; lastly, the tourmaline is in small black needles. Frequently hollow spaces occur between these concretions, which are partly filled with crystals of quartz and topaz, but rarely contains tourmaline. The lithomarge occurs amongst these crystals, and has generally an ochre yellow, rarely green, and seldom white colour. It is worthy of remark, that the colour of the crystals of topaz, and also its intensity, depends on that of the lithomarge; as if this substance, or at least its colouring matter, was the same as that of the topaz.

Topaz rock is very distinctly stratified, and the strata are of considerable thickness. It rests upon granite, and is covered by clay-slate.

It has hitherto been found only near to Auerbach, in Voightland, in Saxony, where it forms a rock named *Schneckenstein*, which was formerly of considerable extent, but has been much diminished by the operations of the miners in procuring topazes.

The inconsiderable extent of this mass prevents our viewing it as a distinct species of mountain rock.

II. *Gneiss.*

Gneiss.—*Werner.*
Gneiss and Granite Veinè —*Saussure.*
Gneiss.—*Kirwan.*—*Jameson.*

1. *Name.*—The name *Gneiss* is of Saxon origin, and was applied by miners in the vicinity of Freyberg, to the decomposed stone that forms the walls of their metalliferous veins. Henkel describes gneiss as an indurated stone, mixed with a steatitical and clayey matter; but Werner ascertained that it was a compound of felspar, quartz, and mica.

2. *Constituent Parts.*—This rock, like granite, is a compound of felspar, quartz, and mica; but it contains more mica than granite. It is granular in the small, and slaty in the large; hence it is said to be granular-slaty. The granular felspar and quartz form plates, which are separated from each other by the mica.

Felspar, although the predominant mineral, is still in less quantity than in granite. The felspar is usually greyish, yellowish, and reddish-white; and sometimes so much altered that it appears earthy. The mica is most commonly grey, which passes through various shades into blackish-grey. The quartz is almost always greyish-white, and generally in smaller grains than the felspar.

3. *Imbedded Minerals.*—Besides felspar, quartz, and mica, it sometimes contains schorl; more rarely garnet, and also hornblende. The schorl occurs more rarely, and in less quantity, than in granite: but the garnet is more frequent and abundant than in granite.

4. *Kinds of gneiss.*—There are three principal kinds of gneiss, of which we shall now give short descriptions.

(1.) In this kind the mica occurs in small quantity: the scales of mica, although separated from each other, are arranged in parallel ranges, and the rock breaks in a direction conformable with these. It is the parallelism of the ranges of mica which distinguishes this kind of gneiss from granite, because its slaty structure is very indistinct, and the quantity of felspar is nearly the same as in granite. The quartz and the mica form each separate layers; those of the felspar are thicker, and such varieties, when broken across, have a ribbon-like aspect. Sometimes the quartz, in place of being disposed in layers or plates in the felspar, is in small parallel rods or bars; and when the rock is cut perpendicular to their direction, it appears not unlike petrified wood.

(2.) This, which is named *common gneiss*, consists of small layers, or lenticular plates, composed of grains of felspar and quartz, placed over each other, and separated by layers formed of scales of mica. It is sometimes glandular, or contains balls of quartz, or of compounds of quartz and felspar, or of mica. This variety has been confounded with conglomerate. The island of Fetlar, one of the Shetlands, affords an example of this variety.

(3.) This, the third variety, is very slaty, and very micaceous. The scales of mica, from their smallness, appear indistinct, and form continuous plates. The felspar and quartz are in very small grains, and are sometimes so enveloped in the mica, that it is difficult to distinguish them. It is also sometimes glandular, and in some instances almost an aggregation of balls of mica.

The gneiss which passes into granite belongs to the first variety, as that which passes into mica slate does to the third.

5. *Stratification.*—It is distinctly stratified, and the strata are parallel with the slaty structure. But when the beds rest upon granite, they sometimes follow all the sinuosities of the irregular surface of that rock, and form the mantle-shaped stratification; in other cases the stratification is saddle-shaped, or it does not appear affected by the granite, the strata passing without change of direction from one mass of granite to the other.

6. *Decomposition.*—This rock, like granite, decays on exposure to the atmosphere, but the decomposition is in general more rapid. The felspar is at first changed into kaolin, and, owing to the greater abundance of mica, the disintegration of the mass is more rapidly effected. Hence it is that this rock does not occur so often in great isolated blocks as granite; and hence also it is that mountains of gneiss are often less sharp in their outline than those of granite, that their summits are generally roundish, and that they rarely shoot into needles, or are formed into denticulated ridges.

Sometimes the decomposition, in penetrating the gneiss, loosens the adherence of the parts; the folia are then easily separated by the finger, and the mass appears as if rotten.

7. *Foreign beds.*—These beds are more considerable and more numerous in gneiss than in granite. The following may be enumerated.

Limestone.—It is generally highly crystallized. Occurs in Aberdeenshire, Perthshire, and other parts of Scotland; and on the continent of Europe, in the Pyrenees, in Dauphiny, &c.

Trap.—This rock, in the form of hornblende rock, hornblende-slate, and greenstone, occurs in beds, and in imbedded masses, and is often very much intermixed with the gneiss. When the gneiss abounds in hornblende, it is named *hornblendic gneiss.*

Porphyry.—Beds, imbedded masses, and veins of porphyry, sometimes of great magnitude and extent, are not unfrequent in some gneiss districts. Perthshire, Aberdeenshire, and Inverness-shire, afford fine examples of porphyry in beds, imbedded masses, and veins.

Compact and granular felspar.—The white stone. Weisstein of *Werner.*—This rock sometimes occurs in layers, which are not more than a few inches thick; in other instances in beds, so thick as to form whole mountains. The felspar is white, and is very fine granular, like dolomite: it contains numerous grains of red garnet, even grains of quartz, and sometimes scales of white mica. In short, it is to be considered as a granular felspar, generally containing scales of mica, with some grains of quartz, and of other minerals. It forms beds and whole hills in Saxony, Moravia, and Sweden.

Quartz Rock.—This rock occurs in great beds, and sometimes also in veins in gneiss districts.

Besides the beds above described, gneiss contains occasionally granite, mica-slate, and clay-slate.

Glance Coal.—The slaty kind sometimes occurs in beds in gneiss.

8. *Metalliferous Minerals.*—Gneiss is one of the most metalliferous of the primitive rocks. The metals occur in veins, beds, and imbedded masses, but in greatest variety in veins. There are few metals that do not occur in it. Most of the Saxon, Bohemian, and Saltzburgian mines, are situated in this rock. The oldest gneiss in the Saxon Ergebirge, that with reddish-coloured felspar, is the least productive in ores; but the newer, with white-coloured felspar, is the most productive; and the veins, though small, are numerous. The oldest venigenous formation appears to be that which contains tinstone. The tin-ore is accompanied with wolfram, molybdena, arsenic-pyrites, fluor-spar, chlorite, topaz, and opal. The second venigenous formation appears to be lead-glance. The third formation consists principally of copper, and the ores are grey copper-ore, copper-glance, copper-pyrites, and variegated copper-ore. The fourth formation, which is very extensive, contains ores of cobalt. The newest formation is that which contains ores of silver. Veins, containing antimony and red ironstone, occur in gneiss, and these are supposed to be newer than any of the preceding. Veins of quartz with gold also occur in gneiss.

The metalliferous beds that occur in this rock contain magnetic iron-ore, argentiferous lead-glance, blende, copper and iron pyrites.

The lead-mines of Strontian, in Argyleshire, are situated in gneiss.

Geographical distribution.—It is a very widely distributed rock. It is found in almost every country where granite occurs; and is often interposed between granite and mica-slate, or is contained in mica-slate, or even in clay-slate. It is an abundant rock in Scotland, forming extensive tracts in the middle and northern divisions, and also in the islands. It is the principal rock in Sweden and Norway. It occupies almost the whole of the Saxon metalliferous mountains: it abounds in Bohemia and Silesia; it is not uncommon in the Black Forest, the Upper Palatinate, in Carinthia, in the Southern Alps, the Pyrenees, and the Vosges. It occurs also in Greece; and, in the vicinity of Athens, the old mine-works of the ancients are situated in it. It is an abundant rock in the United States of America, and in South America: Humboldt met with it in the high chain of the Andes of Quito, in the mountains of Parima, and Venezuela.

III. *Mica-Slate.*

Glimmer-Schiefer.—*Werner.*
Micaceous Schistus.—*Kirwan.*
Mica-Slate.—*Jameson.*
Schiste micacé.—*Brochant.*
Rocke Feuilletée, et quartz, ou Schiste micacé.—*Daubuisson.*—*Saussure.*

1. *Constituent Parts.*—This rock is composed of mica and quartz, and, like gneiss, has a slaty structure. The mica is generally the predominating ingredient: its colour is grey, sometimes inclining to green, sometimes to yellow, and more rarely to brown. It is often disposed in continuous plates, not in distinct scales, as in gneiss. The quartz is grey, with its usual vitreous lustre, and is disposed in thin lenticular masses, interposed between the plates of mica. Sometimes these masses increase in magnitude, and become globular, and then the rock acquires a conglomerated structure. Although the mica forms the principal and predominating ingredient in mica slate, yet it sometimes happens that the quartz is the most abundant, and thus a transition is formed into quartz rock.

2. *Varieties.*—We can distinguish different kinds of mica-slate. These are *Common*, *Undulated*, *Talcky*, *and Fine Slaty.* The *common* is straight, and rather thick slaty, and contains garnets, and sometimes felspar. The *undulated* has a waved structure, and contains neither garnets nor felspar. The *talcky* is straight slaty; contains thick layers of quartz, and the mica has a green colour, and inclines to talc. The *fine slaty* borders on clay-slate, (the next rock in the order of succession,) has a light yellowish grey colour, and contains extremely little quartz; it passes imperceptibly into clay-slate. Of these, the oldest is the Common, and the newest the Fine-slaty.

3. *Imbedded Minerals.*—It frequently contains imbedded minerals of different kinds. The principal of these are the following:

(1.) *Garnet*, either in grains or in crystals, and is so frequent and abundant, that it may almost be considered as a characteristic and principal ingredient of the rock. It abounds in mica-slate districts in Scotland, and on the continent of Europe.

(2.) *Tourmaline and Schorl.*—These are met with in the mica-slate of Scotland, and in other countries.

(3.) *Grenatite.*—This mineral occurs in the mica-slate of the county of Wicklow in Ireland, and in districts of the same description on the continent of Europe.

(4.) *Chiastolite.*—This curious mineral is found in mica-slate in the Pyrenees.

(5.) *Kyanite.*—Is found in the mica-slate of the Shetland islands, and also in a similar rock in Banffshire.

(6.) *Emerald.*—The beautiful emerald, found in Egypt, occurs in mica-slate.

Besides the minerals already enumerated, many others, as vesuvian, rutile, graphite, &c. occur in mica-slate.

4. *Stratification* and *Position.*—It is very distinctly stratified. The strata are sometimes variously convoluted, and the same character occurs in the substance of the strata. It often rests on gneiss, and is covered by clay-slate. It passes, on the one hand, into gneiss, and the transition is made by the common kind; and on the other into clay-slate, and the transition is made by the fine-slaty kind. The out-goings of the strata are frequently lower than those of the gneiss, on which they rest, and higher than those of the clay-slate that cover them. It sometimes also occurs in beds in gneiss, and clay-slate, and even in granite.

5. *Foreign Beds.*—It contains more foreign beds than gneiss. The following have been observed: Granular-limestone, dolomite, hornblende-slate, and hornblende-rock, actynolite, garnet, talc, serpentine, chlorite, quartz-rock, magnetic iron-stone, magnetic pyrites, copper-

pyrites, iron-pyrites, arsenic-pyrites, blende, lead-glance, and red ironstone.

6. *Form of Mountains.*—The acclivities of the mountains are gentle, but the cliffs it forms are not so considerable as those in gneiss mountains. When mural precipices occur, they are seldom of great height. The summits of the hills are round backed.

7. *Metalliferous Minerals.*—It is one of the most metalliferous of the mountain-rocks. The ores it contains occur frequently in beds, but more rarely in veins, which is directly the reverse of gneiss, where ores occur more frequently in veins than in beds. The ores that occur in beds are the following: magnetic ironstone, iron-pyrites, copper-pyrites, arsenic-pyrites, red-iron ore, lead-glance, blende, gold, and glance-cobalt; and these ores are accompanied with actynolite, garnet, and asbestus.

The veins that occur in mica-slate contain in general the same ores as those in gneiss.

The gold mines at the foot of Monte Rose are principally in mica-slate; and this is also the case with some of those in the country of Salzburg. The silver mines of Johan-Georgenstadt and Braunsdof in Saxony; those of Sweden and Norway are in these rocks. Many of the mines in Silesia and Bohemia are in mica-slate.

The most important mines in Sweden, as those of Dalecarlia and Fahlun; those of Roraas in Norway; many in Hungary and Salzburg, Saxony and Bohemia, are situated in this rock.

8. It occurs in great abundance in Scotland; as in the valley between Dunkeld and Blair-in-Athol; the mountain of Schihallion, and the neighbouring country; island of Arran; islands of Jura and Isla, &c. It is also very widely distributed in the continent of Europe; as in Saxony, Bohemia, Silesia, France, Spain, the Bannat, Transylvania, Switzerland, Salzburg. It also occurs in the United States, in South America, and in the continents of Africa and Asia.

IV. *Clay-Slate.*

Thonschiefer.—*Werner.*
Primitive Argillaceous Schistus, *Kirwan.*
Clay-Slate.—*Jameson.*
Schiste argileux, *Brochant.*
Phyllade.—*Daubuisson.*

1. *Characters.*—*Clay-Slate* is a simple mountain-rock, having a slaty structure, with a fine grained, and dull cross fracture; it is opaque and soft, with a grey streak, whatever may be its colour. Its most frequent colours are grey, or bluish black; very often greenish-grey; more rarely yellowish-grey and brownish-red. Oxide of iron is the general colouring ingredient; but in the black varieties it is carbon, which gives the tint of colour. The greater number of varieties split easily into slates, which are either plain or variously convoluted. Their surface is sometimes smooth, in other instances it is traversed by deep striæ; and it is sometimes dull, sometimes shining with a silky or pearly lustre. It is intimately connected with mica-slate, and there is a distinct transition from it into that rock, by the gradual disappearance of the quartz, thus shewing that it is entirely composed of mica in very minute and closely aggregated scales.

2. *Varieties.*—There are four varieties of clay-slate. The *first kind* has a yellowish-grey colour, and a shining lustre: it is the oldest kind, to use the language of Werner, and is that which reposes immediately on mica-slate; it is in short the link that connects clay-slate with mica-slate. The *second kind* is dark-grey; sometimes even bluish-grey and greyish-black, forming what is denominated *roof-slate*, from the circumstance of its splitting into thin and large tables. We must be careful, however, not to consider all roof-slate as of primitive formation. To this follows, in the order of succession, the *third kind*, which has a greenish-grey colour. The *fourth* and last, which is the newest kind of clay-slate, is bluish-grey, and reddish: it contains a very few intermixed scales of mica; possesses but little lustre; and is the link that connects the primitive clay-slate with the transition clay-slate.

3. *Stratification.*—It is distinctly stratified, and its slaty structure is generally parallel to the seams of the strata; in some cases, however, a double cleavage is observable; and Count de Bournon observes, that many clay-slates break under angles of 60° and 120°, which he supposes may be owing to the presence of mica. The strata are in general much inclined, and are often variously convoluted and waved, and sometimes they appear to be composed of different concretions.

4. *Imbedded minerals.*—Independent of the grains of quartz and scales of mica irregularly distributed through it, we find it containing large imbedded masses of quartz, of hornblende, and crystals of chiastolite.

5. *Subordinate Beds.*—It contains a greater variety and number of foreign beds than gneiss or mica-slate; and of these some are nearly peculiar to it, and characterise the whole formation. We shall first mention those which are common to gneiss and mica-slate, as well as clay-slate, and then those that are peculiar to clay-slate.

(1.) Rocks that occur in gneiss, mica-slate, and clay-slate. 1. *Limestone.* 2. *Hornblende-rock.* 3. *Primitive Greenstone.* 4. *Hornblende-slate.* 5. *Porphyry.* 6. *Quartz.* 7. *Actynolite.*

(2.) *Rocks peculiar to the clay slate formation, or which occur very frequently in it.* 1. *Whet-slate.* It occurs in beds, in Saxony, Bavaria, Silesia, Stiria, and other countries. 2. *Roof-slate.* This is but a variety of clay-slate, distinguished by its bluish or ash-grey colour; its straight slaty fracture; its splitting into large tables, and its being nearly pure and unmixed. It seldom or never forms whole mountains, but occurs usually in single thick beds with other kinds of clay-slate. 3. *Chlorite-slate.* This usually follows the preceding. It forms whole beds, and includes garnets, crystallized magnetic iron-stone, iron-pyrites, common schorl, tourmaline, and quartz. 4. *Talc-slate.* This is usually the next in the order of succession. 5. *Alum-slate.* It occurs in considerable beds in clay-slate; and the two sub-species, the common and shining, alternate with each other. It contains a portion of carbon, and also iron-pyrites. 6. *Drawing-slate.* It occurs usually in the vicinity of alum-slate, and is very nearly allied to it. It contains more carbon than alum-slate, but less iron-pyrites. 7. *Potstone* occurs in considerable beds. 8. *Flinty-slate* occurs in considerable beds in this great formation. 9. *Lydian-stone* occurs in beds and imbedded masses.

6. *Formations.*—This rock occurs along with mica-slate, and sometimes in beds in gneiss, and even in granite.

7. *Form of mountains.*—It sometimes forms whole

mountains, and even chains of mountains. Its mountains have usually a gentle acclivity; and its cliffs are not so steep and rough as those of mica-slate or gneiss. It is more favourable to vegetation than any of the rocks we have hitherto described; and it is observed that the quantity of vegetation increases from granite to clay-slate; and this appears to depend, not so much on the lower level of the outgoings of its strata, as on the nature of the rock itself.

We can thus observe a gradual change in the shape of mountains, also of their cliffs and valleys, from granite to clay-slate; and these differences are so striking and characteristic, that a long experienced eye can, at a glance from the summit of a mountain, point out with considerable certainty the different formations of which a country is composed. Landscape-painters, by confounding together all these differences, or by combining them irregularly, fail not only in accuracy, but in giving their work that appearance which shows, at first glance, that it is not only a copy of nature, but a copy by one who has formed a distinct conception of the most general and particular features of the inequalities observable on the surface of the earth. Some affect to maintain, that the grand features of mountains and plains are different in different zones. Thus, that in the torrid zone, for example, the shape, cliffs, and other appearances in mountains, are different from those in the temperate zone. This, however, is a mistake; for the same formation in all countries presents similar external characters; and as the great formations are universal, no such differences can exist. It is true, that the blue colour of the heaven, its degree of illumination, the appearance of distant mountain-vapour, the shape of animals, the luxuriance of vegetables, combined with the features of mountains, will form a particular character for each climate; but still the aspect of the rocks of the same formation, in whatever country they occur, will be the same. Thus cliffs of granite and mica-slate have the same appearance in India and Siberia as in Scotland; and the valleys of the Urals do not differ in shape and other features from those formed by similar rocks in this neighbourhood.

7. *Metalliferous Minerals.*—Clay-slate is rich in metals. It contains many of the venigenous formations that occur in the preceding primitive rocks, as tin, lead, cobalt, and silver. Very considerable metalliferous beds also frequently occur, and these contain copper pyrites, red copper-ore, copper-green, blue copper, malachite, iron-pyrites, magnetic pyrites, glance-cobalt, grey cobalt-ore, arsenic-pyrites, blende and lead-glance. Gold also occurs in this formation, and it is said also cinnabar.

8. *Geographical distribution.*—It is a very widely extended rock. In this country, it skirts the Highlands from Lochlomond by Callender, Comrie, and Dunkeld; in the whole of that extensive district, resting on and gradually passing into mica-slate; the same appearances are to be observed in many other quarters in Scotland. On the continent of Europe, it has been traced through a great extent of country; thus it occurs in Saxony, Bohemia, Silesia, Franconia, Bavaria; the Alps of Switzerland, Austria, Hungary, and many other parts in Europe. It occurs also in considerable quantity in North America, as Pennsylvania; also in immense quantity in South America; thus it is said, that nearly the whole country between Potosi and Lima is composed of it. In some of the districts above enumerated, transition clay-slate has been confounded with the primitive kind.

V. *Primitive Limestone.*

Ur. Kalkstein.—*Werner.*
Primitive Limestone.—*Kirwan.*
Primitive Limestone.—*Jameson.*
Calcaire Primitif.—*Brochant.*

Characters.—This is a simple mountain rock. Its most common colours are snow, yellowish, greyish, greenish, and reddish white; it is sometimes also grey, and the newer varieties incline to yellow. Its structure is always granular. Those varieties which are associated with granite and gneiss are generally more crystalline than those contained in mica-slate and clay-slate; and, in general, primitive limestone is more crystalline than secondary. Werner remarks, that in the oldest members of the series, that is, in those contained in granite, the colour, of the limestone is pure white, translucent, and coarse granular; in the newer members, the colour is less pure, the translucency less considerable, and the granular distinct concretions smaller; and in the newest, the concretions are so small as only to be discoverable by their glimmering lustre.

2. *Imbedded Minerals.*—It frequently contains accidental ingredients, and these occur more frequently in the older than in the newer members of the series. We shall mention some of these: 1. *Quartz.* It occurs in massive pieces of greater or less magnitude, and sometimes also in crystals. 2. *Mica.* It sometimes occurs in such quantity as to give the stone a slaty fracture. These two minerals, namely, quartz and mica, are the most common accidental minerals that occur in primitive limestone. Those of less frequent occurrence are the following: common hornblende, actynolite, asbest, serpentine, augite, talc, steatite, felspar, epidote, tremolite, garnet, calc-spar, slate-spar, and pyrites.

3. *Stratification.*—It occurs more or less distinctly stratified. It was once the opinion, that granular aggregated stones, as primitive limestone, granite, sienite, and greenstone, were never stratified. This, however, is a mistake. Primitive limestone also occurs in beds of greater or less magnitude; sometimes these beds are short and thick, and are then said to form lying masses (liegende Stöcke;) or the beds are so thick as to form whole mountains; but this latter is a rare occurrence.

4. *Formations.*—There are several formations of primitive limestone. Thus it forms one formation in granite, another in gneiss, a third in mica-slate, and a fourth in clay-slate. It is more abundant in mica-slate than in granite or gneiss, or even in clay-slate.

5. *Metalliferous Minerals.*—It frequently contains ores of different kinds, and these occur often in beds, but seldomer in veins. The metalliferous beds contain ores of different kinds, as lead-glance, blende, magnetic ironstone, magnetic pyrites, auriferous arsenic pyrites, and native gold. The veins are very inconsiderable, and by some mineralogists are said to contain principally manganese.

6. Several beautiful varieties occur in this country, as in the islands Tiree, Icolmkill, and Skye; also in Perthshire, as in Glen Tilt, in Assynt, in the county of Sutherland, and many other places. The promontory of Athos, in the Archipelago, is said to be composed of primitive limestone; also the Island of Paros, and part of the Appenines, as about Carrara and Massa, many parts of the

Alps of Switzerland, the Pyrenees, Carrapatos in Portugal, Bohemia, Saxony, Silesia, and many other parts of the continent of Europe.

8. *Uses.*—The finest statuary marbles are found in primitive mountains, and also many of the varieties used in ornamental architecture.

Primitive Gypsum.—Hitherto this rock has not been observed to form masses or beds of considerable extent in primitive mountains. Nearly the only authentic example recorded of primitive gypsum, is that given by Daubuisson, who informs us he discovered a bed of it in mica-slate, in the valley of Aoste, and near the village of Cogne.

VI. *Primitive Trap.*

Ur-Trap.—*Werner.*
Primitive-Trap.—*Jameson.*
Granitelles, Trap, Corneennes.—*Saussure.*
Trapps Primitifs.—*Brochant.*
Amphibolite.—*Daubuisson.*

1. *Name.*—The name trap is derived from the Swedish word *trappa*, signifying a stair. It would appear that this name was first used by Rinman, in a memoir on ferruginous stones, published in 1754. The Swedes applied this name to rocks, which, on exposure to the air, assumed shapes resembling the steps of a stair. It was, however, soon extended to a considerable variety of rocks of very different formations; hence Werner found it necessary to restrict its signification. He understands by trap, rocks principally characterized by the presence of hornblende and black iron-clay. Hence all rocks occurring in the primitive class, having hornblende as a characteristic or predominating ingredient, belong to the Primitive Trap Formation.

2. *Varieties.*—Hornblende occurs in trap rocks, either alone or mixed with other minerals, and having different structures; and this arrangement affords a good basis for their subdivision. In the oldest trap, no iron-clay occurs; it first makes its appearance in the transition period, and increases in the newer periods.

Primitive Trap, in particular, is almost always distinguished by a great predominance of hornblende, so that some of the kinds are wholly or almost entirely composed of hornblende. This character affords the first sub-division of primitive trap.

There are three principal species of primitive trap, and these again have their subordinate kinds.

The following table exhibits the rocks of this series.

1. Common hornblende rock.
   - *a.* Granular hornblende rock.
   - *b.* Hornblende-Slate.
2. Hornblende mixed with felspar.
   - *a.* Greenstone. *Diabase.—Brongniart.*
     - α. Common Greenstone.
     - β. Porphyritic Greenstone.
     - γ Greenstone Porphyry. } *Aphanite.—Hauy.*
     - δ. Green Porphyry. }
   - *b.* Greenstone Slate. *Diabase schisteuse.*
3. Hornblende mixed with mica.

The three principal species are, 1. *Common Hornblende-rock*; 2. *Hornblende mixed with felspar*; and, 3. *Hornblende mixed with mica.*

1. *Common Hornblende-rock* is almost entirely composed of Hornblende. It contains two subordinate kinds; the first is denominated *Granular Hornblende-rock*; the second, which differs from the first only in having a slaty structure, is denominated *Hornblende-slate.* It passes sometimes into gneiss, and sometimes into chlorite-slate, and often into hornblende-rock. These two rocks occur in beds, in gneiss, mica-slate, and clay-slate, but the beds are thicker and more numerous in the clay-slate than in mica-slate or gneiss.

It occurs in the islands of Arran, Coll, and Tiree; also in the district extending from Loch Lomond to Dunkeld, and many other places of the Highlands of Scotland. It abounds also in Bohemia, Saxony, the Tyrol, Siberia, and many other countries.

2. *Hornblende mixed with Felspar.*—This species contains two subordinate kinds; the first is *Greenstone*, the second *Greenstone slate.*

(1.) *The Greenstone* comprehends the following varieties: *Common Greenstone*, *Porphyritic Greenstone*, *Greenstone-Porphyry*, and *Green Porphyry.*

a. *Common Greenstone* is a granular aggregate of hornblende and felspar. b. *Porphyritic Greenstone* is the preceding kind, including large crystals of felspar, and consequently having a porphyritic structure. c. *Greenstone Porphyry.* In this variety the granular basis, which is with difficulty distinguishable, includes crystals of felspar. It is the Black Porphyry of the ancients. d. *Green Porphyry.* In this variety the granular nature of the basis is no longer visible to the naked eye; it appears uniform and simple; has a blackish green or pistachio green colour, and includes crystals of compact felspar. It is the *Porfire verte*, or antique green porphyry of antiquaries. The Variolite probably belongs to the green porphyry.

Greenstone appears sometimes stratified. Its different varieties first appear in gneiss, then in mica-slate, and lastly in clay-slate. In mica-slate, but more particularly in gneiss, the beds are few and inconsiderable; whereas in clay-slate they are numerous and of great magnitude. It probably, in some instances, occurs in an unconformable and overlying position, and hence may be sometimes considerably newer than clay-slate.

It occurs abundantly in this country. Thus the clay-slate and mica-slate that form so great a portion of the country extending from Loch Lomond, by Callender, Comrie and Dunkeld, contain numerous beds of greenstone; and there, as is the case in all other countries, the clay-slate contains more numerous and larger beds than the mica-slate. It is also very abundant on the continent of Europe, as Norway, Saxony, Bohemia, Silesia, Thuringia, Hungary, the Alps of Switzerland, and Savoy.

(2.) *Greenstone-slate* is composed of hornblende and compact felspar, and has a distinct slaty structure. The felspar in general is rather more abundant than the hornblende. It sometimes contains scales of mica.

It occurs only in clay slate, and according to Werner is the newest of the primitive traps. It occurs in great beds, and even mountain-masses; so that in some countries, as Sweden, it is said to form ranges of hills. It is very metalliferous. The celebrated mining district of Gersdorf, in Saxony, is situated in this rock. The mining district of Rudolstadt in Silesia, and of Adelfors in Sweden, are also in greenstone-slate.

3. *Hornblende mixed with Mica.*—This is an intimate mixture of hornblende and felspar, that includes scales of mica. It occurs, in beds, in gneiss and mica slate.

VII. *Serpentine.*

Serpentine.—*Werner.*
Serpentine.—*Kirwan.*

Serpentine.—*Jameson.*
Serpentine.—*Brochant.*

1. *Minerals imbedded in it.*—It is to the eye a green coloured simple mountain rock, of which a description will be given in our account of Simple Minerals. It frequently contains accidental minerals, or is indeterminately mixed with another mineral. Of the latter only one instance is known. It is the mixture of limestone and serpentine, forming what is denominated *verde antico.* The accidental mixed minerals are common talc, indurated lithomarge, steatite, common asbestus, amianthus, mica, schiller-stone, native magnesia, magnesite, meerschaum, actynolite, rock-cork, rock-wood, diallage, pyrope, opal, chrysoprase, hornstone, amethyst, quartz, and hornblende crystals.

2. *Subordinate beds.*—The only beds it contains are limestone and euphotide.

3. *Stratification.*—It is scarcely ever stratified, and when traces of stratification do appear, they are very indistinct.

4. *Metalliferous minerals.*—It always contains magnetic ironstone, either in imbedded grains and masses, or in small veins, and these are sometimes so considerable as to be worthy of being worked as mines. There are mines of this description in the Alps. The chromate of iron, so much valued in the arts, occurs disseminated, also in imbedded masses and in veins in this mountain-rock, in the Shetland Islands, and at Portsoy. On the continent of Europe, in Provence, and in Stiria, and in the New World in the United States of America. With exception of iron, this rock contains but few metalliferous minerals; nevertheless, near to Joachimsthal, in Bohemia, it contains so much galena, that a mine is established in it; and in Cornwall, and in the Shetland Islands, it contains native copper.

5. *Formation.*—It occurs in beds and mountain masses in gneiss, mica-slate, and clay-slate.

6. *Decomposition.*—On exposure to the weather, its surface becomes earthy, and the colour changes from green to ochre-yellow, owing to the change of the protoxide of iron into hydrate of iron. It resists the destroying effects of the weather more obstinately than the gneiss, mica-slate, or clay-slate, with which it is associated, and hence peaks and other projecting forms of serpentine, are observed on the Alps rising through the softer and less durable surrounding gneiss and other rocks.

Like all other magnesian rocks, it is inimical to vegetation. The mountains of which it is composed are bare and bleak; and this nakedness, joined to the sombre colour, gives a dreary and monotonous aspect to most serpentine districts.

7. *Geographical distribution.*—It occurs in great beds in the Shetland islands, along with gneiss, mica-slate, chlorite-slate, and quartz-rock; in beds at Portsoy in Banffshire, along with quartz-rock, trap-rock, mica-slate, and limestone; near Cortachie in Angushire; in Invernesshire, and other parts of Scotland; and abundantly in Cornwall in England.

It is very abundant in the Alps, in beds often of enormous thickness. It also occurs in the Pyrenees, but not so frequently as in the Alps. It is frequent in the mountains of Silesia, Saxony, the Fichtelgebirge, &c.

It is common in the mountains of the United States of America. It occurs in the mountains of Valentiana in Mexico, where it alternates with beds of sienite, primitive-trap, and clay-slate; and in the island of Cuba it is associated with sienite.

8. *Uses.*—It is cut and polished, and used as an ornamental stone.

VIII. *Euphotide.*

Euphotide.—*Hauy.*
Euphotide.—*Jameson.*
Gabbro of the *Italians.*
Diallage Rock of others.

Constituent parts.—It is a compound of saussurite and diallage, and these two minerals are sometimes intermixed with talc, hornblende, actynolite, garnets, grains of pyrites, &c.

Geographical distribution.—It occurs along with serpentine in the Shetland islands and in Cornwall. Von Buch found it in great abundance in Norway, even as far north as the North Cape, and it has been met with in Germany, Switzerland, and Italy.

Uses.—When cut and polished, it presents a very beautiful surface, hence it is much esteemed in some countries, as Italy, as an ornamental stone. The *nero di prato, verde di prato, granito di gabbro*, of the Italians, are either varieties of euphotide, or serpentines with disseminated metalloidal diallage.

IX. *Porphyry.*

Porphir.—*Werner.*
Porphery.—*Kirwan.*
Porphyry.—*Jameson.*
Porphyre.—*Brochant and Daubuisson.*

1. *Name.*—The Grecian word from which the name porphyry is derived, signifies *red*; hence the name of the formation is borrowed from that kind, which is denominated Antique Red Porphyry. It is worthy of remark, that red, or colours bordering on it, or passing into it, prevail in rocks belonging to the porphyry formation.

2. *Composition and varieties.*—It is a compound rock, having a basis, in which the other cotemporaneous constituent parts are imbedded, either in the form of grains or crystals. Neither the base nor the imbedded parts are always of the same kind. On the differences of the first, depends the distinction of the different kinds of porphyry. The base is sometimes claystone, forming *claystone porphyry*, hornstone forming *hornstone porphyry*, compact felspar forming *felspar porphyry*, pitchstone, when it is named *pitchstone porphyry*; and if it contains much hornblende, it has been named *sienitic porphyry.* The imbedded parts are most commonly felspar and quartz, which are usually more or less perfectly crystallized. The quartz is usually crystallized, and in double six-sided pyramids. The felspar crystals are broad six-sided prisms, but usually very indistinct. The felspar is more or less fresh, sometimes even glassy, sometimes completely disintegrated and earthy, or only in white specks. The frequency and magnitude of these mixed parts, of quartz and felspar, modify the appearance of the different kinds of porphyry very much. Sometimes one, sometimes the other, but more frequently both occur together, and along with several other minerals which are less frequent, as crystals of hornblende and mica. The basis and the mixed parts of the porphyry also differ in colour and several other properties. It sometimes contains chalcedony and agate,

which are in massive pieces, or in small layers or plates. Further, there sometimes occur balls of a greater or less size; in clay-porphyry the centre of these balls is chalcedony, but their exterior is hornstone porphyry; but in pitchstone-porphyry, these balls are composed of a particular kind of conchoidal hornstone, but the centre is quartz. It sometimes also contains precious and common opal, and these are either disseminated through it, or traverse it in the form of very small veins.

3. *Structure.*—Porphyry is seldom stratified, and when it is stratified, the strata are very indistinct. It is usually either massive, and merely traversed by numerous accidental rents, or disposed in distinct concretions, which are tabular and columnar, or they are globular, and these again are composed of concentric lamellar concretions.

4. *Foreign beds.*—It contains few foreign beds, with exception of granite, gneiss, and greenstone, which are intermixed with it. One of the best examples of porphyry with foreign beds is that given by Beudant, who describes three different sorts of beds in the sienitic porphyry, in the environs of Schemnitz in Hungary. These are, 1. Small beds of mica-slate that alternate with small granular sienite. 2. Beds of quartz. 3. Beds of compact limestone impregnated with steatite, and intermixed with serpentine.

5. *Metalliferous minerals.*—It contains many metalliferous minerals. They occur more frequently in veins than in beds; but as the porphyry is seldom stratified, and as the surface of superposition is not often seen, it is difficult to determine to which of the two kinds of repositories they belong. The richest mines at present known, those of Mexico, are situated in enormous veins that traverse sienitic porphyry. The mines of Hungary, the most considerable on the continent of Europe, are situated in the same kind of porphyry; and it would appear that the famous mines of Cyprus, so much extolled by the ancients, were also in porphyry. The numerous veins of lead, copper, and silver, worked at Giromagny, in the Vosges, are in a porphyry tract.

6. *Formations.*—Porphyry occurs in imbedded masses, beds, and veins of granite, gneiss, mica-slate, and clay-slate.

7. *Form of mountains.*—They are often conical, sometimes like truncated cones, or appear dome-shaped.

8. *Geographical distribution.*—It occurs in the Shetland islands, in several of the Hebrides, and on the mainland of Scotland, in Sutherland, Ross-shire, Inverness-shire, Perthshire, &c. In England it is met with in Cornwall, and in other districts. On the continent of Europe, it occurs in Sweden; it forms a part of the Vosges, and rises in mountains in the granite district of Forez, also in France. It has not been met with in the Pyrenees, nor is it mentioned as occurring in the Alps of Switzerland, nor in the northern side of the grand chain of the Alps, but it occupies a considerable tract on the southern side, from the lake of Como to Carinthia and Carniola. It appears, although not very abundantly, in Silesia, Saxony, and Thuringia, and forms extensive tracts in Hungary. It abounds in some districts in Upper Egypt, Siberia, and in North and South America.

Uses.—It was formerly used extensively in ornamental architecture, and is still worked in considerable quantity as an ornamental stone, in Elfdal in Sweden, where there are considerable quarries of porphyry.

X. *Quartz Rock.*

Quartz fels.—*Werner.*
Quartz Rock.—*Jameson.*
Quartz en Roche.—*Daubuisson.*
Quartzite.—*Brongniart and Bonnard.*

1. *Characters.*—Quartz occurs not only as an essential constituent part of granite, gneiss, and mica-slate, and disseminated in beds and veins in these rocks, but also in mountain masses and mountains. Quartz-rock, properly so called, is generally of a white colour, and sometimes reddish or bluish. It has a granular structure; the concretions vary from the smallest size, visible to the naked eye, to that of an egg, or even larger; or it is compact. It frequently contains grains of felspar, and also scales of mica. When the felspar and mica increase in quantity, it passes into granite, or into gneiss, when only the mica into mica slate.

Structure.—It occurs either distinctly stratified, or massive, and without the stratified structure.

2. *Metalliferous minerals.*—It often contains disseminated iron pyrites, and occasionally lead-glance, copper-pyrites, and blende.

3. *Form of mountains.*—Mountains of quartz-rocks are often conical, sometimes even peaked, or they are crenated.

4. *Geognostic situation.*—It occurs in beds and mountain masses, in granite, gneiss, mica-slate, and clay-slate, and indeed in a certain degree associated with most of the rocks of the primitive series.

Geographical distribution.—It abounds in many districts in Scotland, as in the islands of Jura and Isla, the Shetland Islands; on the mainland, in Sutherland, Caithness, Inverness-shire, Argyleshire, &c.

Class II. Transition Rocks.

Ubergansgebirge.—*Werner.*
Transition Rocks.—*Jameson.*
Terrains Intermediaires.—*Daubuisson.*

The rocks of the primitive class, as already remarked, are distinguished in a general view by their highly crystalline structure, and want of petrefactions, or fossil organic remains. In some countries we observe resting upon them, and even alternating with them, a series of rocks, of which clay-slate is a predominating member, having less of the crystalline aspect, and which contains fossil organic remains. Werner considers this set of rocks as interposed between the grand series of primitive and secondary rocks; and that, although it occasionally alternates, on the one hand, with the primitive, and on the other with some members of the secondary class, still its characters are so well marked, that he views it as a distinct class, to which he gave the name *Transition*, from its forming, as it were, the transition or passage from the primitive to the secondary rocks. Although some mineralogists have abandoned this view, and now arrange the transition rocks along with those of the primitive or secondary classes, we are still inclined to consider them as deserving a separate place in the geognostic system. It is true, that the transition rocks are but a continuation of the primitive, and, on a general view, might with propriety be considered as a portion of that series; but their imbedded fossil organic remains, less crystalline aspect, and particular rocks, such as grey-wacke, appear to characterise them, if not as a distinct class, yet as a separate group in the grand series of rock formations.

The following are the rocks of this class:

1. Grey-wacke.
2. Transition limestone.
3. Granite and porphyry.
4. Gneiss, mica-slate, &c.
5. Serpentine.
6. Quartz-rock.
7. Red sandstone.
8. Transition-trap.
9. Gypsum.

I. *Grey-wacke.*

Grauwacke.—*Werner.*
Greywacke.—*Jameson.*
Traumate.—*Daubuisson.*
Psamite.—*Brongniart.*
Breche, Poudingue, and Gres, *of some French geologists.*

Composition.—It is composed of angular or other portions of quartz, felspar, Lydian-slate, and clay-slate, connected together by means of a basis or ground of the nature of clay-slate, which is often highly impregnated with silica, thus giving to the mass a considerable degree of hardness. The imbedded portions vary in size, but seldom exceed a few inches in breadth and thickness. When the imbedded portions become very small, the rock assumes a slaty structure, and forms the *Grey-wacke slate* of geognosts. When the grains almost entirely disappear, and the rock is principally composed of clay-slate, it is named *transition clay-slate*. This clay-slate has frequently a much more earthy aspect than the varieties found in the primitive districts. Besides the grey-wacke already described, which has the conglomerated structure, another, having the same structure, is occasionally met with in transition districts. It has been named *transition conglomerate*, or *pudding-stone.* It is composed of roundish or angular masses of granite, porphyry, gneiss, and clay-slate, often larger than a man's head, imbedded in clay-slate, or nearly without a basis or ground.

Common grey-wacke does not occur so frequently as greywacke slate and transition clay-slate.

Subordinate beds.—Transition clay-slate, and greywacke, contain occasionally different kinds of rocks in subordinate beds, or in veins. The following are the principal of these:

1. *Quartz.*—It occurs in beds, imbedded masses, and veins, and frequently in very considerable quantity.

2. *Talc.*—This mineral occurs in imbedded masses, and in layers in transition clay-slate. There is a fine example of it in the clay-slate of Glaris, in Switzerland, which is remarkable for the petrified fishes it contains.

3. *Whet-slate.*—This mineral forms beds in the clay-slate.

4. *Serpentine*—Beds of serpentine, often of great thickness, and of considerable extent, occur along with transition clay-slate.

5. *Lydian stone.*—Beds of this rock occur in clay-slate.

6. *Alum slate.*—This rock is clay-slate impregnated with carbon and sulphur. The sulphur is either combined with the carbon, or united with iron, forming iron pyrites. On exposure to the weather the sulphur becomes oxygenated, is converted into sulphuric acid, which acts on the alumina of the slate, and thus forms a sulphate of alumina.

7. *Drawing slate*, or *black chalk.*—This also is clay-slate, but more highly impregnated with carbon than the alum-slate. When soft, it is cut, and forms crayons for sketching.

8. *Glance coal.*—This mineral occurs in beds subordinate to clay-slate and greywacke, which sometimes contain vegetable impressions. Of this, there are examples in Switzerland and in the kingdom of Saxony.

9. *Compact felspar.*—Beds of this mineral occur in the transition clay-slate and greywacke of Dumfries-shire, and along with rocks of the same description in France, Italy, and Spain.

10. *Greenstone.*—This rock is met with in the transition ranges in the south of Scotland, and in similar mountains on the continent of Europe.

11. *Vegetable remains.*—Transition clay-slate occasionally contains vegetable impressions, particularly those varieties which are associated with glance coal. Animal remains are seldom met with in the clay-slate, and still less frequently in the grey-wacke. These are *madreporites*, *trilobites*, *ammonites* of a particular description, and *hysterolites*, which are, in some degree, characteristic of this formation, and which appear to be the nucleus of the *terebratulites valvarius*, and *paradoxus.* It sometimes also contains *turbinites* and *camites.* But the rarest and most interesting of the animal remains which occur in transition clay-slate, are those of *fishes*, of which there is an instance at Plattenberg, two leagues south-east of Glaris, in Switzerland. This fact is stated by several geologists, but we are of opinion, that it has not been fully proved that the rocks of Plattenberg are truly transition.

Metalliferous Minerals.—Ores of various descriptions abound in greywacke and transition clay-slate; thus the lead mines of Leadhills, and of Wanlockhead, are situated in these rocks, and the same is the case with the productive lead and silver mines of the Hartz in Hanover, of Vorespotack in Transylvania, of Brittany in France, and of Guanaxuato and Zacatecas in Mexico.

Geographical Distribution.—Grey-wacke and transition clay-slate abound in all the mountain ranges to the south of the Frith of Forth, are also frequent to the north of the same boundary, and are widely distributed in England. On the continent of Europe, they form a principal feature in the mountains of the Hartz, extend through Switzerland and the Pyrennees, and occur in vast abundance both in North and in South America.

II. *Transition Limestone.*

Übergangs Kalkstein.—*Werner.*
Transition Limestone.—*Jameson.*
Calcaire Intermediaire.—*Daubuisson.*

1. *Characters.*—This limestone is in general more compact than that met with in decided primitive districts; yet it is not always so, for it occasionally occurs, is coarse granular or highly crystallized. Its fracture is, in general, splintery, usually combined with very minute foliated, and is translucent on the edges. It varies very much in colour. It is often black, and frequently many colours occur together, these forming what are termed *variegated marble.* Many of the varieties are traversed by small cotemporaneous veins of cal-

careous spar. Most of the ornamental marbles used in architecture belong to the transition class, while the statuary marbles are of primitive, and the coarser marbles of secondary formation.

2. *Subordinate Beds and Imbedded Minerals.*—(1.) *Lydian Stone.*—It occurs abundantly in the bituminous transition limestones in the north of France, where it is disposed, either in irregular masses like flint in chalk, or it forms small plates or tables, or it alternates in beds. The same disposition is met with in the transition limestones of the Pyrennees, Alps, &c.

(2.) *Mica* occurs disseminated or in layers, and sometimes associated with talc or steatite.

(3.) *Quartz.*—It occurs disposed in veins, beds, or disseminated, and sometimes in the form of rock crystal.

(4) *Pyrites.*—This ore is generally denominated,

(5) *Brown Ironstone.*—Occurs in veins and beds.

(6) *Glance-coal.*—Some black transition limestones are highly impregnated with carbonaceous matter, which is sometimes accumulated in particular points, and thus forms imbedded masses of glance-coal, of which there are examples in the north of France.

3. *Petrifactions.*—Fossil organic remains occur but rarely extensively distributed in this rock, but are sometimes abundantly accumulated in particular situations. Petrified madrepores, millepores, orthoceratites, and terebratulites, are the most frequent, and along with these are some entrochites, encrinites, turbinites, ammonites and belemnites.

4. *Geographical Distribution.*—It occurs in Scotland, near the Crook, on the road to Moffat, and in other quarters, both to the south and north of the Frith of Forth. On the Continent, it occurs at Christiania in Norway; in many places in the Hartz, as at Blankenburg, where there are extensive marble quarries, which afford a marble equal to that named *rosso corallino*; in Italy; in the country of Bareuth, in Saxony, where there are several beautiful varieties, one of a black colour, with fragments of entrochi, which nearly resembles the *nero d'Egitto* of the Italians. Werner remarks of this petrifaction, that it occurs most frequently in black marble, while petrified corals are most common in those of a red colour. In the south of France, and in the Pyrennees, it is a very abundant rock; while in the north of France it forms a part of the great transition zone which extends from Flanders to the Hartz. The north side of the Alps, from France to Hungary, is bounded by an enormous deposite of this limestone.

III. *Granite, Sienite, and Porphyry.*

These rocks, which are so nearly allied to each other, occur in considerable abundance in some districts where the predominating rocks are greywacke and clay-slate. The nearest point to Edinburgh where these rocks occur, is Fassneyburn, about 12 miles from Haddington, where transition granite, and porphyry, and also sienite, are met with. These rocks are also found in Galloway, and in other parts to the south of the Frith of Forth. To the north of the Forth, we may mention the vicinity of Macduff in Banffshire, as an example of transition-granite. On the Continent, one of the most striking displays of these rocks occurs in the vicinity of Christiania in Norway, where the following arrangement was detected by Von Buch and Hausmann.

1. Gneiss. 2. Transition clay-slate and limestone. 3. Granite. 4. Clay-slate and limestone. 5. Greywacke-slate. 6. Flinty slate. 7. Sandstone. 8. Porphyry. 9. Granite. 10. Sienite, with imbedded crystals of zircon.

In this series, the gneiss is the undermost, while the zircon-sienite forms the uppermost bed of the series. The limestone, in some places, is white and highly crystallized, and contains tremolite, epidote, garnet, blende, &c. but more frequently it is black and compact, and contains orthoceratites, some feet in length, along with pectinites, chamites, trilobites, &c.

Similar arrangements have been observed in other parts of the world.

IV. *Gneiss, Mica-slate.*

These rocks occur in small quantity, associated with greywacke and greywacke-slate, in the alpine land to the south of the Frith of Forth, and even in some districts to the north of the Forth. An arrangement of the same description is described by Brochant as existing in Switzerland.

V. *Serpentine.*

In some districts in the Alps, serpentine occurs in beds in transition rocks.

VI. *Quartz-Rock.*

It occurs in beds and in mountain masses, along with clay-slate and greywacke, not only on the Continent, but also in this island.

VII. *Red Sandstone.*

This rock, which is very nearly allied to quartz-rock, occupies the same position as that rock in the transition series.

VIII. *Transition Trap.*

Übergangstrapp.—*Werner.*
Transition Trap.—*Jameson.*
Amphibolite.—*Daubuisson.*

The transition trap-rocks are amygdaloid, greenstone, and basalt. These occur in beds and in imbedded masses in Dumfries-shire, and other transition districts in the south of Scotland. In England, they occur in beds along with the alpine limestone, as in Derbyshire and other districts. In Ireland it forms beds also in a limestone which appears to belong to the transition series. The trap-rocks of Oberstein, on the Rhine, of Voightland, also belong to the transition class.

IX. *Gypsum.*

Transition gypsum, according to Brochant, is generally white, very fine granular or compact, and contains particles of calc spar, scales of mica and talc, and portions of rock-salt and of sulphur. He refers the gypsum of Pesey to this class; also that of Brigg in the Vallais, which is covered with a granular micaceous limestone, and also the deposite in the Val-Canaria. The transition clay-slate of Salzburg also contains beds and imbedded masses of gypsum. M. Von Charpentier is of opinion, that the saliniferous gypsum of Bex is situated in beds in a transition limestone.

Class III. Secondary, or Flœtz Rocks.

Flœtz gebirge.—*Werner.*
Secondary, or flœtz rocks.—*Jameson.*
Terrain Secondaire.—*Daubuisson.*

Secondary rocks, in the regular succession, rest on those of the transition class; and sometimes the older rocks of the series, alternate with clay-slate and other members of the preceding class. They are less crystalline than primitive and transition rocks, and are particularly characterised by the number, variety, and abundance of fossil organic species which they contain. The principal secondary rocks are, sandstone, limestone, gypsum, and trap.

We shall now describe the different formations of these sandstone, limestone, gypsum, and trap rocks, beginning with sandstone.

1. *Sandstone.*

This rock is formed of angular or roundish grains of different minerals, connected together by means of a basis or ground, or immediately joined without any basis. When the grains are not larger than a hazelnut, the compound is simply named sandstone, but when they exceed that magnitude, they are denominated *conglomerate*, if the masses are roundish; but *breccia*, if angular. Sandstone is divided into three kinds, named *siliceous*, *argillaceous*, and *marly* or *calcareous*. In the siliceous kind, the particles are connected by a ground or basis of quartz; in the argillaceous by a basis of clay, which is sometimes highly impregnated with red oxide of iron, and gives a red cast to the whole rock; and the particles in the marly or calcareous kind are set in a marly or calcareous basis.

The following are the formations of sandstone:

I. First, or red sandstone, with the coal formation.
II. Second, or variegated sandstone.
III. Third sandstone, or quartzy sandstone.
IV. Fourth sandstone formation.

I. *Red Sandstone, or Old Red Sandstone.*

Œlter, rother Sandstein.—*Werner.*
Old Red Sandstone.—*Jameson.*
Rothe-todte-liegende.—*German Miners.*
Gres Ancien.—*Daubuisson.*

1. *Characters.*—The predominating colour of this rock is reddish-brown; but some varieties are grey, and others white. It occurs in the form, not only of sandstone, but also of conglomerate and breccia. The grains in the sandstone are principally quartz, with occasional intermixtures of felspar, flinty slate, and scales of mica; the roundish and angular masses in the conglomerate and the breccia are frequently of quartz, or of granite, gneiss, mica slate, clay slate, porphyry, sienite, quartz-rock, &c. The basis or ground is generally an iron-shot clay, or it is composed of smaller particles of quartz or felspar, as is often the case in the conglomerates and breccias. The basis is sometimes highly impregnated with silica, and then it is very hard; and, in other varieties, it has a porphyritic character.

2. *Subordinate Beds and Veins.*—It contains beds and veins of porphyry, sienite, quartz-rock, clay-slate, limestone, and various trap-rocks, such as amygdaloid, greenstone, basalt, trap-tuff, and pitchstone.

3. *Petrifactions.*—Very few animal remains occur in this formation, although it frequently alternates with a limestone, which contains abundance of marine shells, and other similar organic productions. But petrified vegetables are not so uncommon, and these are generally of trunks and branches of trees belonging to the monocotyledonous class, as is proved by their being composed of simple longitudinal fibres without concentric rings.

4. *Metalliferous Minerals.*—The principal metals found in this formation are iron, copper, and lead. The iron ores are the brown and red; the copper ores, pyrites, and blue copper; and the lead, galena or lead glance.

5. *Geognostic Situation.*—In Scotland and Ireland, it is observed resting on primitive and transition rocks. The same arrangement occurs in Germany, and in other countries on the continent of Europe.

6 *Geographical Distribution.*—It forms considerable tracts of country in Scotland.

Observation.—The transition red sandstone, which is connected with quartz-rock, is often so nearly allied to the present formation, that it is doubtful if they do not belong to the same series.

Coal Formation.

Coal-measures, or coal-field.—*English miners.*
Steinkohlengebirge.—*Werner.*
Terrain houiller.—*Daubuisson.*
Terrain à charbon de terre.—*Older French Geologists.*

This very interesting and important formation consists of a considerable number of different rocks. The following may be enumerated: 1. Coal. 2. Slate. 3. Sandstone. 4. Quartz-rock 5. Limestone. 6. Ironstone. 7. Clay. 8. Trap. 9. Graphite. Of these rocks, the most frequent are, the sandstone, slate, ironstone, and coal; the others, from their comparative rarity, may be viewed as subordinate members of the formation.

1. *Coal.*—Two species of coal are found in this formation, viz. *black coal*, and *glance coal*, or *blind coal;* the former has a resinous lustre, and is bituminous, and burns with much flame and smoke; while the other is not bituminous, has a metallic lustre, and burns without flame and smoke.

This mineral, whether black coal, or glance coal, occurs only in beds which vary in thickness from a few inches to several yards; and there are rare instances of their attaining a thickness of three hundred feet, as in the vicinity of St. Aubin, in Rouergue; but in this case, the coal is disposed rather in enormous imbedded masses, or kidneys, than in true beds. The thickness of the beds often continues wonderfully regular for a great extent; but in others, they contract and expand in the line of direction; so that, in the course of the same bed, the thickness will vary from an inch to several yards.

2. *Slate.*—Under this head, we include bituminous shale, slate-clay, and flinty slate.

a. Bituminous Shale.—This mineral is clay, more or less impregnated with coally matter, of a black colour, with a slaty fracture, and affording a shining resinous streak. It frequently contains impressions of reeds and ferns. It passes into coal, is frequently intermixed with it, or alternates in beds, often of considerable magnitude, with the other rocks of the coal formation.

b. Slate Clay.—This rock is of a grey or black colour, with a slaty fracture, and affords a grey dull streak. It sometimes contains scales of mica, and grains of quartz and felspar; and when these increase in quantity, it passes into sandstone. It frequently contains *vegetable impressions*, which are principally of ferns and reeds.

Like bituminous shale, it alternates in beds of various magnitudes, with the other rocks of the coal formation.

c. Flinty Slate.—The slate-clay is sometimes highly impregnated with silica, and then it is very hard and flinty-looking, and passes into the mineral named Flinty Slate. Imbedded masses, and beds of flinty slate, occur in the slate-clay, and occasionally associated with other members of the coal formation.

4. *Sandstone.*—The predominating mineral in this sandstone is quartz, in granular concretions, which is variously intermingled with flinty slate, felspar, mica, and portions of different species of rock of the primitive species; all of which are generally connected together by a basis or cement of a grey-coloured and earthy aspect. Sometimes the earthy basis is wanting, when the grains are joined together, in the same manner as in granite, and other rocks of the same description. The constituent parts are sometimes so large as to form conglomerates and breccias; but generally they are small, and when much intermixed with clay, pass into slate-clay; and then they contain more vegetable impressions than usual.

4. *Quartz.*—This mineral, in the form of quartz-rock, sometimes occurs in beds.

5. *Limestone.*—A grey-coloured compact limestone sometimes occurs in considerable beds, in coal-fields, and alternates with the various rocks of the formation. In some districts the limestone is abundant; in others it is rare; and in many it is entirely wanting. It occurs in the coal fields near Edinburgh, and in those in the north of England.

6. *Iron Stone.*—This iron-stone, which is sometimes carbonate, sometimes hydrate of iron, occurs in beds that alternate with slate-clay, or bituminous shale, or it is disposed in balls and lenticular masses, either irregularly, or in regular rows in the strata. It is a very abundant mineral in most of the coal-fields in Scotland and England, and affords nearly all the iron of commerce produced in Great Britain.

7. *Clay.*—The different kinds of fire-clay, so well known in the arts, occur in beds in the coal formation.

8. *Trap and Porphyry.*—Different species of these rocks are met with in the coal-fields of Scotland, and of other countries. We have observed the following, viz. *Greenstone*, *Amygdaloid*, *Basalt*, *Trap-tuff*, and *Porphyry*, in beds and in veins varying in magnitude and extent.

9. *Graphite*, or Black Lead.—Beds of graphite occur but rarely in this formation. There are examples of this arrangement in Ayrshire.

Arrangement of the beds in the Coal Formation.—Although no very regular arrangement of the beds occurs in this formation, nevertheless it has been remarked, that in some districts beds of coal are generally contained in the slate, and that as we recede from the coal the slate becomes coarser and coarser, and at length passes into sandstone; in others, the sandstone most generally forms the floor, while the roof is of slate: and in others the coal is covered with trap or limestone, or rests upon these rocks.

In many coal-fields, the beds of coal and their accompanying rocks are frequently repeated in precisely the same order, and in nearly the same thickness.

The number of beds of coal superimposed on each other in the same field is very considerable. At Newcastle, twenty-five beds have been penetrated in sinking pits. The hill of Dutweiler in Saarbruck, contains thirty-two beds; at Liége, there are sixty beds; and at Anzin more than fifty.

Identity of Character of the Formation in different countries.—In Scotland, the predominating and characteristic members of the formation are sandstone, bituminous shale, slate-clay, clay ironstone, and coal. In England, we find in all the coal-fields precisely the same sandstones, slates, ironstones, and coals, as in Scotland; and the same is the case in all the coal mines of France, Germany, and America. Every where we meet with the same rocks, the same vegetable impressions, and the same general arrangements of the different rocks of the formation.

Stratification.—All the rocks of this formation are stratified, some more, and others less, distinctly. The most perfectly stratified are the sandstone and slate; and those having this structure in the most imperfect degree, are the trap and porphyry rocks. The strata often follow every inequality of the fundamental rock on which they rest; and as the surface of the fundamental rock is frequently remarkably uneven, the superimposed strata acquire a very irregular and contorted aspect. In some cases the strata do not appear to follow the inequalities of the fundamental rock, but have directions that appear independent both of the surface of the rock, and of the cavity or hollow in which they are contained.

Situation.—The rocks of this formation are generally situated at the foot of mountains, or in basin or trough-shaped hollows, which vary from a few hundred yards to many miles in extent. It seldom rises high above the level of the sea, and the countries it forms have generally a waved and soft outline. In this island it rests either on the mountain limestone or red sandstone, and is covered by magnesian limestone and other newer formations.

Dikes.—The strata of this coal formation are frequently traversed by veins, which are composed of earthy minerals, and are named *Dikes*. These dikes are sometimes only a few inches wide, and not many fathoms in extent; in other cases they are upwards of one hundred feet wide, and extend for some miles. Their direction varies, as also their angle of inclination, which latter ranges from the nearly horizontal to the vertical position. The strata in the walls of the dikes, in some cases, correspond on opposite sides, while in others the corresponding strata on the hanging side are depressed some feet, or even fathoms, so that miners, in working a bed of coal for example, when stopped in their progress by a dike, do not find it directly opposite on cutting through it, but some feet or fathoms out of the line of bearing of the bed. When the strata present such an appearance, they are said to *be shifted*. The materials of these dikes, or veins, varies, as appears from the following enumeration of the rocks of which they are sometimes formed: Greenstone, amygdaloid, trap-tuff, porphyry, sandstone, and fragments of the various surrounding strata. The strata, where in contact with dykes, appear sometimes of a different nature from the other parts of their mass; thus beds of coal, where in contact with the dike, appear as if charred, slate-clay hardened, and sand and lime indurated; yet in the midst of these apparently changed portions, there occur unaltered minerals, such as calcareous spar, iron pyrites, and clay.

Metalliferous Minerals.—The ores most frequently met with in this formation are, clay iron ore, and galena, or lead-glance. The iron ore occurs every where in the coal-fields of this island; but the lead-glance is found in quantity only in the coal-districts in the north of England, and in Wales. Copper, silver, and even gold, are enumerated among the metalliferous productions of this formation; and it would appear that cinnabar or sulphuret of mercury is sometimes also contained in it.

Petrifactions.—Mineralized organic remains are not unfrequent in the coal-fields of different countries; and it is worthy of remark, that hitherto the same tribes and species have been met with in the coal formations of Great Britain, Ireland, Germany, and France. Both vegetable and animal remains occur, but of these the former are by far the most varied and abundant. The impressions of plants are frequent, both in the slate-clay and bituminous-shale; and we cannot recollect a coal-mine where these rocks have not been found to contain organic vestiges of this description. Many belong to the monocotyledonous class of plants, and are principally aquatic, such are the *large reeds* and *bamboos;* besides these, we meet with numerous remains of *ferns*, and species of the genera *lycopodium, equisitum, euphorbia, casuarina, &c.* Impressions of the branches and fruit of palms, or of vegetables resembling this tribe, are also occasionally met with. None of these plants are identical with any of the present known living species; and many of them have a tropical aspect.

These vegetable remains seldom occur in the coal, but are abundantly distributed in the slate, particularly where it is near the surface of the bed of coal; and the most frequent remains are those of leaves or of flattened trunks, sometimes changed into coal, enclosed in the layers of the slate; but in other instances the reeds, and other vegetables of large diameter, are upright, and are filled with clay, or with the same substances as that in which they are contained.

The animal remains found in the coal formation are principally of shells, and of these the most frequent are those which resemble the fresh water species; such are the different species of mytulites.

Origin of Coal.—Two opinions are entertained in regard to the origin and formation of coal. According to the one, it is of vegetable origin; and according to the other, it is an original chemical formation. Its chemical properties, and numerous accompanying vegetable remains, which are sometimes changed into coal, are the principal facts adduced in favour of its vegetable origin; while its distribution in regular conformable beds, its occurrence in veins, and embedded masses, its manifold alternations and connections with different strata, some of which never contain vegetable remains, its rhomboidal structure, external characters, its connection with glance coal on the one hand, and with bituminous shale and sandstone on the other, are the appearances which are considered as illustrating its formation as an original deposit, from a state of chemical solution.

II. *New Red or Variegated Sandstone.*

Bunter Sandstein.—*Werner.*
Red Ground—*English Geologists.*
New Red.—*Buckland.*
New Red or Variegated Sandstone.—*Jameson.*
Second formation de Gres, et Gres avec argile.—*Daubuisson.*
Gres Bigarre.—*French Geologists.*

Characters.—It is small granular, with an argillaceous, or marly basis. Its colour varies extremely, being frequently disposed in bands or zones, of red, grey, green, yellow, and brown, hence the name variegated, given to it by Werner. These different colours are owing to the different states of oxidation of the iron in the basis or cement, but it may be remarked, that these deep colours are often very superficial, the interior of the rock being of a grey or white colour, while the exterior, by exposure, becomes brown or red.

This sandstone frequently contains masses of variously-coloured clay or marl, which are often lenticular, and vary very much in size, and contribute very much to increase its liability to decomposition. The clay is sometimes greasy to the feel, and forms a kind of fuller's earth. Although the most common cement or basis of this sandstone is clay, yet some beds have a marly, and others a quartzy basis.

It sometimes contains mica, and sometimes in such quantity that sandstone passes into sandstone slate.

It alternates with beds of a red-coloured clay, or marl, which is often slaty, and generally intermixed with sand and mica, and sometimes passes into sandstone slate. These beds are sometimes of great thickness, and from their being frequently short, and very thick, appear like great imbedded masses. Sometimes the marly or calcareous basis increases so much, that the sandstone passes into limestone. The colouring principle in the clay is occasionally so abundant in some parts of the beds, that a red crayon is formed. The thick beds of clay occur principally towards the upper part of the formation, which indeed is principally red clay. Sometimes beds of conglomerate occur associated with the sandstone, marl, and clay.

Subordinate Beds.—1. *Limestone.*—Beds of limestone are met with in this formation; but, in general, the limestone is very impure, being mixed with clay and sand; and thus forms a more or less arenaceous marl.

2. *Oolite* or *Roe-stone.*—This curious kind of limestone occurs but in small quantity, and generally in beds varying from a few inches to two or three feet in thickness.

3. *Iron Ore.*—It sometimes occurs in considerable quantity, and is generally the red ore. It is either in imbedded portions, disseminated, or so minutely diffused, as to colour some of the sandstones of a deep red colour.

4. *Heavy Spar, Sulphate of Barytes.*—This mineral occurs in veins in the sandstone.

5. *Celestine*, or *Sulphate of Strontites.* This mineral occurs in the clay and sandstone, in the form of veins and beds, near Bristol.

6. *Gypsum.*—It occurs in imbedded masses, and beds and veins, in the marl or sandstone of this formation.

7. *Rock Salt.*—The salt of the principal salt mines in Europe is arranged in beds, and imbedded in this formation.

8 *Copper Ore.*—Traces of copper ore are rarely met with in this formation.

9. *Coal.*—This mineral occurs very rarely, and usually in inconsiderable beds.

10. *Petrifactions.*—The most frequent petrifactions are pectinites, pinnites, pholades, turbinites, and large ostracites; and sometimes petrified wood, and impressions of leaves.

Geognostic Situation.—It rests upon the magnesian or second limestone, and sometimes even alternates with it, and is immediately covered with the oolite formation.

Geographical Distribution.—It is a very widely distributed formation in England, extending, with little interruption, from the northern bank of the Tees in Durham, to the northern coast of Devonshire: Also occurs in Scotland, particularly in the southern division.

III. *Third Sandstone Formation.*

Green Sand of *English Geologists*.
Third Sandstone Formation.—*Jameson.*
Troisieme Formation de Gres.—*Daubuisson.*
Quader-Sandstein.—*Werner.*
Gres presque entièrement quartzeux.

This formation, the characters of which are still but imperfectly known, is described by English geologists, under the name Green-sand, and, according to Mr. Buckland, is associated with various strata.

Characters.—The sandstone is composed of particles of white quartz, which are either cemented by a calcareous basis, or are united without any cement, and frequently contain scales of mica, and embedded grains, and portions of a green substance, of the nature of chlorite or augite.

The quartzy particles are sometimes so arranged and connected, that the sandstone is as massive and compact as quartz, while, in other instances, it occurs in the state of loose grains or sand.

It frequently contains imbedded cotemporaneous masses of *chert*, and the same mineral occurs also in beds; and sometimes both the green-sand and chert are traversed by veins of calcedony.

Subordinate Beds.—Limestone of a blue and reddish colour, in the form of beds, is occasionally met with, and sometimes the limestone is also distributed through the sandstone in masses of varying magnitude. Mr. Buckland enumerates the following beds as occurring in this formation: 1. Lead-coloured clay; 2. Micaceous and sandy blackish clay, with disseminated green earth; 3. Iron-sand, usually red and yellow, and containing subordinate beds of clay, ochre, and fuller's earth, either pure, or inclosing nodules of heavy spar.

Petrifactions.—It contains musculites, mytillites, and tellinites, and sometimes impressions of leaves and stems resembling those of the palm tree and the pine.

Coal.—It sometimes contains beds of coal, but these are in general so thin, as to be of no value in an economical point of view.

Geognostic Situation.—It rests upon the upper oolite, and is covered by the chalk formation.

Geographical distribution.—It occurs abundantly in England, as in Wilts, Dorset, Sussex, Devon, Oxford, Isle of Wight, Surrey, &c. And on the Continent of Europe it is met with, both in Upper and in Lower Saxony.

IV. *Fourth Sandstone Formation.*

This formation is associated with the rocks that rest upon chalk, and will, therefore, be described along with these.

II. *Secondary or Flœtz Limestone.*

The limestones of this series are more compact and less translucent than those of the transition class; and further, they abound much more in organic remains of different kinds. The following are the formations which have been enumerated by authors, viz.

I. First Secondary Limestone.
II. Second Secondary Limestone.
III. Third Secondary Limestone.
IV. Fourth Secondary Limestone.
V. Fifth Secondary Limestone.

I. *First Secondary Limestone.*—Jameson.

Premier formation du Calcaire Secondaire. *Daubuisson.*

Alpine and Jura Limestones of German and some French Geologists, Mountain Limestone of English geologists.

Characters.—The colours of this limestome are grey, blue, and black. Its lustre varies from glistering to dull; the fracture is splintery, or granular foliated; and it is opaque or translucent in the edges. Some of the varieties are *stinkstone*, while the black varieties are those known under the name *lucullite*, and both these, when pounded, emit a very disagreeable smell.

It is distinctly stratified, and the strata are sometimes undulated and contorted.

Caves and caverns are not unfrequent in this formation, and extensive fissures frequently trasverse it, which either reach to the surface, or extend to a greater or less distance under ground, and afford channels for great springs and subterranean rivers.

It frequently contains imbedded portions and beds of Lydian stone, of quartz in the form of *chert*, which is either of a grey or black colour, and very much resembles the flint in chalk in the various relations it bears to the limestone.

Petrifactions are not unfrequently met with in this formation; and the following are the kinds which have been found in England, viz. entrochites, tubeporites, encrinites, corallites, madreporites, ammonites, pectinites, orthoceracites, &c.

Subordinate beds.—These are amygdaloid, greenstone, trap tuff, and basalt; also sandstone, magnesian limestone, slate-clay, bituminous shale, coal, and clay.

Metalliferous minerals.—This formation in some districts, as in the north of England and in Derbyshire, is particularly abundant in ores of different descriptions. The lead mines of Northumberland and Durham, and the lead and copper mines of Derbyshire, are situated in mountain limestone.

Geognostical position.—In what is called the regular succession, it comes immediately after the old red sandstone, and therefore rests upon it.

Geographical distribution.—It abounds in the north of England, also in Derbyshire, Wales, and Gloucestershire.

Observations.—It is said to occur sometimes in clay-slate, and also in the coal formation. If this statement be correct, then probably the coal formation, red sandstone, and this limestone, belong to the transition class.

II. *Second Secondary Limestone.*—Jameson.

Erster Flœtz Kalkstein.—*Werner?*

Magnesian limestone of English geologists.

Characters.—The colours of this limestone are yellow, and sometimes brown and grey. It is generally small granular, and glimmering or glistering. One variety is flexible. It contains about 20 per cent. of carbonate of magnesia. Its surface is, in many places, covered with a poor herbage, uncommon in limestone, which is said to be owing to the magnesia, which is known to be unfavourable to vegetation.

Petrifactions.—Organic remains are found in it, such as madreporites, encrinites, producti, and fishes.

Geognostic Position.—It rests upon the coal formation, and sometimes alternates with new red sandstone, and with a breccia composed of angular portions of sandstone and limestone, cemented by magnesian limestone. When it comes in contact with coal it deteriorates it. It frequently contains imbedded balls of fœtid limestone, from the size of a pea to two feet in diameter, and which have a stellular radiated structure. The limestone, containing these balls, is generally soft, marly, and magnesian, although the balls themselves contain no magnesia. It forms hills in some places 600 feet high.

Geographic Situation.—It abounds in some districts in England; thus it extends from Sunderland to Nottingham; the coal formation near Whitehaven lies under it, and the same is the case in Derbyshire.

III. *Third Secondary Limestone.*—Jameson.

Muschel Kalkstein.—*Werner ?*
Oolite *of Buckland*,
Lias and Oolite *of others*.

Geognostic Situation.—This formation, according to Mr. Buckland, is divided into the following principal members: viz. *Lower oolite*, including the *Lias limestone*. 2. *Middle oolite*. 3. *Upper oolite*. The first or lower oolite rests upon the variegated or new red sandstone, and the upper oolite lies immediately under the third sandstone-formation. The following is Mr. Buckland's account of this formation.

1. *Lower oolite.*—The lowest member of this portion of the series, or that which rests upon the new red sandstone, is the *lias*, which is a blue, grey, or white argillaceous limestone, disposed in thin beds, in a bluish-grey slaty marl, or clay. It rarely contains chert, more frequently various petrifactions, such as ammonites, pentacrinites, plagiostomites, ostracites, and occasionally remains of crocodiles, as near Lyme, in Dorsetshire.

Geographic Situation.—It extends from a little to the west of Ilchester, in Somersetshire, by Bath and Gloucester, nearly through the centre of England, and terminates a little beyond Lincoln. A few miles beyond Gloucester, it rises to the height of 1124 feet above the sea.

Above the *lias* is the *sand of the inferior oolite*, which is thus described by Buckland:

Sand of inferior oolite	Fine grained yellow, micaceous, loamy sand.
	Green and yellow calcareo-siliceous sandstone, highly micaceous.
	Green and yellow sandy marl, abounding in large concretions, called sand bats.

It occurs in Gloucestershire, Somersetshire, and Oxfordshire.

Above this sand, sandstone and marl is the *inferior* or *bastard oolite*, described as a coarse calcareous freestone, granular, with shelly fragments, and usually ferruginous. It occurs around Grantham, and in other parts of England.

The inferior or bastard oolite is immediately covered by *fuller's earth*, which forms the uppermost layer of the lower oolite. This fuller's earth occurs in layers in a grey-coloured clay, in the middle region of hills around Bath.

2. *Middle Oolite.*—The lowest member of this series is named *Great Oolite*, or Ketton stone, and is described as a durable yellow freestone, composed of oolitic concretions and shelly fragments, united by a calcareous cement. It occurs at Ketton in Northamptonshire, and Windrush in Oxfordshire. Resting on it is the next member of the series, named *Stonesfield Slate*, which is a calcareo-siliceous oolite, sometimes passing into sand, and associated with thin beds of bad coal. The coal of Cleveland Hills, in Yorkshire, belongs to this slate. Above the Stonefield slate is the *Forest marble*, which is a coarse slaty limestone, full of large fragments of shells (Yeovil marble,) and met with near Bath, and in Dorsetshire. The *Cornbrash* rock lies upon the Forest marble, and is a soft, earthy, yellow limestone, of blue and sandy, and occurs in Oxfordshire, and in Wiltshire. Resting on the Corn-brash is the *Kelloway rock*, which is a coarse sandy limestone, with many peculiar ammonites, and other shells, found at Kelloway Bridge, near Calne, in Wilts. A thick deposit of clay, named *Oxford*, *Forest*, or *Fen Clay*, is the next member of the series. The clay is of a bluish-grey colour, and includes hard and large septaria. It occurs in the vale of Thames, from Oxford upwards; vale of Ouse, from Bedford downwards; and the vale of Blackmoor, Dorset.

3. *Upper Oolite.*—The lowest member of this series, or that next in succession to the uppermost of the middle oolite, is a *calcareous grit or sandstone*. It is a siliceous sand and sandstone, with calcareous cement, often shelly, and is met with at Filey, near Scarborough, in Yorkshire, and near Abingdon in Berks. The next member in the series is *Coral rag*, which is a loose earthy oolite limestone, full of coraline remains, and found at Kiddington, near Oxford; at Highworth and Calne, Wilts; and Kirkby Moorside, Yorkshire. *Oxford oolite* is the next rock of the series. It is a perishable freestone, composed of oolitic concretions and shelly fragments united by a calcareous cement. It occurs at Heddington in Oxfordshire; Calne, Wilts; and New Malton, Yorkshire. *Kimmeridge clay* is the rock next in succession. It is a blue slaty clay, with selenite, and is sometimes highly bituminous: Occurs at the base of Shotover Hill, near Oxford; in the island of Portland; and at Kimmeridge, in isle of Purbeck, Dorset. Above the Kimmeridge clay is the *Portland stone*, which is a calcareo-siliceous durable freestone, often oolitic, containing beds and nodules of chert. It occurs in the isles of Purbeck and Portland; Chilmark, Wilts; Twindon; Aylesbury. The uppermost rocks of the series are the *Purbeck beds*. These are strata of slaty clay and marl, alternating with beds of coarse shelly limestone. They occur at Sandwich, Lulworth Cove, and Upway, Dorset; Lady Down, near Tisbury, Wilts.

IV. *Fourth Secondary Limestone, or Chalk.*

Kreide-Gebirge.—*Werner.*
Formation crayeuse.—*Daubuisson.*

This formation consists of three members, viz. *chalk marl*, *hard chalk*, and *soft chalk*.

1. *Chalk marl.*—This is an argillaceous grey-coloured chalk, without flints or chert, passing into a fine micaceous grey sand, or into a grey marl or clay. It rests upon the third sandstone formation, which therefore separates it from the oolite formation. It occurs at

Benson in Oxfordshire; Cherhill and Norton, Bevant, Wilts; Lewes; Guilford; Folkstone; Byarsh near Wrotham, Kent.

2. *Hard Chalk, or Lower Chalk.*—This chalk is harder than that which forms the upper part of the formation, and is sometimes of a brick-red colour. It contains few flints or petrifactions. It occurs near Warminster, Shakespeare's Cliff, Dover; Flamborough Head, Yorkshire; county of Antrim, Ireland. The red varieties occur in Lincolnshire and Yorkshire.

3. *Soft Chalk, or Upper Chalk,*—This is the common chalk of mineralogists, which is soft enough to mark with. It contains abundance of flint, in the form of tuberose, roundish, and ovoidal masses, either irregularly distributed in the mass, or disposed in horizontal layers; the flint is sometimes also arranged in beds, which occasionally extend, without interruption, for more than a mile; and, in other cases, veins of flint traverse the chalk in all directions. The flinty masses are sometimes hollow in the centre, and the walls of the cavities lined with crystals of common quartz. The petrifactions found in the chalk and flint are belemnites, echinites, alcyonites, spongites, ostracites, pectinites, terebratulites, ammonites, plagiostomites, milleporites, &c.; also teeth and palates of fishes of the shark tribe. At the hill of St. Pierre, near to Maëstrich, the remains of a species of *monitor* have been found in a kind of chalk.

Both the hard and soft chalks occur stratified: the strata are generally horizontal; sometimes inclined at a considerable angle, or even perpendicular; and there are instances, as in the Isle of Wight, of perpendicular strata meeting with horizontal, and also of horizontal, or slightly inclined strata resting on vertical strata. Metalliferous minerals occur rarely in this formation, and almost the only species hitherto met with is iron pyrites, which is sparingly disseminated through the chalk.

Geognostic situation.—It rests upon the third sandstone formation.

Geographic situation.—Chalk does not occur any where in Scotland, but in England it forms extensive tracts of country, and has been traced from near Sidmouth in Devonshire to Filey Bay in Yorkshire. It also occurs in Ireland, as in the county of Antrim. Chalk forms a considerable portion of the north of France; it also occurs on the shores of the Baltic, in the Danish islands, in Holstein, Mecklenburg, and Pomerania; it constitutes the principal rock formation in Poland and in southern Russia; and has been found in the Crimea. The following are descriptions of some chalk districts in England, as given by Mr. Phillips from the *Geological Transactions.*

"The chalk cliffs between Deal and Folkstone are extremely interesting. A short distance on the west of Deal, the chalk, with numerous flints, rises from beneath alluvial sand, and continues to rise, constituting the whole cliff for about five miles; namely, as far as St. Margaret's Bay, where the summit is about 150 feet above the sea. West of that place its rise is gradual as far as the cliff above which Dover Castle stands; and the greater part of it, beneath the castle, consists of the chalk with numerous flints; but the lower part of the bed is full of organic remains; of sponges and echinites, &c. of which the traces are visible on the surface of the cliff, projecting from it in the form of knobs, of a colour somewhat darker than the chalk itself. The beds of flint between Deal and St. Margaret's Bay are numerous and thin; but between the latter place and Dover they increase in thickness; and the flints are not nodular, but form beds of irregular thickness, with occasional cavities. The lower part of the cliff, beneath the castle, consists of *chalk with few flints*, in which lie some beds of soft chalk-marl, which, as it falls away by exposure, leaves crevices, by which the stratification is easily traced. These crevices rise from the beach, mid-way between St. Margaret's and Dover, are visible beneath the castle about one-third of the way up the cliff: are again seen in the cliff at the back of the town at a higher elevation, and again near the summit of Shakespeare's cliff on the west of Dover: proving the regular stratification of the chalk, and its gentle dip The low cliff commencing on the west of Dover, consists of a stratum of chalk, containing numerous beds of sponges, and other organic remains, but no flints; this bed forms the great body of Shakespeare's cliff, from the base, to where it underlies the chalk with few flints near the summit, and continues to rise five miles westward, until, near Folkstone, where the cliff is 550 feet high, it forms the greater part of the upper half. Immediately at the foot of Shakespeare's cliff, a new stratum rises from the beach, consisting of chalk, also without flints, containing few organic remains, and above 50 feet thick; it is separated from the superincumbent bed by a bed of marl, which may be seen with little interruption for five miles. A little on the west of Shakespeare's cliff, the *grey chalk* rises, and may be traced to where the high cliff terminates above Folkstone. This chalk is of a grey colour, is softer than common chalk, contains some alumina, and the same kind of organic remains as are commonly found in chalk, and some thin beds of sandstone, but no flints. But it is impossible to discover the thickness of this body, for though the cliff near Folkstone is 550 feet high, a most enormous and picturesque ruin covers its base. It is, however, probable that the chalk there rests upon a bed of blue marl, and that the giving way of this stratum has been the cause of the ruin. The marl is seen lying on the green sand at Copt Point near Folkstone, and at places between that point and the chalk-hills. In the cliffs east and west of Dover, therefore, we have all the members of the chalk formation, except the marls; which, in the Isle of Wight, lie above and below the chalk properly so called."

The chalk of Cambridgeshire is described as consisting of two varieties; the *upper*, containing the common black flint in abundance, and the *lower* or *grey chalk*, which contain little or none. If a line be drawn from Royston by Balsham to Newmarket, it will pretty exactly define the limits of both varieties; the hills to the eastward of it being composed of the upper beds, while those to the west consist of the lower or grey chalk, which composes by far the greatest part of the hills of Cambridgeshire. It is considerably harder than common chalk, and its colour is usually some shade of grey. Its provincial name is *clunch*, and it yields the best lime. Some of the beds are hard enough to serve the purpose of building stone. It also endures the fire well; and is used, like that of Ryegate and Measham in Surrey, for the backs of grates. In the northern extremity of the Cambridgeshire hills, the chalk appears to rest upon an extensive bed of blue clay, termed *gault;* but there is no decisive line of separation between them; they are considered to pass into each other by degrees, the lower beds of the grey chalk becoming more sandy, and assuming gradually the nature of an argillaceous loam

In the wolds of Lincolnshire, the chalk has two colours, red and white, each lying in regular strata, the red being generally undermost; in the white, seams of flint are frequently met with from two to six inches thick. The chalk rests upon a coarse brown pebbly-sand, without organic remains, consisting of quartz and oxide of iron.

V. *Fifth Secondary Limestone.*

This formation is one of the members of the series above chalk, and will be included in the description of the Paris formation.

III. *Secondary Gypsum.*

Flœtz Gyps.—*Werner.*
Secondary Gypsum.—*Jameson.*

There are two principal formations of this rock; one is associated with the rocks of the variegated or new red sandstone, and the other is a member of the series above chalk, or what is called the Paris formation.

1. *First Secondary Gypsum, including Salt.*

Erster und Zweiter Flœtz Gyps, and Steinsalzgebirge. *Werner.*

Characters.—It occurs granular, foliated, fibrous, compact, in crystals (selenite,) and sometimes anhydrous. Its principal colours are white and grey, seldom red or brownish. It occasionally contains imbedded crystals of different kinds, such as quartz, boracite, arragonite, and sulphur; and sometimes disseminated, and imbedded masses of clay, marl, sandstone, limestone, sulphur, and salt.

Subordinate beds.—It contains beds of marl, clay, limestone, sandstone, sulphur, and salt. These beds of salt afford the mineral salt of commerce, and are worked in the salt mines of Cheshire, Austria, and Poland.

Structure.—It is either distinctly stratified, or is disposed in short but thick and unstratified beds. Caves, varying in magnitude from a few yards to many fathoms in extent, occur in it; and of these there are striking examples in Thuringia, and in other countries. It is conjectured that they owe their origin to masses of salt which they formerly contained, and which have been removed in the course of ages by the action of subterranean waters. The magnitude of these caves is further increased by the action of percolating water traversing the gypsum itself. Frequently the roofs of the caves yield and fall in, and thus hollows, often funnel-shaped, are formed in the surface of the country.

Petrifactions.—It rarely contains petrifactions; and of these, species of the following genera have been met with: viz. madreporites, ammonites, tellenites, and branches and trunks of trees variously bituminized.

Geognostic Situation.—It is contained in, or rests upon the new red or variegated sandstone.

Geographic Situation.—It occurs but in small quantities in Scotland, whereas in England it is abundant in some districts, as in Cheshire, Worcestershire, &c.

2. *Second Secondary Gypsum.*

This formation occurs along with the rocks of the Paris formation, and will be described under that head.

IV. *Secondary or Flœtz Trap-Rocks.*

Under this division we include, as a matter of convenience, the secondary trap and porphyries. We shall first describe the traps, and next the porphyries.

Flœtz Trap.—*Werner.*

The rocks of this series are compounds of augite and felspar, with occasional intermixtures of hornblende. The following are the different kinds of these rocks, viz. 1. Greenstone; 2. Amygdaloid; 3. Wacke; 4. Basalt; and 5. Trap tuff.

1. Greenstone.—*Jameson.*
Grünstein.—*Werner.*

Composition.—Is a granular aggregate rock of augite and felspar. The felspar is sometimes red, but more frequently of grey colour, and the augite is almost always blackish-green. It varies from rather coarse granular to the compact, when the concretions are only discernible by means of their glimmering, and then the mass has much of the basaltic character.

Imbedded Minerals.—These are augite, basaltic hornblende, felspar, calcareous spar, diallage, and iron pyrites. In the true porphyritic greenstone, as that of Arthur Seat, the imbedded crystals are of felspar.

Structure.—It is sometimes amygdaloidal, and the amygdaloidal portions are of zeolite, calcareous spar, or quartz. Frequently it is disposed in columns or pillars, and these are again composed of globular and concentric lamellar concretions. Sometimes the whole mass of the bed is arranged into balls or globular concretions, or is disposed in tabular concretions. The beds vary in thickness from a few inches to many fathoms, and in the thicker beds stratification is discernible.

Cotemporaneous Veins.—Very often beds of secondary greenstone include veins of various descriptions, that appear to be of cotemporaneous formation with the rock. The following enumeration contains a few of the veins met with in the secondary greenstones of Scotland:

1. Calcareous spar. 2. Calcareous spar and quartz; the quartz sometimes in the form of amethyst or rock-crystal, but more frequently as common quartz. 3. Calcareous spar, common quartz, and calcedony. 4. Calcareous spar, heavy spar, and quartz. 5. Calcareous spar, and heavy spar, with glance coal. 6. Calcareous spar, heavy spar, and brown hematite. 7. Quartz, with red hematite and iron glance. 8. Calcareous spar, brown spar, and sparry iron. 9. Calcareous spar, heavy spar, prehnite, and zeolite. 10. Felspar, either grey or red. 11. Iron pyrites. 12. Red cobalt. 13. Yellow copper pyrites.

Petrifactions.—Fossil organic remains are of rare occurrence in trap rocks. Petrified shells have been found in greenstone, and also in that slaty rock (slaty compact felspar) frequently associated with it.

Geognostic Situation.—Occurs in beds, imbedded masses, and veins, in the old red sandstone, coal formation, variegated sandstone, and in various secondary limestones. Veins occur in primitive and transition districts. It is occasionally associated with a *secondary sienite.*

Geographic Situation.—It is a very abundant rock in the sandstone and coal districts of Scotland, and is not unfrequent in many primitive and transition tracts also in this country. Veins of it traverse the coal formations in the north of England, and although met with in other parts of England, is by no means so abundant there as in Scotland.

2. Amygdaloid.—*Jameson.*
Mandelstein.—*Werner.*

Characters.—This rock has a basis or ground including amygdaloidal portions of various minerals. The basis or ground is generally an intimate combination of augite and felspar in a very imperfectly crystallized state. Its colour is frequently green; sometimes reddish when much iron-shot; or nearly black when the predominating material is augite. The amygdaloidal masses vary in their nature; some are calcareous spar, or brown spar, or heavy spar, while others are green earth, quartz, steatite, or lithomarge.

Imbedded Minerals.—Besides amygdaloidal masses, the rock sometimes contains crystals of felspar, augite, or hornblende, thus affording examples of the union of the amygdaloidal and porphyritic structures.

Structure.—It occurs in columnar, globular, and also in tabular distinct concretions; and occasionally it is imperfectly stratified.

Geognostic Situation.—It generally occurs in mountain masses or beds, and sometimes in veins, and principally associated with rocks of the sandstone and limestone series.

Geographic Situation.—It is an abundant rock in the south and middle divisions of Scotland, both on the mainland and among the islands, as in Arran, Mull, Rum, Eigg, Canna, and Skye.

3. Wacke.—*Jameson.*
Wacke.—*Werner.*

Characters.—This rock has generally a greenish-grey colour; less frequently it is reddish, or of a brown or blackish cast. The fracture surface is dull, or only faintly glimmering, and the fracture is even, or flat conchoidal. It is opaque, and more or less shining in the streak; soft; sectile; easily frangible; and specific gravity about 2.8.

Composition.—It appears to be a very intimate combination of earthy augite and earthy felspar.

Structure.—Sometimes occurs in globular and imperfect columnar concretions, and occasionally it has the amygdaloidal structure.

Geognostic Situation.—It occurs in beds, imbedded masses, and in veins in sandstone and limestone.

Geographic Situation.—It occurs along with amygdaloid and greenstone in our coal-fields in different parts of Scotland, and also in the new red sandstone, and some other secondary formations.

4. Basalt, *Jameson.*
Basalt, *Werner.*

Characters.—Its colours are generally greyish, or greenish-black, and rarely inclines to grey. Internally it is dull or feebly glimmering. The fracture in the coarser varieties is large, or small-grained uneven; of the more crystalline varieties, even inclining to large and flat conchoidal, and seldom to splintery. It is opaque, or feebly translucent on the edges. It yields a pale grey-coloured streak. It is semi-hard, bordering on hard. It is rather brittle, and is difficultly frangible. Specific gravity = 3.08.

Structure.—It occurs in distinct concretions of various descriptions. They are generally columnar, varying from a few inches to some fathoms, even to upwards of 100 feet in length; the number of sides varies from three to nine, and of these the nine-sided are the rarest; they are straight, curved, and either parallel or diverging; sometimes they are articulated, and the joints have concave and convex faces. In mountains, these concretions are collected into large groups, and many of these groups or colossal concretions form a hill or mountain. Sometimes it occurs in tabular, sometimes in globular concretions; these latter are frequently composed of concentric lamellar concretions, or of columnar concretions radiating from a centre. Some varieties are composed of large, coarse, and fine granular concretions.

There is sometimes a tendency to stratification, and varieties occur with the amygdaloidal, and also with the porphyritic structures.

Imbedded Minerals.—The most frequent imbedded minerals are olivine and augite; besides these, grains and crystals of felspar, and also of basaltic hornblende, calcareous spar, and magnetic iron ore, are met with.

Decomposition.—Some varieties are easily decomposed, particularly those that incline to wacke and amygdaloid, while others long resist the action of the atmosphere. The earth formed by their decomposition has a greasy feel, and the great fruitfulness of basalt countries is owing to this basaltic earth. Sometimes the imbedded minerals decompose, at length fall out, and thus leave the basalt with a vesicular structure. Olivine is one of the most easily decomposable of the simple minerals met with in basalt, being even more easily broken down by the influence of the weather than calcareous spar; on the contrary, we often find augite and hornblende unchanged, after the basalt has been reduced to a clayey mass.

Forms.—It occurs frequently in the form of mountain caps, having tabular or conical forms; or it is distributed in long ridges, or in scalarlike cliffs and terraces.

Geognostic and Geographic Situations.—It occurs in beds, imbedded masses, and veins, in sandstone and limestone formations in Scotland, England, and Ireland.

5. Trap-tuff, *Jameson.*
Trap-tuff, *Werner.*

Composition.—This rock has a conglomerated structure, and therefore has a basis or ground, with imbedded masses of various forms and sizes. The ground or basis varies in its nature; sometimes it is wacke or greenstone, or it inclines to basalt or amygdaloid. The imbedded masses, which are of various roundish and indeterminate angular forms, are of wacke, amygdaloid, greenstone, and basalt; and intermixed with these are sometimes masses of sandstone, limestone, slate clay, bituminous shale, and jasper. The masses vary in size, from that of a pea, to several yards, or even fathoms, in length, breadth, and thickness.

Petrifactions.—It sometimes contains trunks and branches of trees, more or less bituminized.

Structure.—It occurs in beds, which are from a few inches to many fathoms in thickness; is sometimes distinctly stratified, and occasionally it is disposed in globular distinct concretions, the balls varying from a few inches to several feet in diameter, and also in columnar concretions.

Geognostic Situation.—It occurs in imbedded masses, beds and veins, along with the other rocks of the secondary trap series already enumerated.

Geographic Situation.—A considerable portion of Arthur Seat is composed of this rock; it abounds in many of our red sandstone and coal districts, and is very frequently met with among the Hebrides, as in Canna and Eigg.

B. Secondary Porphyry, *Jameson.*
Flœtz Porphir, *German Mineralogists.*

The secondary porphyries are composed of felspar in various states of aggregation, hornstone, and pitchstone, with intermixed grains and crystals of felspar, quartz, and other minerals.

The following are the rocks, arranged under this head:

1. Claystone. 2. Claystone porphyry. 3. Felspar. 4. Felspar porphyry. 5. Clinkstone. 6. Hornstone porphyry. 7. Pitchstone. 8. Pitchstone porphyry.

1. Claystone, *Jameson.*
Thonstein, *Werner.*

This rock, which is described in p. 462, appears to be felspar in a comparatively loose state of aggregation. It is sometimes conglomerated, and then is named claystone tuff. It is disposed in beds and veins in sandstone districts, and in coal-fields, both in England and Scotland. It is always an accompanier of rocks of the secondary porphyry formation.

2. Claystone Porphyry. *Jameson.*
Thonstein Porphir, *Werner.*

Composition.—This porphyry, as its name intimates, has a basis of claystone, in which imbedded crystals of felspar are contained.

Structure.—It occurs in columnar, tabellar, and globular distinct concretions; is sometimes conglomerated, rarely vesicular, and occasionally imperfectly stratified.

Imbedded Minerals.—These are felspar, quartz, either in grains or in double six-sided pyramids, mica, augite, hornblende, and iron pyrites.

Petrifactions.—Trunks, branches, and twigs of trees, occur imbedded in this rock, and these are generally penetrated or petrified with wood-stone.

Geognostic Situation.—It occurs in imbedded masses, beds and veins, in secondary sandstone and limestone districts, and is sometimes associated with the secondary trap-rocks.

Geographic Situation.—The Pentland and Ochil hills, near Edinburgh, contain abundance of secondary porphyry, and the same is the case in some districts in the south and north of Scotland, and also in England and Ireland. It is a frequent rock in similar situations on the continent of Europe.

3. Felspar, *Jameson.*

This mineral occurs as a mountain rock, with red or grey colours, and either very minutely foliated, or in a compact state.

Geognostic and Geographic Situations.—It occurs along with porphyry and claystone, in the Pentlands and Ochils; also in Arran, and in several places on the east coast of Scotland, associated with old red sandstone.

4. Felspar Porphyry, *Jameson.*
Felspath Porphir, *Werner.*

This rock differs from the preceding, in always containing imbedded grains and crystals of felspar.

Geognostic and Geographic Situations.—It occurs along with clay-stone porphyry, and other rocks of this series, in the Pentlands and Ochils, and in other parts of Scotland.

5. Clinkstone Porphyry, or Porphyry-slate, *Jameson.*
Klingstein Porphir, *Werner.*
Phonolith, *Daubuisson.*

This rock has a basis of that kind of felspar named clinkstone, with imbedded crystals of felspar, whence it is named clinkstone-porphyry, or porphyry-slate, from its slaty structure. The colour of the basis is greenish, yellowish, smoke, bluish, or ash-grey; sometimes, also, blackish-green; and when much impregnated with iron, liver-brown and reddish-brown. Sometimes several colours occur in the same mass, and it is occasionally marked with greyish-coloured spots, and frequently shows dendritic delineations on its surface. Its fracture is splintery in the small, but slaty in the large. Hardness same as that of felspar. It is more or less translucent on the edges, and some varieties are opaque.

Imbedded Minerals.—Besides the imbedded grains and crystals of felspar, it also occasionally contains crystals of augite and basaltic hornblende, zeolite in drusy cavities, and very seldom quartz, calcareous spar, iron-pyrites, and iron-sand. It is sometimes vesicular.

Structure.—It is frequently arranged in columns and tables, like those of basalt.

Decomposition.—It long resists the action of the weather, but in course of time it becomes covered with a thin crust, which has usually a greyish white colour in the pure, but of a reddish colour in the iron-shot varieties.

Forms.—Like basalt, it frequently forms conical and tabular hills, and exhibits numerous striking and rugged cliffs.

Geognostic Situation.—It occurs in imbedded masses, beds, and veins, in red sandstone, in the coal-formation, and also in secondary limestone.

Geographic Situation.—It is a frequent rock in the islands of Arran and Lamlash in the Frith of Clyde; is met with in the Girleton hills near Haddington, North-Berwick Law, Traprain Law, and Braid Hills, near Edinburgh.

6. *Hornstone Porphyry.*

Hornstein Porphir.—*Werner.*

This porphyry occurs in imbedded masses, beds, and veins, along with clay-stone porphyry, and in similar situations, both geognostically and geographically.

7. *Pitchstone.*

Pechstein.—*Werner.*

This rock, of which a description is given in the oryctognostic part of this article, occurs in considerable abundance in the form of beds and veins in red sandstone, in Arran, and other districts in Scotland.

8. *Pitchstone Porphyry.*

Pechstein Porphir.—*Werner.*

This rock, which has a base or ground of green or black pitchstone, always contains imbedded grains and crystals of felspar, which is generally the glassy kind.

Structure.—It occurs in globular, columnar, and tabular concretions.

Imbedded Minerals.—Besides felspar, it sometimes contains imbedded calcedony, common quartz, calcareous spar, and also zeolite.

Geognostic Situation.—It occurs in beds, imbedded masses and veins, in various secondary trap rocks, also in red sandstone, and in secondary limestone.

Geographic Situations.—It abounds in the island of Arran, occurs also in Lamlash, and is met with in Mull, Eigg, Sky, and other parts of Scotland.

V. *Formations above Chalk, or Paris Formation.*

Terrain Tertiaires.—*Daubuisson.*

Under this division, we include all the different secondary beds which are of posterior formation to chalk. They are principally marl, clay, and sand, interstratified with beds of limestone, sandstone, and gypsum. The only metalliferous minerals they contain are, iron pyrites, and brown ironstone, but many of them abound in organic remains. This set of rocks appears more of a local nature than any of those hitherto described. The following description is illustrative of this formation, as it occurs around Paris.

Geographic Distribution.—It extends all around Paris; to the north, as far as Senlis and Laon; to the east, to Rheims and Epernay; to the south, to Orleans; and to the west, to Chartres and Mantes. It may be considered as composed of seven systems of beds, viz.

1. Plastic clay with sand.
2. Coarse limestone, or limestone with cerites, and accompanying sand and sandstone.
3. Siliceous limestone.
4. Gypsum and marl.
5. Marl.
6. Sand and Sandstone.
7. Fresh-water limestone and mill-stone or buhr-stone,

The chalk on which they rest presents numerous inequalities, in and over which these beds are arranged, and generally in a horizontal or slightly inclined position.

1. *Plastic Clay and Sand.*

This bed, which rests immediately upon the chalk, consists of an unctuous, tenacious, and variously coloured clay, employed by potters, and named by Brongniart, plastic clay. It contains little chalk, but is frequently intermixed with sand, particularly towards its upper part; sometimes this sand is divided into two beds. It varies in thickness, in some points not exceeding a few inches, in others being many fathoms. It contains few shells, and these are marine.

2. *Coarse Limestone, with Sand and Sandstone.*

Above this clay is a bed principally of a calcareous nature, composed of an alternation of beds of coarse limestone, marl, and slate-clay, which occur always in the same order, over an extent of 25 leagues of country. The average thickness of the whole together is about 90 feet.

The lower beds are very sandy, and often contain grains of a green matter, resembling that found in the *green sand*, already described as lying under the chalk formation, and abounds on marine shells.

In the superior beds, there are layers several feet thick, of a pale-yellow limestone, which is pretty hard, and in large grains, and forms the principal building-stone at Paris. They contain great abundance of petrifactions, and particularly of cerites, and are covered by marly beds. Siliceous productions occur principally towards the upper part of the formation, and these are flint, or flint passing to hornstone, and crystals of quartz. In some places the siliceous matter occurs in considerable masses, even whole beds, sometimes in the form of sandstone, which abound in marine shells, and occasionally also contains fresh-water shells, such as lymnæa and cyclostomæ.

3. *Siliceous Limestone.*

Above the coarse limestone is a limestone which contains fresh-water shells. It is stratified, and the strata are sometimes soft and white, sometimes grey and compact, and penetrated with silica, in all directions. Sometimes the walls of cavities and fissures are lined with calcedony and small crystals of quartz; in other instances the siliceous matter is formed into masses of vesicular and corroded quartz, named *buhr* or *millstone*, which has been regarded as the skeleton body of a siliceous limestone, the calcareous portion of which has been removed.

4. *Gypsum.*

The gypsum formation rests on the beds just described. It consists of an alternation of beds of gypsum and marl. Where thickest, as at Montmartre, near Paris, it is divided into three beds. The *lowest bed* is composed of thin layers of gypsum, which is often lamellar, of solid calcareous marl, and slaty argillaceous marl, in which menilite is found; and the under part of this bed sometimes encloses marine shells. In the *second bed*, the gypsum is in great quantity, but the marl in small quantity; no shells occur, but petrified fishes are met with. The *uppermost bed*, which is the principal one, is four times thicker than the others, and is that which is quarried on account of its gypsum; thin beds of marl occur; the gypsum is sometimes 60 feet thick; it is naturally divided into large irregular prisms like basalt; it is pure, and is granular foliated; the lower part often contains flint, and the superior part passes into marl. This bed is particularly distinguished by the multitude of bones, particularly of quadrupeds, which it contains; and it also contains some fresh water shells. This formation, at its line of junction with the rock of limestone, on which it rests, is intermixed with and passes into it.

5. *Marl.*

The marls that rest upon the gypsum, and which often replace it, are of two kinds; one is of the same nature as that which alternates with the gypsum, and contains fresh water shells, while the other contains marine shells.

The first are in general white and calcareous; they contain silicified trunks of the palm tree, and species of lymneus and planorbis. Above these are beds of argillaceous marl, which are sometimes 60 feet thick. In these beds, balls of celestine or sulphat of strontites occur. It is succeeded by several thin beds, and the whole is terminated by two beds, containing vast abundance of oysters.

6. *Sand and Sandstone.*

Resting upon the marls when the succession of beds is complete, there is a great bed composed of sand and sandstone, sometimes 300 feet thick.

The sand consists of angular particles of quartz, mixed with earthy carbonate of lime, and fragments of shells; sometimes it is quite pure and thin; it is used for making plate glass. There arises from amongst this sand a kind of sandstone, which is used in paving the streets of Paris, and the roads in its vicinity. It is composed of transparent shining angular particles of rock-crystal immediately connected together, or without any basis or cement. Sometimes the particles are so loosely aggregated, that they can be separated by the simple pressure of the finger, while in other cases they are so closely aggregated as to pass into a state nearly approaching to that of compact quartz. The sandstone or quartz is disposed in the sand in various ways; sometimes it is in large or small imbedded masses, or in beds sometimes several feet thick, and extending to a considerable distance. This bed of sand and sandstone, contains few marine organic remains, and those that do occur are confined to its upper part, where it is intermixed with a calcareous sand. It is indeed a general observation, that animal remains occur very rarely in quartzy rocks, but abundantly in those of a calcareous nature.

Sometimes the sandstone contains cotemporaneous portions of flint, hornstone, flinty-slate, and thus a conglomerate is formed.

7. *Fresh Water Limestone, with Millstone, or Buhrstone.*

There frequently rests immediately upon the preceding sand and sandstone, a thick bed consisting of layers of sand, marl, clay, and millstone. The mill or buhrstone is quartz, in a vesicular and corroded form, and which forms beds sometimes upwards of one hundred feet thick. Its vesicular form adapts it for millstones, and hence it is very extensively quarried for this purpose, and exported to England and other countries.

Above these layers, and forming the uppermost portion of the series of rocks which rests upon chalk, is a formation of limestone different from those already described, and which extends to very considerable distances. It is highly impregnated with quartzose matter, and contains abundance of fossil shells, which are said to belong to the division of *land and fresh water shells*, and hence this limestone has been named *fresh water limestone*. It is of a yellowish white colour, fracture earthy or conchoidal, varies in hardness from that of compact limestone to that of the softer marls. It frequently contains flint and hornstone, and also beds of the vesicular quartz, or buhrstone, which, in general, is more compact than that found in the preceding formation. It is further particularly distinguished by its containing numerous irregular cylindrical cavities, and by the animal remains it contains, resembling, in characters, the genera lymnæa, planorbis, cyclostoma, and helix of our present marshes.

Observations on the Paris Formation.

This remarkable group of rocks has been sometimes distinguished into four divisions or beds, according to the kind and distribution of the organic remains it contains. The *first* or *lowest bed* includes the plastic clay, coarse limestone and inferior sandstone, in all of which the organic remains are said to be entirely *marine*. The *second bed* contains the lower siliceous limestone, and the lower gypsum and marls, both of which contain scarcely any other petrifactions than those of land and fresh water animals; and hence is called a *fresh water formation*. The *third bed* is composed of the superior marls, sands, and sandstones, and the few petrifactions it contains are of *marine shells*. Lastly, the *fourth bed* is a great *fresh water formation*.

A series of rocks, possessing many of the characters of those around Paris, occurs in the Isle of Wight, and the neighbouring districts in the south of England, and has been well described and illustrated by an excellent man and good observer, Mr. Webster of the Geological Society of London. Beudant describes rocks of the same nature as occurring in Provence, and informs us that the famous quarries of Aix, which afford so many different kinds of petrified fishes, are situated in a marl belonging to the Paris formation. The famous district of Oeningen on the banks of the Lake of Constance, so well known to naturalists on account of the great variety of petrifactions it affords, agrees in its general characters with the Paris formation. The fresh water limestone has been found in Auvergne, in the vicinity of Montpellier, to the north of Tarn, between Montauban and Agen; also in Spain, in the vicinity of Burgos and Seville; in Germany, near Ulm; and in Italy, in the Roman States.

8. *Brown-Coal, assosiated with Rocks above Chalk.*

Associated with a group of rocks above chalk, there are sometimes extensive formations of brown-coal. There is a fine example of this arrangement of brown-coal in the North of France, in the country extending from Beauvais to the vicinity of Rheims. There are five beds of brown-coal, varying from two to six feet in thickness; and are separated from each other by layers of gravel and loam. Both the coal and the layers between it are impregnated with iron pyrites. The whole is covered with beds of marl and limestone; those beds which rest immediately upon the coal contain fresh water shells, while those at a distance from it include marine shells; and it is said that the uppermost part is a shelly sandstone. M. Marcel de Serres informs us, that in the vicinity of Beziers fresh water shells are found in a bed of brown-coal, which is covered by bituminous beds, bituminous limestone, with fresh water shells, compact limestone, without shells, and, lastly, with a limestone containing impressions of cerites. Sometimes this brown-coal is covered with trap-rocks or lavas.

The brown-coal formation contains a few imbedded minerals, such as iron-pyrites, bog-iron ore, selenite, honey-stone, retin-asphalt, and a mineral of an inflammable and waxy nature.

Class IV. Alluvial Rocks.

This class comprehends those rocky substances formed from previously existing rocks, of which the materials have been broken down by the agency of water and air; they are therefore generally loose in their texture, and are never covered with any real solid and rocky secondary strata.

Werner divides them in the following manner:

1. *Mountain alluvial formations.*
   - *a*. On the summits of mountains.
   - *b*. On the sides of mountains, and at the foot of mountain ranges.
2. *Alluvial formations of low or flat lands.*

1. Mountain alluvial formations.

a. On Summits of Mountains.

The alluvium found on the tops of mountains, and mountain-chains, consists generally of a thin bed formed by the decomposition of the immediately subjacent rocks. This bed, particularly when covered with vegetable matter, forms a coat which long protects the solid strata from the wasting influence of the weather.

b. In Valleys.

The disintegrated rocks on the sides of valleys, yielding to their own weight, or carried downwards by torrents, are stopped at the foot of the mountain; they are accumulated there, and, in the course of time, form a deep protecting cover for the lower part of the mountain, and fill up the bottoms of the valleys.

c. At the foot of Mountain Ranges.

Besides the alluvial covering on the bottoms of valleys, and on the basis of their bounding hills and mountains, there often occurs very extensive alluvial formations, extending to a greater or lesser distance from the general foot of the acclivity of the great mountain-chains, or mountain groups. These formations are composed of fragments of the neighbouring mountains, but are arranged in a vast horizontal bed; thus intimating that they must have been levelled by the action of a great mass of water, in the form of a lake or inland sea. The plains of Piedmont and Lombardy, at the foot of the Alps, present a colossal example of this kind of alluvial formation.

2. Alluvial formations of the low or flat lands.

The alluvial substances met with in the great plains are principally sands and clays of different descriptions. These occasionally include various minerals, such as calcareous tuffa, peat, &c.

We shall first describe the sand and clays, and afterwards the calcareous tuffa, and other subordinate substances met with in them.

a. Sand.

Sand, as is well known, is formed of small grains supposed to have been derived from previously existing rocks of a quartzy nature. It sometimes covers immense tracts of country, and forms great deserts, as those of Barbary and of Arabia.

The extreme fineness of the particles renders the sand moveable by the slightest breath of wind, so that when the storm rages, the desert presents a picture of moving waves, mountains, and pillars, that baffle all description, and which overwhelm vast tracts of country, carrying every where desolation and destruction.

Downs.—When the sea-coast is low, and the bottom consists of sand, the waves push this sand towards the shore, where, at every reflux of the tide, it becomes partially dried; and the winds, which almost always blow from the sea, drift up some portion of it upon the beach. By this means, *downs*, or ranges of low sand hills, are formed along the coast. These, if not fixed by the growth of suitable plants, either disseminated by nature, or propagated by human industry, would be gradually, but certainly, carried towards the interior, covering up the fertile plains with their sterile particles, and rendering them unfit for the habitation of mankind; because the same winds which carried the loose dry sand from the shore to form downs, would necessarily continue to drift that which is at the summit further towards the land.

b. Clays.

Many extensive plains are covered with clays and loams of various descriptions; these also occur filling up hollows in plains, and forming extensive tracts on the sides of lakes, and at the mouths of rivers where they enter lakes, or meet with the waters of the ocean. These clays are formed by the disintegration of felspar, micaceous, and slate rocks.

1. *Substances that occur in the sand and clay.*

These are, 1. Calcareous tuff; 2. Bog-iron ore; 3. Ores, metals, and gems in grains; 4. Common salt; 5. Subterranean and submarine forests; 6. Peat.

1. *Calcareous tuff.*—There are two kinds of this rock, one of old formation, and another which is daily forming. The first appears to have been deposited from the waters of lakes that formerly existed in limestone districts, but which have long since disappeared. Thuringia affords striking examples of this formation of calc-tuff. The tuff there rests upon gravel, or on the rocks of which the country is composed: it forms beds sometimes upwards of fifty feet thick, and which are composed of strata of compact and porous tuffa, which frequently alternate with each other, and between them are sometimes thin beds of a brown bituminous earth. When the lakes contain no plants, then the tuff deposited in it is always compact, but if, on the contrary, they abound in reeds, rushes, confervæ, &c. the tuff, owing to this intermixture, is porous, and loose in its texture. These tuffs in Germany contain osseous remains of elephants, rhinoceroses, megatheria, deers, &c. and sometimes also remains of fresh water shells, analogous to the species at present met with, and also impressions of indigenous plants; and very lately fossil human skulls are said to have been met with in this formation.

The waters which flow along the surface of the globe, and which are charged with calcareous earth, deposit it on the districts they traverse, and thus form tuffas, which are either porous or compact. An example of this formation occurs at Starlyburn near Burntisland in Fifeshire.

2. *Bog-iron ore.*

Water, in its passage over and through rocks containing iron, abstracts a portion of it; it also carries away the iron contained in the beds of decaying vegetable matter it passes through, and in both cases a portion of the water combines with the iron, so that when the iron comes to be deposited on the bottom of lakes, or spread over the flat country, it appears in the form of hydrate of iron, and thus gives rise to the beds of *bog-iron ore*, met with in alluvial districts. In many districts in Scandinavia, where the primitive strata are very richly impregnated with iron, bog-iron ore is found in great abundance in the bottom of lakes, and so rich as to yield 60 per cent. of hydrate of iron. The iron is dredged out in some instances every ten, in others every twenty and thirty years, thus showing the rapid renewal of the deposite. Some lakes or morasses, the bottoms of which are covered with these ferruginous deposites, dry up, and become covered with a bed of soil and grass, and thus form *meadow-ore*:—Werner gives the following account of the formation of this ore of iron, as observed by him in Lusatia. He distinguishes three principal varieties, which he refers to three periods of formation; that which is obtained from swamps, and which is still soft at the time of its being removed, he names *swamp-ore*; that which is hard and covered with marsh plants, is his *marsh-ore*; and lastly, that which is dug from districts entirely dry and covered with a thin layer of soil, is named *meadow-ore*.

3. *Ores, metals, and gems in grains.*

Some kinds of alluvia, particularly those in mountainous districts, contain masses and grains of ores and native metals, which are derived from metalliferous veins, metalliferous beds, or from rocks through which the metalliferous minerals have been disseminated. If the minerals yield easily to decomposition and trituration, they are reduced to very minute particles, and become intimately mixed with various clays and loams; but if their hardness and tenacity is such that they resist obstinately, then they appear in rolled pieces, and in grains of various sizes and forms. The ores and metals most frequently met with in this situation, are iron-pyrites, tin-ore, native gold, and platina. The three latter are those which, on account of their value, are extracted from the sands and clays by washing.

The washing for gold is practised in many countries, and in some, as in Brazil, to a great extent. Indeed, nearly three-fourths of the gold of commerce are obtained from sand by washing.

Platina is obtained by washing the alluvial soil of the province of Choco in Peru; and there it is accompanied with fragments of basalt, zircon, titanium, iron sand, and grains of gold. The metals known under the names palladium, rhodium, osmium, and iridium, are also obtained from the sands of Choco.

Tin-ore is found in considerable abundance in alluvial soil in Cornwall, Saxony, and in the island of Banca.

Many of the gems are obtained by washing alluvial sands and clays; the pyrope or garnet of Bohemia, zircons, rubies, topazes, and diamonds, are collected in alluvial districts.

4. *Common Salt.*

Rock-salt occurs in great abundance in the deserts of Africa and Arabia, the plains of Persia, and the steppes of Siberia.

5. *Subterranean and Submarine Forests.*

Sometimes whole forests are found covered with alluvial deposites, and these are either under alluvium on the dry land, or extend under the waves of the ocean. The first are denominated subterranean, and the latter submarine forests. There is an extensive subterranean forest in Lincolnshire, and another in Lancashire; and on the coast of Lincolnshire there is an immense submarine forest, which has been particularly described by Mr. Correa. The sinking and sliding of the alluvial strata, and the breaking down of natural sea-barriers on front of flats, marshes, and lakes, easily explain all the phenomena exhibited by submarine forests.

6. *Peat.*

There are six different kinds of peat, viz. *mountain*, *marsh*, *lake*, *forest*, *marine*, and *transported*, all of which we shall describe in our natural and economical history of this substance under the head PEAT.

CLASS V. VOLCANIC ROCKS.

We include under this class all those rocks which are alleged to have been formed by the agency of volcanoes. They may be divided into the following orders. 1. Pseudo-volcanic. 2. Thermal, or those formed from the water of hot springs. 3. Those formed from torrents of hot water issuing from volcanoes. 4. Rocks formed by torrents of mud flowing from subterranean volcanic lakes. 5. Rocks formed by air or mud volcanoes. 6. Volcanic.

1. *Pseudo-volcanic.*—Pseudo-volcanic rocks are portions of previously existing strata, which have been more or less altered by the action of heat emanating from beds of coal in a state of combustion. The following species are enumerated by geologists. 1. *Burnt-clay.* 2. *Porcelain-jasper.* 3. *Earth-slag.* 4. *Columnar clay-iron ore.* And 5. *Polishing-slate.*

1. *Burnt-clay.*—Its colour is usually red, and sometimes grey, yellow, and brown, and occasionally spotted or striped. Sometimes it encloses impressions of plants. It is clay or slate-clay burnt, but not so much changed as to form a porcelanous mass.

2. *Porcelain-jasper.*—It is slate-clay, or common clay, changed into a kind of porcelain by the action of heat. Like the preceding species, it sometimes contains impressions of plants, a fact which shows that it has not been completely melted.

3. *Earth-slag.*—This is clay, or clay iron-stone, converted into a kind of slag. It is black, brownish, or reddish, and it has occasionally a tempered steel tarnish. It is amorphous or vesicular, and has sometimes metallic lustre.

4. *Columnar clay iron-ore.*—This is clay iron-ore, which is supposed to owe its columnar concretionary form to the action of heat.

5. *Polishing-slate*—Is a grey or white coloured thin slaty light mineral, which Werner conjectures to be the ashes of burnt coal, which have been carried by water into low situations, and deposited in a slaty form.

Situation.—Pseudo-volcanoes usually occur in low situations, and sometimes also in hilly country, and always in rocks of the coal formation.

Phenomena.—They are discovered by the heat of the surface of the earth in their vicinity; sometimes by smoke, and more rarely by flames issuing from rents in the ground. Sulphureous and ammoniacal vapours frequently occur, and these, in their course upwards, incrust the fissures of rocks, and even the surface of the ground, with sulphureous and ammoniacal matters.

2. *Thermal-Rocks, or those formed from Water of Hot-Springs.*

Olafsen, Povelsen, Menge, and others, speak of thermal rocks having many of the characters of basalt, porphyry, wacke, &c. which occur in districts where formerly hot-springs existed, and even say they have observed them actually forming around many of the magnified hot-springs at present in a state of activity in Iceland. These thermal trap-rocks, viz. thermal, basalt, wacke, amygdaloid with calcareous spar, porphyry, &c. are alleged to be brought from the interior of the earth, by the water of hot-springs, partly in a state of solution, partly in a state of mud, and are deposited over flat or hilly tracts of country, when they gradually harden, sometimes crystallize, and assume their various permanent characters. The amygdaloidal traps appear to be formed in those cases where carbonate of lime is present; the obsidian where dissolved silica prevails; and in the same general way we might account for the formation of the other rocks.

The hot-springs of Carlsbad in Bohemia are of this description, and the well known hot-springs of San Filippo in Tuscany, have formed a hill of calcareous tuffa, in many places as compact and hard as limestone. The famous rock named *travertino* by the Italians, and which abounds in South-western Italy, is a product partly of hot, partly of cold springs. The ancient temples, and the gorgeous palaces and churches of Rome, and indeed the whole of the streets and squares of the former Mistress of the World, are built of concretionary masses which have been deposited by springs.

There are many considerable hot-springs around Guancavelica in South America, the waters of which spread over the neighbouring country, and deposit upon it an ash-grey or whitish substance, (calc-tuff, sinter and travertine?) which acquires a great degree of hardness. The spring-water is so highly impregnated with the earthy matter, that the inhabitants receive it in square boxes or moulds, which it fills in a few days, and the blocks, thus formed, are used for building. Indeed the greater part of Guancavelica, like Rome, is built of the concretionary rock formed from springs.

3. *Rocks formed from torrents of Hot Water issuing from Volcanoes.*

There are on record authentic instances of torrents of hot water flowing from the crater or the sides of volcanoes, when in a state of activity, which, when collected in hollows, or spread over plains, deposits various earthy matters, which at length assume the character of rocks. In the year 1751, a torrent of salt water burst from Ætna, and continued to flow for a quarter of an hour, and was so considerable that the inhabitants named it *Nilo d' Acqua*. Dolomieu and Hamilton observed traces of a frightful torrent of hot water which had issued from the great crater of Ætna; and Spallanzani is of opinion, that part of the tuffas of Italy have been formed by muddy eruptions. In those volcanic mountains whose summits are above the snow line, as is the case in Iceland and in South America, great floods of hot water, charged with earthy matter, burst from the mountains and devastate the surrounding country. Bouger and Condamine saw dreadful ravages committed by these torrents; and the latter writer informs us, that after an explosion of Cotopaxi, a village situated thirty leagues in a straight line, and probably sixty leagues following the wavings of the ground, was entirely carried away by one of those torrents. These torrents from the ice-capped volcanoes appear to be entirely external, while those first mentioned seem to come from the interior of the volcanoes.

4. *Rocks formed by Torrents of Mud flowing from Subterranean Lakes.*

In the interior of volcanic mountains, there sometimes occur caverns or hollows partly filled with water, thus forming subterranean lakes. The earthquakes that often agitate these mountains, are occasionally so violent as to produce great rents, which give free passage to the water of the lakes, which bursts forth with tremendous violence, deluges the neighbouring country, and covers it to a greater or less extent, and with a more or less deep crust of muddy matter. In the earthquake of the year 1746, which overturned Lima, four volcanoes opened at Lucanas, and in the mountains of Conception, and occasioned frightful deluges. The volcanoes of the kingdom of Quito sometimes exhibit phenomena of the same kind, but accompanied with circumstances so extraordinary that we shall now state them. The enormous volcanic cones of Cotopaxi, Pichincha, Tungouragua, &c. in South America, never throw out lava, but frequently ashes, scoriæ, and pumice, and sometimes vomit forth immense quantities of water and mud. These eruptions take place more frequently from the sides than from the craters of the volcanoes, and the muddy waters appear to be derived from lakes situated in the interior of the mountains, which burst forth with incredible fury, when any accidental cause, such as an earthquake, splits, and thus opens the side of the mountain. In the year 1698, the mountain of Carguarazo, near to Chimboraco, fell down and covered eight square leagues of country with mud. In the earthquake of the fourth February, 1791, 40,000 persons were destroyed by eruptions of water and mud, (moya.) Muddy waters, resembling those which flow from volcanic mountains, are vomited forth in great quantity, from districts where no volcanic rocks occur, when these are agitated by earthquakes or other causes. In Peru and Quito, the devastations occasioned by volcanoes are not caused *by streams of lava*, but by water and *enormous streams of mud*, which, when hardened, is found to contain crystals of felspar, and to resemble porphyry.

5. *Rocks formed by Air or Mud Volcanoes.*

In some countries, jets or great bubbles of water, highly impregnated with mineral matter, are thrown out of the earth by means of gas. The earthy matter is deposited in the state of mud, principally around the mouths of the cones from whence it is expelled; and as these cones somewhat resemble volcanoes in form, they have been named *air-volcanoes*. One of the most remarkable of these air-volcanoes hitherto described, is that of Macalouba in Sicily, of which an account has been published by Dolomieu. It consists of a hillock of hardened mud, about one hundred and fifty feet in height. Its superior part forms a plain more than half a mile in circumference, and rising from it are numerous small cones not more than three feet in height, each of which has a crater or hollow filled more or less deeply with a liquid mud, which is in a state of perpetual agitation, owing to the constant passage of great bubbles of air through it. Portions of the mud are constantly thrown out, and thus add to the bulk and height of the cones.

There are many small *mud-volcanoes* in the neighbourhood of Modena, whose height is not more than a few feet. They are named *Salses*, on account of the saltness of the water they throw out; and which, indeed, is also the case with the water of Macalauba, and of that of most other muddy eruptions observed in different countries. These volcanoes, during their paroxysms, which are attended with slight agitations of the earth, throw out much mud, which extends to the distance of three thousand feet. The gas which occasions the eruptions, is sulphuretted hydrogen mixed with petroleum, and a little carbonic acid. Similar air-volcanoes are described by Pallas as occurring in the Crimea, particularly in the island of Taman. In the year 1794, one of these burst with a noise like that of thunder, and flame and smoke rushed from it to the height of more than three hundred feet. Great masses of dried mud were projected from it to great distances, and it vomited forth currents of *a bituminous mud or slime*, to the amount of one hundred thousand cubic fathoms. Humboldt describes air-volcanoes which he saw in the middle of an elevated plain, in the province of Carthagena in South America. There were twenty small cones, having an eleva ion of from twenty-one to twenty-seven feet in height, and formed of bluish coloured clay. Their summits were hollow or crater-like, filled with water, from the surface of which air arose, and burst with an explosion, and often threw out mud. In the island of Trinidad, and also in Java, there are considerable air or mud volcanoes.

6. *Volcanic Rocks.*

These are the mineral substances formed or thrown out by true volcanoes when in a state of activity. The following are the most characteristic of these substances. 1. Lava; 2. Tuffa; 3. Volcanic ashes; 4. Volcanic glass.

1. *Lava.*—Many different kinds of lava are enumerated by geologists, and of which a particular account will be given in the *article* Volcano. For our present view it will be sufficient to arrange them under the following heads, viz. compact, vesicular, slaggy, and spumous.

a. Compact Lava.—Colour grey; massive, and sometimes in columnar distinct concretions. Lustre glimmering. Fracture uneven or splintery. Opaque. Semihard, approaching to hard. Brittle and easily frangible. Feels dry and rough. Sp. gr. = 2.80.

It always occurs in the form of streams, (coulè) and generally forms the middle part of the stream.

b. Vesicular Lava.—Colours grey, black, and brown. Structure vesicular. Generally occurs in the upper, and also on the under sides of streams of lava, when they have run over moist ground.

c. Slaggy Lava.—Colour black or brown, and has a completely slaggy aspect. It occupies the uppermost part of lava streams.

d. Spumaceous Lava.—Colour red or brown, and so very vesicular that it sometimes will float in water. Like slaggy lava, it always occurs on the surface of streams.

2. *Tuffa.*—Is a conglomerated volcanic rock, with an earthy basis, including masses of different kinds of lava, volcanic glass, &c.

3. *Volcanic Ashes.*—These are the loose powdery earthy matters thrown out when volcanoes are in a state of activity.

4. *Volcanic Glass.*—Certain varieties (if not all) of obsidian, described at page 476, are to be considered as volcanic glasses. These are lavas which have been in a state of perfect fusion.

*Veins.

Veins are tabular-shaped masses, that almost always traverse the direcion of the strata, and are composed of materials that either differ more or less from those of the rocks which they intersect, or are of the same nature.

1. External Relations of Veins.

Breadth and Extent of Veins.—Veins vary very much in their magnitude, yet the length and depth always bear a certain proportion to each other, and the breadth to the length and depth. The length and depth are frequently nearly alike, yet the length, on a general view, may be considered as generally somewhat more considerable than the depth.

1. *Breadth or width of Veins.*—In most metalliferous mountains, we find that metalliferous veins extend a few hundred fathoms, and then their width does not exceed two feet.

Veins whose width exceeds a few fathoms are to be considered as uncommon, and those whose width is still greater are to be viewed as exceptions to their general appearance. Humboldt and Friesleben observed veins of calc-spar 140 feet wide, traversing gneiss, in the valley of Lauterbrun, in the Alps of Switzerland. In the island of Arran we observed a vein of porphyry-slate nearly 160 feet broad, traversing sandstone. Born mentions that the Spitaler vein at Shemnitz, in Hungary, is from 14 to 15 fathoms wide. In that part of the Fichtelgebirge that belongs to Bavaria, there is a vein from 42 to 70 feet wide; and in the country of Holberg, near Rotleberode, there is a vein of fluor-spar 35 feet wide. In this country there are veins of pitchstone and greenstone from 10 to 100 feet wide.

The width of veins does not continue the same throughout, but changes considerably, and in some particular veins in a remarkable degree.

2. *Length of Veins.*—Veins differ very much in their length: when their length exceeds 6000 feet, it is to be considered as uncommon. The following may be mentioned as instances of metalliferous veins of uncommon length: The Halsbrückner-spath near Freyberg, which has been traced above four miles and a half; the Mordlauer-flach vein in the Fichtelgebirge, 9000 fathoms; and the Friedensgrubner-flach vein, in the same mountains, 5000 fathoms. Greenstone and pitchstone veins may be traced some miles in this country, as in the island of Arran.

3. *Depth of Veins.*—Few metalliferous veins reach above 200 fathoms below the surface of the mountains in which they are situated, and still fewer continue metalliferous to the depth of 300 fathoms. The following are instances of veins which are metalliferous at the depths mentioned:

	Fathoms.
The Küchschat vein near Freyberg, at .	207
The Junghohebirke vein near Freyberg, at .	158
The Thurmhofer vein, also near Freyberg, at	300
The Samson vein at Andreasberg, at .	250
The Thurmhofer-shaft at Clausthal, at .	312
The deepest shaft on a vein is that at Küttenberg in Bohemia, ...	500

4. That part of a vein which appears at the surface of a mountain is denominated its *outgoing* or *crop*; the directly opposite boundary, its *bottom*; and the lateral extremities, its *ends*. Those planes that bound the vein according to its greatest extent, are termed its *saalbande* or *sides*.

5. Veins continue in general in one direction. It must be understood that we here allude to the general direction. A vein of a mile in extent may stretch north and south in general, but there may be many deviations from that during so long a course.

6. Veins are usually much inclined, always more so than beds; the average inclination of beds is 45°, that of veins much higher. In inclined veins, the upper

side is denominated the *hanging side*, and the lower side the *lying side*.

2. Structure and Internal Relations of Veins.

1. The mass or body of a vein, as we have already observed, is almost always different from that of the rock which it traverses. In some cases, however, we discover resemblances between mountain-rocks and vein-stones. Instances of this kind are porphyry and granite.

2. A principal character of veins is their division into branches. The vein is sometimes divided into many branches by fragments of the *walls* (nebengestein;) or branches shoot out from the sides of the vein in different directions, and either terminate gradually in the rock at a greater or less distance from the vein, or, by winding, again join it.

It is observed that small veins usually terminate in the manner of these lateral branches; but large veins, on the contrary, divide into numerous branches at their ends and bottom, but less frequently at the bottom than at the ends.

3. The mass of the greater number of veins is separated from the rock through which it passes, by a very delicate seam; but in others this is not the case. Sometimes the sides of the vein are coated with a clayey substance, which is denominated *Besteg* by the German miners; but this does not always continue throughout the whole extent of the vein in which it occurs. In other cases the substance of the vein is intimately mixed with its walls.

4. Veins are composed either of earthy masses, as clay or loam, or rocks, as granite, clay-slate, alum-slate, porphyry, sandstone-conglomerate, sandstone, flœtz-limestone, coal, basalt, wacke, greenstone, pitchstone, porphyry-slate, or ores of different kinds. There is scarcely any species of ore that does not occur in veins.

5. Some veins are composed of but comparatively few minerals, and these are massive and intimately aggregated together; others are composed of a greater variety of minerals, but which show little regularity in their structure; and lastly, veins frequently occur, having a regular structure, where the different materials are arranged in layers parallel among themselves and to the walls of the vein; and these throw great light on the origin of veins, and on the formation of the minerals they contain.

When veins are composed of different layers, or are stratified, the same succession of layers is to be observed from both sides towards the middle. Each succeeding layer rests on the preceding, in such a manner that the crystals of the second layer are always impressed by those of the first. A beautiful example of the venigenous bedded structure occurs in the vein Hulfe-Gottes, at Gersdorf in Saxony. This vein is from six to nine feet wide, and is composed of parallel layers, which sometimes amount to forty in number. These layers are composed alternately of calc-spar, fluor-spar, lead-glance, grey copper-ore with fluor-spar, heavy-spar, and a very small portion of quartz. Similar appearances occur at Leadhills, and in many other mining districts.

In veins of this kind, in particular, we frequently meet with openings or unfilled spaces, which are generally situated towards the middle of the vein, and are by miners denominated *Druses*. They have usually a longish shape, and are always parallel with the vein. They have various contractions and widenings. They vary much in size, being from a few inches to several fathoms in magnitude. Their surface is covered with crystals, which are usually of the same minerals as those that form the massive part of the vein. Thus, the druses in veins composed of quartz, are lined with quartz-crystals; those in veins of brown-spar, with brown-spar crystals. When druses are lined with a variety of crystallizations of different minerals, we observe that the one series is laid on the other in a determinate order; the oldest part of the formation being that on which all the other crystals rest; the newest, that which covers all the others. Druses are sometimes filled with water; and when they are of great size, the quantity of water they contain is so considerable, as to endanger the lives of miners when they are cut into. It is also observed, that druses occur most abundantly, and of greatest size, in the upper part of veins, but become gradually smaller, and less numerous, in the deeper parts.

Veins composed of mountain-rocks sometimes present a stratified appearance. There are many interesting examples of this fact in the island of Arran. In that uncommonly interesting spot, wacke and greenstone occur in layers in the same vein. In other cases, veins are composed of layers of greenstone, porphyry-slate, and pitchstone. Other kinds of stratified veins occur in Arran and other parts of Scotland, which we shall take another opportunity of describing particularly.

6. Besides the drusy cavities, there sometimes occur very considerable open spaces in veins, that reach from the one side to the other, or from the hanging to the lying side.

7. When we attend to the masses of which veins are composed at different depths, we observe that they approach nearer and nearer to the centre, towards the lower part of the vein, but expand or recede from it in the upper part. Thus, those layers, which in the upper part of the vein are near to its sides, are at a considerable distance from them lower down, and, still deeper, approach nearer to the middle of the vein.

8. The appearances produced by the meeting, and intersecting of veins, are highly curious and important.

a. When a number of veins, that do not intersect one another, occur in the same district, it is observed that they have usually the same direction and constituent parts; thus intimating, that all of them are of the same general formation. When different venigenous depositions occur in the same district, then the direction of the veins of these different depositions is various, and they are arranged in such a manner, that each particular formation has a certain direction.

b. Veins running in different directions, either cross, or simply meet one another. When they cross, that which is crossed or intersected is said to be the *oldest*, and that which crosses or intersects, the *newest*, an opinion, the accuracy of which may be questioned.

c. Veins sometimes cross each other, without causing any change of direction; but more frequently we find the direction considerably changed.

d. When veins meet under an acute angle, the newer frequently traverses the older; runs parallel with it to a considerable extent, on its lower side, and then again diverges under the same angle it crossed it; sometimes the newer vein does not fully traverse the older, but changes its direction in the middle of the older vein; runs through the body of the vein; and after a longer or shorter course, again diverges at the same angle it entered. Sometimes the newer vein does not even traverse the older; only meets it; then runs parallel with it; again diverges; and this is sometimes frequently repeated in the course of the vein.

Sometimes newer veins do not ever run parallel with the older, but fairly terminate in them; and this takes place usually on the hanging or upper side.

9. In the same veins, we sometimes meet with two or three different formations. Thus, in some Saxon metalliferous veins, we find the lowest formation to be lead-glance; immediately above it, a formation of native silver; and the uppermost sparry-ironstone. In France, there are veins, whose lowest formation is copper-ores; immediately above it, a formation of silver-ore; and the uppermost is a formation of iron-ore. Many more examples of the same kind might be mentioned.

10. Great metalliferous veins usually run parallel with the general direction of great valleys.

11. Veins also occur more frequently in flat hilly country, than in steep mountainous country, and generally on the ridges of the hills. Beds, on the contrary, are equally, if not more abundant, in steep mountainous country.

12. Sometimes the strata or beds, traversed by veins, are merely separated; so that the strata or beds on opposite sides of the vein correspond. In other cases, there is a dislocation. or what miners call *a shift* of the strata, that is, the similar strata or beds on opposite sides of the vein do not correspond, but are depressed or sunk generally on the hanging or upper side of the vein. The degree of depression or dislocation usually corresponds to the magnitude of the vein.

13. The walls of veins are frequently more or less altered; and this alteration is caused either by an intermixture of the materials of the vein with that of the wall, or by a decomposition of the wall, owing to the agency of percolating water, or the substances of which the vein is composed.

Mode of formation.—Veins are either of simultaneous formation with the rock which they traverse, as in granite, metalliferous veins, &c. or are rents that have been filled up from above with the mineral matter they now contain, as in those veins that contain true fragments.

The various economical relations of veins will be discussed in the article Vein.

*** Age of Metals.

Age of Metals.—It appears from the details already given in our account of mountain-rocks,

1st, That metals differ very much as to the period of their formation

2d, That the variety and quantity of metalliferous substances decrease in general from the primitive to the alluvial period of the earth's formation.

3d, That molybdena, titanium, tin, scheele, cerium, tantalum, uran, chrome, and bismuth, are metals of the oldest primitive formation, and that only feeble traces of them are to be observed in newer periods.

4th, That although arsenic, cobalt, nickel, silver, and copper occur in old primitive mountains, they also extend to newer mountains.

5th, That gold, tellurium, antimony, and manganese, are metals of a middle age, occurring in the newer primitive, the transition, and the oldest secondary-rocks.

6th, That lead, zinc, and mercury, are of later date, when compared with those metals we have already mentioned, because they occur in greatest quantity in the newer or secondary formations.

7th, That iron is found in every rock, from the oldest granite to the newest alluvial deposit; hence is universally distributed, and is therefore a production of every period.

8th, That the more crystalline ores abound in the primitive mountains, but continue decreasing in quantity and variety from the primitive rocks to the newest alluvial deposits.

*** Theory of the Formation of the Earth.

This curious but very extensive subject cannot be discussed in the present article, but will be considered in all its bearings, and in connection with such new facts and views as may occur to travellers and geologists, or may result from our own investigations, under the article Theory of the Earth.

Part II. ORYCTOGNOSY.

This branch of mineralogy, as already explained, makes us acquainted with all the properties and relations of simple minerals. In treating this subject, we shall consider it in the following order:

1. Describe the character of simple minerals.
2. Explain the system of arrangement.
3. Describe the different species according to their external characters and chemical composition; and trace their geognostical and geographical distributions; and, lastly, explain their various uses.

1. *Characters of Simple Minerals.*

The characters of minerals are of different kinds, viz. *External*, *Chemical*, *Physical*, *Geognostical*, and *Geographical.*

1. *External Characters*,—are those which we discover by means of our senses, in the aggregation of minerals, and which have no reference to their relation to other bodies, or to chemical investigations.

2. *Chemical Characters*,—are those which are afforded by the complete analysis of the mineral, by trials with the various re-agents, the blowpipe, and the pyrometer.

3. *Physical Characters*,—are those physical phenomena which are exhibited by the mutual action of minerals and other bodies; such are the magnetic and electric properties exhibited by some minerals.

4. *Geognostical Characters*,—are those derived from various geognostic relations of minerals.

5. *Geographical Characters*,—are derived from the geographical distribution of minerals.

We shall first consider the external characters, and then the others, in the order already mentioned.

External Characters of Minerals.

The external characters of minerals are either *generic* or *specific*. The generic characters are certain properties of minerals used as characters, without any reference to their differences, as colour, lustre, or weight. The differences among these properties form the specific characters, as adamantine lustre, and glassy or vitreous lustre. The generic characters are divided into *general* and *particular*. Under the first, are comprehended those that occur in all minerals, whether solid, friable, or fluid: under the second, those which occur only in particular classes of minerals. In the following tabular view, the external characters are arranged nearly in a natural succession, and in the order in which they are employed in the descriptions of minerals.

A Tabular View of the Generic external characters of Minerals.

GENERAL GENERIC EXTERNAL CHARACTERS.

1. Colour.
2. The Cohesion of the Particles, according to which minerals are distinguished into

Solid, Friable, Fluid.

		Particular generic characters of Solid minerals.	Particular generic characters of Friable minerals.	Particular generic characters of Fluid minerals.
Characters for the sight.	External aspect.	External shape.	External shape.	
		External surface.		
		External lustre.		The lustre.
	Aspect of the fracture.	Lustre of the fracture.	The lustre.	
		The fracture.	Aspect of the particles.	
		Shape of the fragments.		
Characters for the sight.	Aspect of the distinct concretions.	Shape of the distinct concretions.		
		Surface of the distinct concretions.		
		Lustre of the distinct concretions.		Transparency.
	General aspect.	The transparency.		
		The streak.	The soiling.	Fluidity.
		The soiling.		
Characters for touch.		The hardness.		
		The tenacity.		
		The frangibility.	The friability.	
		The flexibility.		
		The adhesion to the tongue.		
For the hearing.		The sound.		

Remaining general generic external characters.

For the touch.
3. The Unctuosity.
4. The Coldness.
5. The Weight.

For the smell. 6. The Smell.

For the taste. 7. The Taste.

Colours of Minerals.

1. *Colours.*—We begin our description of the external characters of minerals with that of colour, as it is the character which first particularly strikes the eye. It exhibits very great variety, and hence its determination is often attended with considerable difficulty. Although it is an important and useful character, it was but ill understood before the time of Werner, and it is even at present, by some mineralogists, considered as of little or no value. The older mineralogists had no very accurate nomenclature of colours, and rarely gave any definition of them; hence it was, that this character, in their systems, did not afford satisfactory descriptions. Some modern mineralogists, particularly those of the French School, use, in their descriptions, only single, and often unconnected varieties of colour, which is an erroneous practice; because in describing species we ought to enumerate all the varieties they exhibit, and in a natural order, so that we may obtain a distinct conception of the arrangement of these varieties into groups or suites that characterise the species. Werner was early aware of the utility of this character, and, by a careful study of all its appearances and varieties, was enabled to form a system of colours for the discrimination of minerals, in which he established a certain number of fixed or standard colours, to which all the others could be referred, defined the varieties, and arranged them according to their resemblance to these standard colours, and placed them in such manner, that the whole colours in the system formed a connected series.

In establishing the fixed or standard colours, he thought he could not do better than adopt those as simple colours, which are considered as such in common life; of these he enumerates eight, which he denominates *chief* or *principal* colours; they are *white*, *grey*, *black*, *blue*, *green*, *yellow*, *red*, and *brown*. Although several of these colours are physically compound, yet, for the purposes of the oryctognost, it is convenient to consider them as simple.

Werner remarks, "I could not here enter into an adoption of the seven colours into which the solar ray is divided by the prism, as principal colours, nor into the distinction of the colours accordingly as they are either simple or compound; nor could I omit white and black, the former being considered as a combination of all colours, and the latter as the mere privation of light or colour; for these are distinctions that pertain to the theory of colours among natural philosophers, and cannot be well applied in common life, in which black is ranked among the colours as well as white and yellow; and green, which is mixed, considered as a principal colour, as well as red, which is simple.

"In the adoption of the principal colours enumerated above, I am countenanced by Dr. Schœffer, who has exhibited them, with the exception of the grey, in his sketch of a general association of colour, Regensburg, 1769. I am, however, justified in adding the grey colour, by observing, that it occurs very frequently in the mineral kingdom; that the attempt to bring it under any one of the other colours would be attended with many difficulties, and that, if we have respect to denominations, it is considered in common life as actually differing from the others." Werner's *External Characters*, p 38, 39.

Each of the principal colours contains one which is considered pure or unmixed with any other, and which is called the *characteristic colour*: thus, snow-white is the characteristic colour of white; ash-grey, of grey; velvet-black, of black; Berlin-blue, of blue; emerald-green, of green; lemon-yellow, of yellow; carmine-red, of red; and chesnut-brown, of brown.

Werner having thus established eight characteristic colours, he next defined and arranged the most striking subordinate varieties.

The definitions were obtained principally by occular examination, which enables us speedily to detect the different colours of which the varieties are composed. In detailing the results of this kind of *ocular analysis*, if we may use the expression, the predominant component parts are mentioned first, and the others in the order of their quantity. Thus apple-green is found to be a compound colour, and we discover, by comparing it with emerald-green, that it is principally composed of that colour and another, which is greyish-white: we therefore define apple-green to be a colour composed of emerald-green and a small portion of greyish-white. The method he followed in arranging the varieties is simple and elegant. He placed together all those varieties which contained the same principal colours in a preponderating quantity, and he arranged them in such a manner, that the transition of the one variety into the other, and of the principal colour into the neighbouring ones, was preserved. To illustrate this by an example: Suppose we have a variety of colour which we wish to refer to its characteristic colour, and also to the variety under which it should be arranged. We first compare it with the principal colours, to discover to which of them it belongs, which in this instance we find to be green. The next step is to discover to which of the varieties of green in the system it can be referred. If, on comparing it with emerald-green, it appears to the eye to be mixed with another colour, we must, by comparison, endeavour to discover what this colour is; if it prove to be *greyish-white*, we immediately refer the variety to *apple-green*; if, in place of *greyish-white*, it is intermixed with *lemon-yellow*, we must consider it *grass-green*; but if it contains neither greyish-white nor lemon-yellow, but a considerable portion of *black*, it forms *blackish-green*. Thus, by mere ocular inspection, any person accustomed to discriminate colours correctly, can ascertain and analyse the different varieties of colour that occur in the mineral kingdom.

The transition of the principal colours and their varieties into each other, he represents by placing the characteristic colours in the middle of a series of which all the members are connected together by transition, and whose extreme links connect them with the preceding and following principal colours. Thus, emerald green is placed in the middle of a series, the members of which pass, on the one hand, by increase of the proportion of blue into the next colour-suite, the blue; on the other hand, by the increase of yellow into yellow, siskin-green forming the connecting link with yellow, and verdigris green with blue.

Names of the Colours.

The names of the colours are derived, 1st, From certain bodies in which they most commonly occur, as milk-white, siskin-green, liver-brown; 2d, From metallic substances, as silver-white, iron-black, and gold-yellow; 3d, From names used by painters, as indigo-blue, verdigris green, and azure-blue; 4th From that colour in the composition which is next in quantity to the principal colour, as bluish-grey, yellowish-brown, &c.; and, 5th, From the names of persons, as Isabella-yellow, now called cream-yellow.

The principal colours are divided into two series, the one comprehending what Werner terms *bright colours*, the other *dead colours*; red, green, blue, and yellow, belong to the first; and white, grey, black, and brown, to the second. They may also be divided into *common colours*, as emerald-green, &c.; and into *metallic colours*, as gold-yellow, &c. The metallic colours are the most important as characters in describing minerals.

Arrangement of the colours.—The different characteristic colours and their varieties pass into each other, forming suites of greater or less extent, in which the colours either differ more and more from the first member of the series, as they approach the extremity, thus forming *straight series*, or, after reaching a certain point of greatest difference from the first colour, again gradually approach, and at length pass into it; thus forming *circular series*. In this way the eight principal colours pass into each other in the order in which we have already enumerated them, and thus form a straight series. The blue colour, however, after it has passed through green and yellow into red, passes from this latter colour by several intermediate varieties again into blue, thus forming a circular series or group.

In the system of colours, we do not introduce these various subordinate transitions and series, but simply arrange all the colours as they pass into each other, beginning with the white, and ending with the brown. The varieties of most of the different principal colours are so arranged, that their characteristic colour is placed in the middle of the series, and all those varieties that incline to the preceding principal colour are placed immediately after it; while those that incline to the next or following principal colour immediately precede it. This, however, is not the case with the white and grey colours; therefore the characteristic colours in those series do not stand in the middle; on the contrary, in the white it is placed at the beginning, and in the grey at the end.

I. *Definitions of the different Varieties of Colour.*

A. White.

This is the lightest of all the colours; hence the slightest intermixture of other colours becomes perceptible. The white colour occurs principally in earthy and saline minerals, seldom in metalliferous minerals, and very rarely amongst inflammable minerals. The following are the varieties of this colour:

a. *Snow-white* is the purest white colour, being free of all intermixture, and is the only colour of this suite which has no grey mixed with it. It resembles new-fallen snow. As examples of it, we may mention Carrara marble.

b. *Reddish-white* is composed of snow white, with a very minute portion of crimson-red and ash-grey. It passes into flesh-red. Examples, porcelain earth and rose quartz.

c. *Yellowish-white* is composed of snow-white, with very little lemon-yellow and ash-grey. It passes on the one side into yellowish-grey, on the other into straw-yellow. Examples, chalk, limestone, and semi-opal.

d. *Silver-white* is the colour of native silver, and is distinguished from the preceding by its metallic lustre. Examples, arsenical pyrites and native silver.

e. Greyish-white is snow-white mixed with a little ash-grey. Examples, quartz and limestone.

f. Greenish-white is snow-white mixed with a very little emerald-green and ash-grey. It passes into apple-green. Examples, amianthus, foliated limestone, and amethyst.

g. Milk-white is snow-white mixed with a little Berlin-blue and ash-grey. It passes into smalt-blue. The colour of skimmed milk. Examples, calcedony and common opal.

h. Tin-white differs from the preceding colour principally in containing a little more grey, and having the metallic lustre. It passes into pale lead-grey. Examples, native antimony and native mercury.

B. Grey.

This, which is one of the palest colours, is a compound of white and black, so that it forms the link by which these two colours are connected together, and is therefore placed between them. It occurs very frequently in the mineral kingdom. The following are its varieties.

a. Lead-grey is composed of light ash-grey with a small portion of blue, and possesses metallic lustre. It contains the following subordinate varieties.

α. *Whitish lead-grey.* It is a very light lead-grey colour, into the composition of which a considerable portion of white enters, and nearly approaches to tin-white. Examples, native arsenic on the fresh fracture.

β. *Common lead-grey.* It is the purest lead grey, with a slight intermixture of yellow. Examples, common grey antimony.

γ. *Fresh lead-grey.* It contains rather more blue than the preceding variety, with a slight tint of red, so that it has what is called a fresh or burning aspect. Examples, galena or lead-glance, and molybdena.

δ. *Blackish lead-grey.* Is common lead-grey mixed with a little black. Examples, silver-glance or sulphuretted silver, and copper-glance or vitreous copper.

b. Bluish-grey is ash-grey mixed with a little blue, or is lead-grey without metallic lustre. Examples, hornstone and limestone.

c. Pearl-grey is pale bluish-grey intermixed with a little red. It passes into lavender-blue. Examples, quartz, porcelain jasper, crystallized hornstone, and a very pale variety of pearl.

d. Smoke-grey or *brownish-grey*, is dark bluish-grey mixed with a little brown. Examples, flint, and some varieties of fluor-spar.

e. Greenish-grey is ash-grey mixed with a little emerald-green, and has sometimes a faint trace of yellow. It passes into mountain-green. Examples, clay-slate, whet-slate, potstone, sometimes mica, prehnite, and cat's-eye.

f. Yellowish-grey is ash-grey mixed with lemon-yellow and a minute trace of brown. It sometimes passes into cream-yellow and wood-brown. Examples, calcedony and mica.

g. Ash-grey is the characteristic colour. It is a compound of yellowish-white and brownish-black. It is the colour of wood-ashes. It passes on the one hand into greyish-black, on the other into greyish-white, as also into greenish, greyish, and smoke-grey. It seldom occurs pure in the mineral kingdom. Examples, quartz, flint, mica, and zoisite.

h. Steel-grey is dark ash-grey with metallic lustre. It is the colour of newly broken steel. Examples, grey copper and native platina.

C. Black.

It presents fewer varieties than any of the other colours, owing probably to the intermixture of lighter colours not being observable in it. The discrimination of its varieties is attended with considerable difficulty, and can only be satisfactorily accomplished after much practice. The following are its varieties:

a. Greyish-black is velvet-black mixed with ash-grey. It passes into ash-grey. Is very distinct in basalt.

b. Iron-black is principally distinguished from the preceding variety by its being rather darker, and possessing a metallic lustre. It passes into steel-grey. Examples, magnetic iron-ore and iron-mica.

c. Velvet-black is the characteristic colour of this series. It is the colour of black velvet. Example, obsidian.

d. Pitch-black, or *brownish-black*, is velvet-black mixed with a little yellowish-brown. It passes into blackish-brown. Example, earthy cobalt ochre and mica.

e. Greenish-black, or *raven-black*, is velvet-black mixed with a little greenish-grey. It passes into blackish-green. Example, hornblende.

f. Bluish-black is velvet-black mixed with a little blue. It passes into blackish-blue, and appears sometimes to contain a slight trace of red. Example, black earthy cobalt-ochre.

D. Blue.

The characteristic colour, which is Berlin-blue, is placed in the middle of the series, and all those varieties that contain red in their composition, on the one side, and those containing green, on the other. It is rarer among minerals than the preceding; blackish-blue connects it with black, sky-blue with green; and it is connected with red by violet-blue and azure-blue. The following are its varieties.

a. Blackish-blue is Berlin-blue mixed with much black and a trace of red. It passes, on the one side, into bluish-black, on the other, into azure-blue. Example, blue-copper, the dark varieties.

b. Azure-blue is Berlin-blue mixed with a little red. It is a burning colour. Examples, blue copper, and azure-stone.

c. Violet-blue is Berlin-blue mixed with much red and very little black. It borders on columbine-red. It is the tint of colour we observe in the violet when it is about to blow. It is the most frequent of the blue colours. Examples, Amethyst and fluor-spar.

d. Lavender-blue is violet-blue, intermixed with a small portion of grey. It is intermediate between pearl-grey and violet-blue. Examples, Lithomarge and porcelain-jasper.

e. Plum-blue is Berlin-blue, with more red than in violet-blue, and a small portion of brown and black. It passes into cherry-red and broccoli-brown. Example, Spinel.

f. Berlin-blue is the purest or characteristic colour of the series. Example, Sapphire, rock-salt and kyanite.

g. Smalt-blue is Berlin-blue with much white, and a trace of green. It passes into milk-white. It occurs in pale-coloured smalt, named eschel, also in earthy-blue iron, earthy blue copper, and in some varieties of gypsum.

h. Duck-blue is a dark blue colour, composed of blue, much green, and a little black. Frequently in ceylanite, and in a rare variety of indurated talc.

i. Indigo-blue, a deep blue colour, composed of blue, with a considerable portion of black and a little green. Example, earthy blue iron of Eckardsberg in Thuringia.

k. Sky-blue is a pale blue colour, composed of blue, green, and a little white. It forms the link which connects the blue series with the green. It is named mountain-blue by painters. It is the colour of a clear sky, and hence its name. It occurs but rarely in the mineral kingdom. Example, Lenticular copper.

E. Green.

The varieties of this colour naturally fall into two principal suites; in the one of which the blue colour prevails; in the other the yellow; and between the two is placed the pure or characteristic colour, the emerald-green. Although it is not a common colour in the mineral kingdom, yet it is met with more frequently than the blue. In earthy minerals, the green colours are generally owing to oxide of iron; in a few cases to the oxide of chrome; in others to oxide of copper; and in a very few to oxide of nickel.

The following are the varieties of this colour.

a. Verdigris-green is emerald green mixed with much Berlin-blue, and a little white. It is the link which connects the green and blue colours together. Examples, Copper-green and green Siberian felspar.

b. Celandine-green is verdigris-green mixed with ash-grey. Examples, Green earth, Siberian and Brazilian beryl.

c. Mountain-green is emerald-green, mixed with much blue, and a little yellowish-grey; or verdigris-green with yellowish-grey. It passes into greenish-grey. Examples, Beryl, aqua marine topaz, glassy actynolite, common garnet, and hornstone.

d. Leek-green is emerald green, with bluish-grey and a little brown. It is the sap-green of painters. In this colour the blue and yellow colours are in equal proportions. Examples, Nephrite, common actynolite, and prase.

e. Emerald-green. The characteristic or pure unmixed green. All the preceding green colours are more or less mixed with blue, and at length pass into it; but the following part of the green series, by the increasing proportion of yellow, at length passes into yellow. Examples, Emerald, fibrous malachite, copper-mica, and sometimes also fluor-spar.

f. Apple-green is emerald-green mixed with a little greyish-white. It passes into greenish white. Examples, Nickel ochre and chrysoprase.

g. Grass-green is emerald green mixed with a little lemon-yellow. The colour of fresh newly sprung grass. Example, Uranite.

h. Blackish-green is pistachio-green mixed with a considerable portion of black. It passes into greenish-black. Examples, Precious serpentine and augite.

i. Pistachio-green is emerald-green mixed with more yellow than in grass-green, and a small portion of brown. Examples, Chrysolite, and epidote or pistacite.

k. Asparagus-green is pistachio-green mixed with a little greyish white; or emerald-green mixed with yellow and a little brown. It passes into liver-brown. Examples, Garnet, olivenite and beryl.

l. Olive-green is grass-green mixed with much brown and a little grey. It passes into liver brown. Examples, Common garnet, olivenite, pitchstone, and epidote or pistacite.

m. Oil-green is emerald-green mixed with yellow, brown, and grey; or pistachio-green, with much yellow and light ash-grey. It is the colour of fresh vegetable oil. Examples, Fuller's-earth, beryl and pitchstone.

n. Siskin-green is emerald-green mixed with much lemon-yellow and a little white. It makes the transition to the yellow colour. Examples, Uran-mica, green lead-spar and steatite.

F. Yellow.

Among the varieties of this species of colour, there are three possessing metallic lustre, viz. brass-yellow, gold-yellow, and bronze-yellow. The characteristic colour, which is lemon-yellow, is placed in the middle of the series; the colours which precede it are greenish-yellow, and those which follow it are reddish-yellow. The one side of the series, by the increase of the green, passes by sulphur yellow into green; the other, by the increase of red, passes, by means of orange-yellow, into red. It is a frequent colour in the mineral kingdom. The following are its varieties.

a. Sulphur-yellow is lemon-yellow mixed with much emerald green and white. It is the colour of native sulphur. Example, Native sulphur.

b. Brass-yellow differs from the preceding colour principally in having a metallic lustre; it contains a small portion of grey. Example, Copper-pyrites.

c. Straw-yellow is sulphur-yellow mixed with much greyish white. It passes into a yellowish-white and yellowish-grey. Example, Calamine, serpentine and yellow cobalt-ochre.

d. Bronze yellow is brass-yellow mixed with a little steel-grey, and a minute portion of reddish brown. The colour of bell-metal. Example, Iron-pyrites.

e. Wax yellow is lemon-yellow mixed with reddish-brown, and a little ash-grey; or it may be considered as honey-yellow with greyish white. It is the colour of pure unbleached wax. Examples, Opal and yellow lead-spar.

f. Honey-yellow is sulphur-yellow mixed with chestnut brown. It passes into yellowish brown. Examples, Fluor-spar and beryl.

g. Lemon-yellow is the pure unmixed colour. It is the colour of ripe lemons. Examples, Yellow orpiment.

h. Gold-yellow is the preceding colour with metallic lustre. Example, Native gold.

i. Ochre-yellow is lemon-yellow mixed with a considerable quantity of light chestnut brown. It passes into yellowish brown. It is a very common colour among minerals. Examples, Yellow earth and jasper.

k. Wine-yellow is lemon-yellow mixed with a small portion of red and greyish-white. The colour of Saxon home-made wine. Examples, Saxon and Brazilian topaz.

l. Cream-yellow or *Isabella-yellow.* It contains more red and grey than the wine-yellow, and also a little brown. It passes into flesh-red. Examples, Bole from Strigau, and compact limestone.

m. Orange-yellow is lemon-yellow with carmine red. It is the colour of the ripe orange. Examples, Streak of red-orpiment, and uran-ochre.

G. Red.

It exhibits more varieties than the other colours, and is very common in the mineral kingdom. The characteristic colour is carmine-red; all the others incline either to yellow or blue: hence there are two principal suites; the first of which contains yellowish-red colours; the second bluish-red colours. The red colours are principally owing to oxides of iron, manganese and cobalt, and combinations of metals with sulphur and arsenic. The following are the varieties.

a. Aurora or *morning red* is carmine-red mixed with much lemon yellow. It passes into orange-yellow. Example, Red orpiment.

b. Hyacinth-red is carmine-red mixed with lemon-yellow and a minute portion of brown; or aurora-red mixed with a minute portion of brown. It passes into brown. Examples, Hyacinth and tile-ore.

c. Tile red is hyacinth-red, mixed with greyish-white. It is the colour of tiles or bricks. Examples, Porcelain-jasper and zeolite.

d. Scarlet red is carmine-red mixed with a very little lemon-yellow. It is a well-known colour of much intensity. Example, Light-red cinnabar from Wolfstein.

e. Blood-red is scarlet-red mixed with a small portion of black. Examples, Pyrope and jasper.

f. Flesh-red is blood-red mixed with greyish-white. Examples, Felspar, calcareous spar, and straight lamellar heavy spar.

g. Copper-red. It scarcely differs from the preceding variety, but in possessing a metallic lustre. Examples, Native copper and copper-nickel.

h. Carmine-red is the characteristic colour. Example, Spinel particularly in thin splinters.

i. Cochineal-red is carmine-red mixed with bluish-grey. Examples, Dark-red cinnabar and red copper-ore.

k. Crimson-red is carmine-red mixed with a considerable portion of blue. Example, Oriental ruby.

l. Columbine-red is carmine-red, with more blue than the preceding variety, and, what is characteristic for this colour, a little black. Example, Precious garnet.

m. Rose-red is cochineal red mixed with white. It passes into reddish-white. Examples, Red manganese and quartz.

n. Peach blossom-red is crimson-red mixed with white. Example, Red cobalt-ochre.

o. Cherry-red is crimson red mixed with a considerable portion of brownish-black. Examples, Spinel, red antimony, add precious garnet.

p. Brownish red is blood-red mixed with brown. It passes into brown. Example, Clay ironstone.

H. Brown.

This, after black, is the darkest colour in the system. The whole species or suite can be distinguished into those which have red, and those which have yellow mixed; between these is placed the fundamental colour, the pure unmixed chestnut-brown, and the last variety, from the quantity of black it contains, connects the brown series with the black. Varieties of this colour occur frequently in the mineral kingdom, particularly among the ores of iron, and the inflammable minerals.

a Reddish-brown is chestnut-brown mixed with a little red and yellow; or chestnut-brown with a small portion of aurora-red. It passes into brownish-red. Example, brown blende from the Hartz, and zircon.

b. Clove-brown is chestnut-brown, mixed with cochineal-red, and a little black. It is the colour of the clove. It passes into plum-blue and cherry-red. Examples, rock-crystal, brown hematite, and axinite.

c. Hair-brown is clove-brown mixed with ash-grey. Examples, Cornish tin-ore, wood opal, and brown iron-ore.

d. Broccoli-brown is chestnut-brown mixed with much blue, and a small portion of green and red. It passes into cherry-red and plum-blue. It is a rare colour. Example, zircon.

e. Chestnut-brown. Pure brown colour. It is a rare colour. Example, jasper.

f. Yellowish-brown is chestnut-brown mixed with a considerable portion of lemon-yellow. It passes into ochre-yellow. It is one of the most common colours in the mineral kingdom. Examples, iron-flint and jasper.

g. Pinchbeck-brown is yellowish brown with metallic lustre. Rather the colour of tarnished pinchbeck. Example, mica.

h. Wood-brown is yellowish-brown mixed with much pale ash-grey. It passes into yellowish-grey. Mountain wood, and bituminous wood.

i. Liver-brown is chestnut-brown mixed with olive-green and ash-grey. It is the colour of boiled, not fresh liver. It passes into olive green. Example, common jasper.

k. Blackish-brown is chestnut-brown mixed with black. It passes into brownish-black. Examples, mineral pitch from Neufchatel, moor-coal, and bituminous wood.*

The immense variety of colours that occur in the mineral kingdom, constitute an almost infinite series, to characterise every individual of which is next to impossible. The colours we have already defined, are a few only of the most prominent features of that great and beautiful series, and serve as points of comparison, and as the boundaries between which every occurring colour lies.

From the small number of colours we have defined, and the great variety that occur in minerals, it is evident that the greater number of occurring colours will not correspond exactly with those defined, but will lie between them. It is this circumstance, in particular, that renders it so difficult to get an acquaintance with colours. To obviate this, in some degree, Werner uses terms which express correctly certain prominent differences which are to be observed between every two colours. Thus, when one colour approaches slightly to another, it is said to *incline* towards it, (es näert sich;) when it stands in the middle between two colours, it is said to be *intermediate*, (es steht in der mitte,) when,

* The most accurate delineations of colours are given in Syme's Wernerian Nomenclature of Colours, published in Edinburgh a few years ago.

on the contrary, it evidently approaches very near to one of the colours, it is said to *fall* or *pass* into it, (es geht über.)

II. *The Delineations or Patterns formed by the Colours.*

The distinctions included under this head depend on the shape which the colour assumes. It is only to be observed in simple minerals. The following are the different kinds enumerated and described by WERNER.

A. *Dotted.* In this variety, dots or small spots are irregularly dispersed over a surface which has a different colour from the spots. It occurs frequently in serpentine, but seldom in other minerals.

B. *Spotted.* If the spots are from a quarter of an inch to an inch in diameter, and the basis or ground still visible, it is said to be spotted. It is either *round* and *regularly spotted*, or *irregularly spotted.* The first occurs in clay-slate; the second in marble.

C. *Clouded.* Here no basis is to be observed; the boundaries of the colours are not sharply marked, and the spots run into each other. It occurs in marble and jasper.

D. *Flamed.* When the spots are long and acuminated, and arranged according to their length, the flamed delineation is formed. It has still a basis. It occurs in striped jasper, marble, &c.

E. *Striped.* Consists of long and generally parallel stripes, that touch each other and fill up the whole mass of the stone, so that it has no ground. It presents two varieties.

a. *Straight striped*, as in striped jasper and variegated clay.

b. *Ring-shaped*, occurs in Egyptian jasper.

F. *Veined.* Consists of a number of more or less delicate veins crossing each other in different directions, so that it is sometimes net-like. We can always distinguish a base or ground. Examples, black marble veined with calcareous spar or quartz, jasper and serpentine.

G. *Dendritic.* Represents a stem with branches, on a ground. Examples, steatite and dendritic calcedony.

H. *Ruiniform.* Resembles ruins of buildings. It occurs in Florentine marble, which is from this circumstance called *landscape marble.*

III. *The Play of the Colours.*

If we look on a mineral which possesses this property, we observe, on turning it slowly, besides its common colours, many others, which are bright, change very rapidly, and are distributed in small spots or patches. A strong light is required, in order to see this appearance distinctly, and it never occurs in opaque or feebly translucent minerals. We observe it in the diamond when cut, and in precious opal.

IV. *The Changeability of the Colours.*

When the surface of a mineral, which we turn in different directions, exhibits, besides its common colours, different bright colours, that do not change so rapidly, are fewer in number, and occur in larger patches than in the play of the colour, it is said to exhibit what is called the changeability of the colours. The changeability of colour is seen only in particular directions, the play of colour in all directions.

We distinguish two kinds of this phenomenon.

A. That which is observed by looking in different positions *on* the mineral, as in Labrador felspar.

B. That observed by looking *through* it, as in the common opal, which shows a milk-white colour when we look on its surface, but when held between the eye and the light is wine-yellow.

V. *The Iridescence.*

When a mineral exhibits the colours of the prism or the rainbow, arranged in parallel, and sometimes variously curved layers, it is said to be iridescent. It is to be observed by

A. Looking *on* the mineral only, as in precious opal, adularia, &c.

B. Both by looking on the mineral and through it, as in calcareous spar, crossed by thin veins, some arragonites, rainbow calcedony, and some amethysts.

VI. *Tarnished Colours.*

A mineral is said to be tarnished, when it shows on its external surface, or on that of the distinct concretions, fixed colours different from those in its interior or fresh fracture.

There are *simple* or *variegated* tarnished colours.

a. *Simple.*

α. *Grey*,—white cobalt.

β. *Black*,—native arsenic.

γ. *Brown*,—magnetic pyrites.

δ. *Reddish*,—native bismuth.

b. *Variegated.*

The variegated or party-coloured, are distinguished according to the intensity of their basis. Of these the following are enumerated in the tabular view.

α. *Pavonine*, or *Peacock-tail tarnish.* This is an assemblage of yellow, green, blue, red, and brown colours, on a yellow ground. The colours are nearly equal in proportion, and are never precisely distinct, but always pass more or less into one another. Example, copper-pyrites.

β. *Iridescent*, or *Rainbow.* In this variety the colours are red, blue, green, and yellow, on a grey ground. It is more beautiful and brighter than the preceding. The radiated grey antimony of Felsobanya in Hungary, and the specular iron-ore, or iron-glance of Elba, are often beautifully iridescent.

γ. *Columbine*, or *pigeon-neck tarnish.* The colours are the same as in the preceding, with this difference, that the tints of colour are paler, and the red predominates. Examples, native bismuth of Schneeberg.

δ. *Tempered-steel tarnish.* It consists of very pale blue, red, green, and very little yellow, on a grey ground. Example, grey cobalt.

VII. *The Permanent Alterations.*

These must not be confounded with the tarnished colours. The tarnish occurs only on the surface; the permanent alteration, on the contrary, proceeds by degrees through the whole mass of the mineral. This change takes place more or less rapidly in different minerals. The colours either become paler, when they are said to *fade*, or they become darker, and pass into other varieties. Thus chrysoprase, rose quartz, and red cobalt-ochre become paler; whereas sky-blue fluor-spar becomes green, pearl-grey corneous silver sometimes changes to brown, and lastly into black, and earthy blue iron changes from white, through different varieties of blue, to indigo-blue.

PARTICULAR GENERIC EXTERNAL CHARACTERS.

I.—PARTICULAR GENERIC EXTERNAL CHARACTERS OF SOLID MINERALS.

Characters for the Sight.

1. The External Aspect.

The External Aspect of a mineral is that outline or contour which it has received from nature. Thus, if we have a piece of lead-glance, as it has been found loose, or imbedded in another mineral, we name the surface which it has received from nature, its Aspect. All those characters which we can discover by the eye, on this outline, are denominated the External Aspect of the mineral. They are of three kinds: 1. The External Shape: 2. The External Surface; and, 3. The External Lustre.

1. *The External Shape,*

Is divided into four classes,

1. Common
2. Particular
3. Regular
4. Extraneous

} External Shape.

All of these classes have their subordinate differences, which we shall now describe; and,

I. *Common External Shape.*

Common External Shapes are those in which there are neither a determinate number of planes meeting under determinate angles, nor any resemblance to known natural or artificial bodies. As they occur more frequently than the other shapes, they are named Common External Shapes.

Six different kinds are enumerated by Werner, which are distinguished according to their relative length, breadth, and thickness, their relative magnitude, and their connections with other minerals. The kinds are *massive*, *disseminated*, *in angular pieces*, *in grains*, *in plates*, and *in membranes*.

A. *Massive*, is that common external shape which is from the size of a hazel-nut to the greatest magnitude, and whose dimensions in length, breadth, and thickness, are nearly alike. It occurs imbedded in other minerals, and it is intermixed with them at their line of junction. Examples, Galena or lead-glance, and copper pyrites.

Many of the varieties of this form are crystallized, although they do not appear so to the eye. This curious fact has been lately well elucidated by Mr. Daniell. He remarks, that if a lump or massive piece of alum, or borax, or of nitre, be immersed in a vessel of water, and left at rest for three or four weeks, the solution will be found to have gone unequally on; the uppermost portion will be found most wasted, and the undermost least; so that the undissolved part of these salts will have assumed a conical form. The lower part of these bodies, after this treatment, will be found embossed over with numerous crystalline forms. These in alum are octahedrons, or figures formed by different sections of the aluminous octahedron. In borax they are fragments of eight-sided prisms, and so on. Mr. Daniell has shewn, in a satisfactory way, that these embossments are not formed by the crystallization of that portion of the salt which has been dissolved; but that they are brought into view by the unequal solution of the lump of salt subjected to the action of the water. Hence it follows, that all these apparently amorphous masses are in reality composed of crystals, though such a structure cannot be distinguished by the eye previous to this natural dissection of it. The same crystalline structure was developed when calcareous-spar, strontian, and witherite, were acted on by vinegar. Bismuth, antimony, and nickel, treated with very dilute nitric acid, likewise exhibited a crystallized structure. From these experiments we may infer, with considerable probability, that the structure of most minerals is in reality crystallized, even when they appear massive; an inference which leads to the highly important conclusion, that, on a general view, a great portion of the crust of the earth is more or less of a crystalline nature.

B. *Disseminated*, is from the size of a hazel-nut until it is scarcely visible, and its dimensions in length, breadth, and thickness are nearly alike. It is imbedded, and is intermixed with the inclosing mineral at the line of junction. It is divided into

a. Coarsely disseminated, which is from the size of a hazel-nut to that of a pea. Examples, Copper-pyrites and brown-spar.

b. Minutely disseminated, from the size of a pea to that of a millet-seed. Example, Tinstone in granular quartz.

c. Finely disseminated, from the size of a millet-seed until it is scarcely visible. Example, Brittle silver glance in brown spar.

C. *In angular pieces.* Minerals having an angular shape, in which the length, breadth, and thickness are nearly alike, which are found loose, or slightly imbedded, and without any intermixture with the inclosing mineral at the line of junction, and from the size of a hazel-nut and upwards, are said to occur in angular pieces. It is distinguished from the massive by its occurring either loose, or not intermixed with the basis at the line of junction. Of this external shape there are two kinds.

a. Sharp cornered, as in quartz and calcedony.

b. Blunt cornered, as in common opal.

D. *In grains.* Minerals having a roundish form, and imbedded or loose, and not much larger than a hazel-nut, are said to occur in grains. This shape is distinguished,

a. With regard to size, into

α. Large, that is, when they are from the size of a hazel-nut to that of a pea. Examples, meadow ore and precious garnet.

β. Coarse, from the size of a pea to that of a hemp-seed. Example, Pyrope.

γ. *Small*, from the size of a hemp-seed to that of a millet-seed. Examples, Precious garnet, Pyrope and iron-sand.

δ. *Fine*, from the size of a millet seed until it becomes nearly undistinguishable. Example, Platina.

The grains are further distinguishable,

b. With regard to the exacter determination of the shape, into

α *Angular grains*, as in iron-sand.

β. *Flattish grains*, as in platina and gold.

γ. *Roundish grains*, as in pyrope and precious garnet.

c. With regard to connection with other minerals.

α In loose grains.

β In imbedded grains.

γ. In superimposed grains.

E. *In plates*. Minerals which occur in external shapes, whose length and breadth are great in comparison of their thickness, in which the thickness is not equal throughout, and is so considerable, as to allow the fracture to be distinguished, are said to occur in plates. The maximum thickness of plates is half an inch. Example, red silver.

F. *In membranes* or *flakes*. This shape is distinguished from the former by its thinness, as it never greatly exceeds the thickness of common paper, and the fracture cannot be seen. Example, iron-pyrites.

II. *Particular External Shape.*

Particular external shapes differ from the common external shapes, in bearing a resemblance to natural or artificial bodies, and in being far more characteristic and varied in their aspect. They are called *particular*, because they are not so common among minerals as the common external shapes. There are four different sets, entitled *longish*, *roundish*, *flat*, and *cavernous*. Each of these sets have their subordinate kinds, which we shall now describe.

A. *Longish Particular External Shapes.*

a. *Dentiform*, adheres by its thick extremity, and becomes gradually thinner, incurvated, and at length terminates in a free point, so that it resembles a canine tooth, whence its name. Its length is from a quarter of an inch to a foot. It is one of the rarer kinds of external shapes, and is peculiar to certain metals. Example, Native silver.

b. *Filiform*, adheres by its thicker extremity, and terminates by an almost imperceptible diminution of thickness, and is usually curved in different directions It is thinner and longer than the dentiform. Example, Native silver.

c. *Capillary*. When the filiform becomes longer and thinner, it forms the capillary. It is generally much entangled, and sometimes the threads are so near each other that it passes into the compact. Example, Native silver.

d. *Reticulated*, is composed of many straight threads, which are sometimes parallel, and sometimes meet each other at right angles, and form a net like shape. The whole is a series of minute crystals, and is distinguished from the capillary by its threads being always straight. Example, Native silver.

e. *Dendritic*. In this external shape we can observe a trunk, branches, and twigs, which are distinguished from each other by their thickness, the trunk being the thickest. Examples, Native copper and brown hematite.

f. *Coralloidal* or *coralliform*. When two or three branches, having rounded or pointed extremities, proceed from one stem, the coralloidal external shape is formed. There are usually many stems together. From its resemblance to coral, it is denominated Coralloidal. The variety of arragonite, called *flos ferri*, is an excellent example of this kind of particular external shape.

g. *Stalactitic*. A mineral is said to possess a stalactitic external shape, when it consists of different straight more or less lengthened rods, which are thickest at their attachment, and become narrower at their free extremity, which is rounded or pointed. Example, calc-sinter.

h. *Cylindrical* consists of long, rounded, straight, imperforated, usually parallel rods, which are attached at both extremities, and are generally thicker at the extremities than the middle. The interstices are either empty, or filled up with another mineral. Examples, galena or lead-glance and brown iron-ore.

i. *Tubiform* consists of long, usually single, perforated tubes, which are somewhat longitudinally knotty. Example. calc-sinter.

k. *Claviform* is the reverse of stalactitic; it is composed of club-shaped parallel rods, which adhere by their thin extremities. Example, compact black hematite.

l. *Fructicose*. This external shape is formed when many branches issue from a common stem and meet together partywise, so that the whole when viewed from above has a fructicose aspect, not unlike the appearance of cauliflower. Examples, calc-sinter and black hematite.

B. *Roundish Particular External Shapes.*

a. *Globular*. Under this are comprehended.

α. *Perfect globular* or *spherical*, as in alum-slate and pisiform iron.

β. *Imperfect globular*, as in calcedony.

γ. *Ovoidal* or *elliptical*. Example, rounded masses of quartz in puddingstone.

δ. *Spheroidal*. When the spherical is compressed the spheroidal is formed. Example, Egyptian jasper.

ε. *Amygdaloidal*. When the ovoidal is compressed in the direction of its length, the amygdaloidal is formed. Examples, zeolite, calcareous-spar and green earth.

b. *Botryoidal* consists of large segments of small balls, which are regularly heaped together, and have many interstices. It resembles grapes, whence its name. Examples, hematite, and calcedony.

c. *Reniform* consists of small segments of large balls, which are so closely set together, that no interstices are formed. Example, calcedony.

d. *Tuberose*. This shape consists of irregular roundish or longish elevations and depressions. Example, flint.

e. *Fused-like* or *liquiform*. It consists of numerous very flat rounded elevations, which are generally depressed in the middle. The whole has a rough and glimmering surface, and resembles the surface of slowly cooled metal. Example, lead-glance.

C. *Flat Particular External Shapes.*

a. *Specular* has on one side, seldom on two opposite sides, a straight smooth shining surface. It occurs in veins. Example, galena or lead-glance.

b. *In leaves.* In this external shape there are thin leaves, which are either irregularly curved, or are straight, and have throughout the same thickness. It is distinguished from the external shape in membranes by the uniformity of its thickness, by its irregular curvatures, its continuity, (the membranous external shape being often interrupted,) and its usual adherence by one extremity, showing that it is a kind of crystalline shoot. It occurs frequently in native gold.

D. *Cavernous Particular External Shapes.*

a. *Cellular.* A mineral is said to be cellular, when it is composed of straight or bent tables, which cross together in such a manner as to form empty spaces or cells. Example, quartz.

b. *Impressed.* That is, when one mineral shows the impression of any particular or regular external shape of another mineral. It borders on the cellular shape, and is formed when a newer mineral is deposited over an older, the form of which it assumes, and retains even after the impressing mineral has been destroyed or removed.

a a. *With impressions of crystals.*

α. *Cubical*, as in quartz or iron-pyrites, from fluor-spar.

β. *Pyramidal*, as in hornstone, originating from calcareous-spar.

γ. *Tabular*, as in quartz, originating from heavy spar.

b b. *With impressions of particular external shapes.*

α. *Conical*, in native arsenic.

β. *Globular*, in silver-glance or sulphuretted silver, from red-silver ore.

γ. *Reniform*, in silver-glance or sulphuretted silver, from red silver-ore.

c. *Perforated*, consists of long vermicular cavities, which occupy but an inconsiderable portion of the mass, and terminate on the surface in small holes. When the holes become very numerous, it passes into spongiform. Example, bog iron-ore.

d. *Corroded.* A fossil is said to be corroded, when it is traversed with numerous hardly perceptible roundish holes. The volume occupied by the holes is nearly equal to that of the basis. It has the appearance of wood which has been gnawed by insects. Examples, quartz, galena or lead-glance, and silver-glance or sulphuretted silver.

e. *Amorphous* is composed of numerous roundish and angular parts that form inequalities, between which there are equally irregular hollows. The whole has the appearance as if a number of small balls and angular pieces were heaped on one another. Examples, silver-glance or sulphuretted silver, and meadow-ore.

f. *Vesicular* When a mineral has distributed through its interior many single, usually round, elliptical, and spheroidal, also amygdaloidal, or irregular-shaped cavities, it is said to be vesicular. The cavities are usually less in volume than the solid part of the mineral, and they are larger than the holes or cavities in the corroded external shape. Examples, wacke and lava.

E. *Entangled Particular External shape.*

a. *Ramose.* It is composed of longish, angular, more or less thick branches, that are bent in different directions, but in which no trunk or common stem is to be observed. It probably originates from the greater magnitude of the vesicles in the vesicular, the vesicles breaking into each other. Examples, meteoric-iron, silver-glance or sulphuretted silver, and native copper.

III. *Regular External Shape or Crystallization.*

Every external shape, whose natural contour or outline is composed of a determinate number of planes, which meet together in a determinate manner, is denominated a crystal.

In describing crystals, we have to consider, *A. Their Genuineness; B. Their Shape; C. Their Magnitude; D. Their Attachment.*

A. The Genuineness of Crystals.

This refers to the division of crystals into *True* and *Supposititious*. The *true* are the forms which the same substance always assumes, and which are peculiar to it; the *supposititious* are those regular figures whose shape does not depend on the substance of which they are composed, but is owing to pre-existing crystals, or crystal-moulds.

Supposititious crystals are formed in two ways:

1. When an imbedded crystal falls out and leaves an empty mould, which is afterwards filled up with fossil matter, a figure or crystal corresponding in shape to the mould is formed. The supposititious crystals formed in this manner are smoother, and have sharper edges and angles than the succeeding kind, and their interior is often hollow and drusy.

2. When a mineral is deposited over a pre-existing crystal, and assumes its figure, the second kind of supposititious crystal is formed. The pre-existing crystal either remains, forming the nucleus, or it disappears when the supposititious crystal is hollow. It differs from the first kind in having generally a rough and drusy surface, blunter edges and angles, and the inner surfaces smooth.

The first kind of supposititious crystal is a cast or filling of the space formerly occupied by true crystals; the second is merely an incrustation of true crystals*.

True and supposititious crystals are distinguished from each other by the following characters:

a. *True crystals,*

α. Are transparent and semitransparent.

β. Their planes are smooth and shining or splendent, or they are regularly streaked.

γ. Their angles and edges are sharp.

δ. Are seldom drusy upon the surface; but when this is the case, it is remarked that all the axes of the small crystals forming the drusy surface are in the same position.

ε. They form particular characteristic suites.

b. *Supposititious crystals.*

α. The planes are never smooth and shining, or

* A third kind of crystal has been particularly pointed out by Breithaupt. He names it the *metamorphosed or changed crystal;* the form is not altered, but the substance is changed by certain processes hitherto but imperfectly known. Thus, cubes of iron pyrites are changed into cubes of brown iron-stone, and crystals of augite, without any change of form, are converted into chlorite, or green earth.—Vide *Ueber die Aechtheit der Krystalle,* von A. Breithaupt, Freiberg, 1815.

regularly streaked; on the contrary, are generally rough and dull.

β. The angles and edges are not so sharp as in true crystals, but are generally somewhat rounded.

γ. They are usually hollow, and their internal surface is drusy.

δ. They are almost always drusy, internally, in those formed by moulding; externally, in those formed by incrustation; and it is remarked, that the small crystals forming the drusy surfaces are disposed irregularly.

ε. They are not, like true crystals, connected by transitions with other crystals of the same species: Thus the octahedral supposititious crystals of quartz, which originate from fluor-spar, do not belong to the suite of quartz.

ζ. Even in their internal structure they are different from true crystals; for they seldom present a fracture inclining to foliated.

η. Single crystals are never all around crystallized.

The following are well known instances of supposititious crystals.

1. Octahedral crystals of quartz, originating from fluor-spar.
2. Cubic crystals of quartz, from fluor-spar.
3. Flint in double three-sided pyramids, from calcareous-spar.
4. Quartz in oblique four-sided tables, from heavy-spar.

B. The Shape of Crystals.

The shape of crystals is determined by the number and form of the planes or faces, and the edges and angles which form the contour or outline*. Amidst the great variety of crystals that occur in the mineral kingdom, there are some simple ones, which are composed of but few planes, that do not vary much in shape; and of others, in which the planes are not only numerous, but present great differences in form. These simple forms are nearly allied to the more complex ones, and gradually pass into them by a change in the shape of their planes. On this circumstance Werner has founded a crystallographic system, remarkable for its simplicity, and the ease with which it enables us to acquire distinct conceptions of the most complicated crystallizations. He considers these simple forms as the basis of the others, and names them *Fundamental figures.* We can distinguish in them one, or at the utmost, two sets of planes, which run in two directions, and enclose the crystal on all sides. The cube is an example of a fundamental figure with one set of planes; the prism, pyramid and table, are examples of fundamental figures with two sets of planes, which are named *lateral* and *terminal planes.* All those crystals in which we observe many different sorts of planes, he considers as changed or altered fundamental figures; and names the other planes, which are generally smaller, and differ from the planes of the fundamental figure in direction, and in being further removed from the centre of the crystal, *Alterating planes.* We have thus, according to this method, to consider, first, *The Fundamental Figures,* and then their *Alterations* or *Modifications.*

I. The Fundamental Figures.

The fundamental figures, as already mentioned, are composed of one or two sorts of planes. In order to discover these planes in the altered fundamental figures, we have only to conceive the planes that lie nearest the centre of the crystal, and which are generally the largest, extended on all sides until they join.

In the fundamental figure are observed and attended to, I. *Its Parts.* II. *Its Varieties or Kinds.* III. *The Differences of each Fundamental Figure in Particular.*

I. *Parts of the Fundamental Figures.*

The fundamental figure is composed of *lateral* and *terminal planes*; of *lateral* and *terminal edges*; and of *solid angles*.

1. *Lateral planes* are the greatest planes that bound the smallest extent. *Terminal planes* are the smallest planes that bound the greatest extent. In the prism they form the *bases*, but in the table they are the smaller planes that surround the two largest planes.
2. *Lateral edges* are formed by the junction of two lateral planes, as in the prism and pyramid; but in the table, where the lateral planes do not meet, the lateral edges are those formed by the meeting of the lateral planes and the terminal planes; or we say, they are the edges of the lateral faces of the table, so that there are eight lateral edges in a four-sided table, &c. *Terminal edges* are formed by the junction of lateral and terminal planes, as in the prism and pyramid; or they are those that surround the terminal planes in the prism or the base of the pyramid: they are also formed by the junction of two terminal planes, as in the table.†
3. *Solid angles.* The point in which three or more planes meet, is called a *solid angle.*

II. *The Varieties or Kinds of the Fundamental Figure.*

Werner admits seven fundamental figures, viz. *icosahedron*, *dodecahedron*, *hexahedron*, *prism*, *pyramid*, *table*, and *lens*

1. *Icosahedron* is a solid having twenty equilateral triangular planes, that meet together under nearly equal obtuse angles; and of twelve solid angles, so that there are always five planes to form an angle. Fig. 1. Plate CCCXCVI. It is rare. Example, Iron-pyrites.
2. *Dodecahedron* has twelve regular pentagonal planes that meet under equal obtuse angles; and of twenty solid angles. Fig. 2. It occurs but seldom. Example, Iron-pyrites.
3. *Hexahedron* is a solid, having six square planes and eight solid angles. It includes the cube, Fig. 3. and the rhomboid, Fig. 4. which is sometimes considered as a double three-sided pyramid, in which the lateral planes of the one are set on the lateral edges of the other. It is very frequent. Example, Calcareous-spar.
4. *Prism* has an indeterminate number of quadrangular lateral planes, terminated by two equal terminal planes, parallel to each other, and having as many sides as the prism has lateral planes, Fig. 5. This is the most frequent of the fundamental figures. Example, Calcareous-spar.
5. *Pyramid* has an indeterminate number of triangular lateral planes converging to a point, and a base possessing as many sides as the figure has lateral planes. Fig. 12. The terminal point is called the *summit* or

* When the faces are very small, they are named *facets*. † The terminal edges in the Table are those that measure its thickness

apex, and the flat part the *base*. It occurs very often. Example, Calcareous-spar.

6. *Table* has two equal and lateral planes, which are very large in comparison of the others, and which are bounded by an indeterminate number of small four-sided terminal planes. Fig. 15. It is but a very short prism. It is proper to observe, that the parts of the table are not denominated as those in the prism, but inversely, the lateral planes of the table corresponding to the terminal planes of the prism, and the terminal planes of the table to the lateral planes of the prism. It does not occur very often. Example, Heavy-spar.
7. *Lens* has two curved faces or planes, Figs. 19. and 20. It occurs but seldom. Example, Sparry-iron.

III. *The differences of each Fundamental Figure in particular.*

Here we have to determine, 1. *The Simplicity.* 2. *Number of Planes.* 3. *Proportional size of the planes to one another.* 4. *Direction of the planes.* 5 *Angles under which the planes meet.* 6. *Plenitude or fulness of the crystals.*

1. *Simplicity.*

With respect to simplicity, the fundamental figures are either *simple* or *double.* This distinction, however, is confined to the pyramid, as the other six kinds of primitive figures occur simple only. Fig. 12. is a simple pyramid; and Fig. 13. a double pyramid.

The simple figure is also distinguished, in regard of its position, into *erect* or *inverted*, according as it adheres by its base or its summit. The inverted has hitherto occurred only in calcareous spar, and is very rare.

In the double figure, we have to attend to the placing of the lateral planes; thus, the lateral planes of the one pyramid are placed either *straight* or *oblique* on the lateral planes of the other pyramid. In Fig. 13. they are placed straight; and in Fig. 14. they are placed obliquely; or the lateral planes of the one pyramid are set either on the lateral edges, as in Fig. 35. or on the lateral planes of the other, as in Fig. 13.

2. *Number of Planes.*

The number of planes in the icosahedron, dodecahedron, hexahedron, and lens, is always determinate, but in the prism, pyramid, and table, is indeterminate. In the prism and pyramid, it is only the lateral planes that vary in number, but in the table it is the terminal planes.

The *prism* occurs with three, four, six, eight, nine, and twelve lateral planes. The trihedral, or three-sided, occurs in schorl and tourmaline. The four-sided, or tetrahedral prism, Fig. 5. occurs very often; we have examples of it in felspar, zeolite, zircon, and heavy-spar. The six-sided, or hexahedral prism, Fig. 8. occurs very often, and is the most common prismatic crystallization; quartz, emerald, beryl, calcareous spar, heavy spar, and actynolite, afford examples of it. The octahedral, or eight-sided prism, is rare; it occurs in augite and topaz. The nine and twelve-sided prisms are merely varieties of the preceding figures; the first is formed by the bevelling of the lateral edges of the trihedral prism, the other by the truncation of the lateral edges of the six-sided prism. Beryl affords an example of the twelve-sided, and tourmaline of the nine-sided prism.

The *pyramid* occurs with three, four, six, and eight sides. The three-sided pyramid, Fig. 9. is either single or double; of the single we have examples in grey copper ore, spinel, copper pyrites, and many other minerals. Examples of the second occur in calcareous spar, as in Fig. 10. The four-sided pyramid is the most common, and is always double, Fig. 11.; when it appears single, the one half is either hid in part, or altogether in the matrix; diamond, zircon, and fluor spar, are examples. The six-sided, or hexahedral pyramid, occurs single, as in Fig. 12. and double, as in Fig. 13. Examples of it occur in sapphire and calcareous spar, red silver, white lead spar, quartz, and amethyst. The eight-sided is always double, and acuminated on both extremities by four planes, as in Fig. 35. Examples of it occur in leucite, garnet, and silver glance, or sulphuretted silver.

The table has four, six, or eight terminal planes. The *three*-sided tables are mere varieties of some of the other figures. The four-sided table, Fig. 15. occurs frequently, as in heavy spar, white antimony, and yellow lead spar. The six-sided table, Fig. 17. occurs still more frequently: we have examples of it in mica, calcareous spar, heavy spar, and native gold. The eight-sided table occurs in heavy spar, and yellow lead spar.

3. *Proportional Size of the Planes to one another.*

This character is not of much importance. The planes are either equilateral or unequal; where they are unequal, they are either indeterminately or determinately unequal. The determinately unequal planes are alternately broad and narrow; with two opposite planes broader; with two opposite planes narrower.

In the hexahedron, dodecahedron, and icosahedron, the planes are alike; when any dissimilarity occurs, it is merely accidental, and is therefore indeterminately unequal. The three-sided prism shews only slight indeterminate inequalities. The four-sided prism is not always equilateral; sometimes two opposite planes are broader than the others, when the prism is said to be broad, as in zeolite. The six-sided prism is almost always equilateral; its varieties are generally accidental, excepting the following, which are somewhat characteristic. 1. The two opposite lateral planes broader than the others, as in actynolite and heavy spar. 2. The planes alternately broader and narrower, as in calcareous spar. The eight and nine sided prisms afford only accidental or indeterminate varieties, as augate, topaz, and tourmaline.

In the pyramid, sometimes the two opposite planes are larger than the others, when it is said to be broad.

The four-sided table is usually equilateral; it has sometimes, however, two opposite lateral planes longer than the others, as in Fig. 16. The six-sided table is sometimes unequilateral, or two opposite planes are larger than the others, as in Fig. 18.; and the eight-sided table is usually longish.

4. *The Direction of the Planes or Faces.*

The direction of the planes or faces is either *Rectilinear* or *Curvilinear.*

Rectilinear is the most common, and is the case with almost all the fundamental figures.

Curvilinear planes* differ partly by the position of the curvature, which is either *concave*, as in fluor-spar; *convex*, as in diamond; *concavo-convex*, as in sparry ironstone; *saddle-shaped*, as in the lens; they differ also by the *shape*, being either *spherical*, as in brown spar; *cylindrical*, in which the convexity is either parallel with the sides, as in iron pyrites, or parallel with the diagonal, as in fluor spar; and *conical*, as in gypsum, and probably also in galena or lead glance.

5. *Angles under which the Planes meet.*

The size of the angles formed by the meeting of the planes is determined either by means of an instrument named *Goniometer*, or angle-measurer, or simply by ocular inspection. Several different kinds of goniometer have been contrived. They are described in the article Crystallography.

The other mode of ascertaining the magnitude of crystals, namely, by ocular inspection, without the aid of the goniometer, is that practised by Werner. In this way he determined the whole of the species in the system. The following are the terms used by him when describing the angles and edges of crystals.

Several different kinds of angles occur in the fundamental figures: these are, the *angles of the lateral edges*, *angles of the terminal edges*, and *the summit angles*.

1. The angles formed by the meeting of the lateral planes, are named the *angles of the lateral edges*, or, to shorten the description, simply *lateral edges*. Thus we say acute and obtuse lateral edges, in place of acute and obtuse angles formed by the meeting of the lateral planes. The lateral edges are either *equiangular* or *unequiangular*. In the icosahedron, all the edges are *equiangular*. In the dodecahedron, the edges are *equiangular*. The hexahedron is either *equiangular* and also *rectangular*, or *unequiangular* and *oblique angular*. The rectangular hexahedron is named *cube*; the oblique angular, *rhomboid*. In the prism, the lateral edges are either *equiangular* or *unequiangular*. The four-sided prism, with unequiangular lateral edges, is denominated an oblique four-sided prism, Fig. 6. Plate CCCXCVI. In the pyramid, the lateral edges are generally equiangular; seldom unequiangular. The same is the case with the table; when the edges are unequiangular, we say the terminal planes are set obliquely on the lateral planes.
2. The *terminal edges* are formed by the meeting of lateral and terminal planes. In the prism they are generally equiangular, as in Fig. 6. Plate CCCXCVI. and sometimes unequiangular, when we say that the terminal planes are set obliquely on the lateral planes, as in Fig. 7. Plate CCCXCVI. They are always equiangular in the pyramid. In the table they are as in the lateral edges of the prism.
3. The *summit angle*. It occurs only in the pyramid. It is measured from plane to plane, or from plane to edge. Werner determines it in degrees in the following manner.

a. Extremely acute, is from 1° to 30°.
b. Very acute, from 30° to 50°. Example, Sapphire.
c. Acute, from 50° to 70°. Example, Calcareous spar.
d. Rather acute, from 70° to 90°. Example, Quartz.
e. Rectangular, 90°. Example, Zircon.
f. Rather obtuse, or rather flat, from 90° to 110°. Example, Honey-stone.
g. Obtuse or flat, from 110° to 130°. Example, Calcareous spar.
h. Very obtuse, or very flat, from 130° to 150°. Example, Tourmaline.
i. Extremely obtuse, or extremely flat, from 150° to 180°.

6. *Plenitude or Fulness of the Crystals.*

A. *Full*, as in almost all crystals.
B. *Excavated at the extremities*, as in green-lead ore.
C. *Hollow*. Olive green-coloured calcareous spar from Schemnitz, in Hungary, occurs in acute hollow three-sided pyramids.

II. The Alterations on the Fundamental Figure.

These are produced by, 1. *Truncation*; 2. *Bevelment*; 3. *Acumination*; and, 4. *Division of the Planes*.

1. *Truncation.*

When we observe on a fundamental figure, in place of an edge or angle, a small plane, such a plane is denominated a Truncation.

These new planes are named *Truncated Planes*, and the edges which they form with the other planes *Truncating Edges*.

We have here to observe what relates to the *situation*, *magnitude*, the *setting on* or *position*, and the *direction* of the *truncation*.

a. In regard to the *situation* of the truncation, it is either on the edges or on the angles, and sometimes a few, sometimes all the angles and edges of the figure are truncated. Fig. 21. a cube truncated on the angles; and Fig. 22. a cube truncated on the edges.
b. In regard to the *magnitude* of the truncation, it is either *deep* or *slight*, according as more or less of the fundamental figure is wanting; and consequently the truncating planes are proportionally greater or smaller.
c. The planes are *set on* either straight or oblique. They are said to be *set on straight*, when they are equally inclined on all the adjacent planes; and *set on obliquely*, when they are not equally inclined on the adjacent planes.
d. The truncating planes, in regard to their *direction*, are either *straight* or *curved*. In the latter case, we also say that the edge or angle is *rounded off*.

2. *Bevelment or Cuneature.*

When the edges, terminal planes, or angles, of a fundamental figure are so altered, that we observe in their place two smaller converging planes, terminating in an edge, they are said to be bevelled. These two newer or additional planes are named *bevelling planes*; and the edge formed by their meeting, the *bevelling edge*. We have here, again, to observe the *situation*, *magnitude*, *angle*, *uniformity*, and *setting on* of the bevelment.

a. In regard to *situation*, the bevelment is generally on the edges, sometimes on the terminal planes, and seldomer on the angles. Fig. 23. is a cube bevelled on the edges; Fig. 24. a three-sided prism, bevelled on the lateral edges; Fig. 25. a four-sided prism, bevelled on the terminal planes. the bevelling planes set on the lateral edges; Fig. 26. a table bevelled on

* It is not geometrically correct to speak of curved planes; yet, as the term plane is more generally used by mineralogists than face or side, we have not thought it necessary to make any alteration.

the terminal planes; and Fig. 27. an octahedron bevelled on all the angles.

b. In regard to *magnitude* of the bevelment, it is either *deep* or *slight*, according as more or less of the fundamental figure is wanting.

c. In regard to the *angle*, the bevelment is *obtuse* or *flat*, or *rectangular* or *acute angular*.

d. The bevelment, in regard to *uniformity*, is either *unbroken*, when it extends in one direction; or *broken*, when each bevelling plane consists of several planes; sometimes of two planes, when it is said to be *once broken*; and sometimes of three planes, when it is said to be *twice broken*.

e. In regard to the *setting on*, we have to attend to the *position* and the *direction* of the bevelling planes.

a. In regard to the *position*, the bevelling planes are either on planes or on edges.

b. The *direction* varies only when the bevelling planes are set on the terminal planes. It is said to be *set on straight*, when the bevelling edge is at right angles to the axis of the crystal; and *set on oblique*, when it forms an oblique angle with the axis of the crystal.

3. *Acumination.*

A fundamental figure is said to be acuminated when, in place of its angles or terminal planes, we find at least three additional planes which converge into a point, and sometimes, but more rarely, terminate in an edge.

We have here to observe the parts of the acumination; these are,

The acuminating planes.

The edges of the acumination, which are,

The proper acuminating edges, those formed by the meeting of acuminating planes.

The edges which the acuminating planes make with the lateral planes of the fundamental figure.

The terminal edges of the acumination, which are formed by the terminating of the acuminating planes in an edge or line.

The angles of the acumination; which are,

The angles which the acuminating planes form with the lateral planes; and,

The summit angle.

We have to determine in the acumination, its *situation*; the *number of its planes*; *proportional magnitude of the planes among themselves*; the *setting on* or *application of the planes*; the *angles of the acumination*; its *magnitude* and *termination*.

a. *Its situation* is either on angles, as in Fig. 28. and 29. or on terminal planes, as in Fig. 30.

b. *The number of planes* is three, as in Fig. 33. and 34.; four, as in Fig. 30.; six, as in Fig. 31.; or eight, as in Fig. 35

c. *The proportional magnitude of the planes among themselves*, is a character of but little importance. They are generally determinately unequal, as in heavy-spar; or undeterminately unequal, as in rock-crystal.

d. *The setting on* or *application of the planes* refers to their position on edges, as in Fig. 29. 32 34. or planes, as in Fig. 28. 30 31. and 33. When the planes of an acumination are not set on all the edges or planes of the fundamental figure, but only on the alternate planes or edges, it is said to be *set on alternately*, as in Fig 33. and 34 and when the acuminating planes on both extremities of the fundamental figure are set on the same planes or edges, it is said to be *conformable*, (rechtsinnig,) as in Fig. 31.; but when the planes on opposite ends of the figure are set on different planes or edges, it is said to be *unconformable*, as in Fig. 33. and 34. The same expressions are applied to alternate Truncations.

e. The *angle of the acumination*, or the *summit angle*, is either obtuse or flat, as in garnet; rectangular, as in zircon; or acute, as in calcareous-spar.

f. The *magnitude*; according to which crystals are *deeply acuminated*, as in cubic crystals of fluor-spar, whose angles are acuminated with six planes; *slightly acuminated*, as in copper-pyrites or grey copper.

g. The *termination*, according as the acumination ends in a point, which is the usual mode, or in a line or edge, which is less frequent.

In order to form a more distinct idea of truncation, bevelment and acumination, let us take a cube, prism, pyramid, or any other perfect fundamental figure represented in wood, and cut off each of the edges or angles at one stroke, so that in its stead a plane shall appear; this will be truncation. But if the terminal planes, the edges, or the angles of any of these fundamental figures, be cut off with two converging strokes, the one from this side, the other from that, so that two planes arise, which, terminating in a line, shall present an edge; this will be bevelling. And if the terminal planes or the angles be cut off at several strokes, all converging together, so that more than two planes arise, commonly terminating in a point, we shall obtain acumination.

4. *The Division of the planes.*

Here the number of the planes of the fundamental figure is neither increased, nor is their figure changed, as is the case with all the preceding alterations, but each plane is divided into a greater or lesser number of smaller planes that meet together under very obtuse angles.

The number of compartments into which a plane is divided, is two, three, four, and six.

The dividing edges run either parallel to the diagonal, or from the centre of the plane of the fundamental figure towards the angles, or towards the middle of the edges and the angles at the same time. Of the first we have an example in the dodecahedral garnet; and of the second in grey copper-ore and diamond.

5. *Multiplied Alterations.*

The various alterations of the fundamental figures just enumerated occur singly, or several together, in the same fundamental figure. In the latter case, they are placed either beside each other, when they are said to be *co-ordinate*, or on one another, when they are said to be *superimposed*. The alterations are considered to be co-ordinate, when they occur in *different places* of the same fundamental figure; of this we have an example in fluor-spar, when the cube is bevelled on the edges, and truncated on the angles. They are named *superimposed*, when they occur in the *same part* of the fundamental figure, and when the first alteration is modified by a second, as in a prism which is bevelled on the terminal planes, and truncated on the bevelling edges. Sometimes, as in topaz, three or more superimposed alterations occur together in the same figure. Crystallizations frequently occur which are so modified, that they may be described in different ways, and referred sometimes to one, sometimes to another fundamental figure. This gives rise to two modes of description, viz. the *representative* and the *derivative*. If a crystal is described as it appears to the eye at first view, without any reference to its relation to other crystallizations of the same mineral, it is said to be described representatively. But if in the description we attend to its relations with the other crystals of the same mineral, and also to its derivation from these, it is described derivatively. Thus, in calcareous spar, we meet with forms, which, if described derivatively, would be considered as very low six-sided prisms, acuminated on both extremities with three planes, the planes set on the alternate lateral planes; and the summits of the acuminations so deeply truncated, that they touch the unaltered lateral planes in a line. But on a first view this figure presents nothing prismatic; and if ignorant of its origin from the prism already mentioned, we would rather consider it as a flat, double, three-sided pyramid, in which the lateral planes of the one are set on the lateral planes of the other, and the summits, and the angles on the common basis, deeply truncated. In the same manner, many very broad prisms, as in rock-crystal, at first sight appear like tables, but must be considered as prisms, on account of their derivation and other relations.

The derivative mode is the most interesting and useful, and is that which ought to be followed whenever it is possible.

In those cases, however, where the choice of the fundamental figure is optional, and when it is not determined by tracing it from other crystallizations, we give the preference to that figure which enables us to describe the crystal with the greatest facility and accuracy, and in the shortest manner. It is sometimes advantageous, and also facilitates our conception of the crystal, when we unite together in our description both the modes, using the derivative as the principal one. Thus many varieties of the cube and the rhomboid are more clearly expressed, when we describe them as double three-sided pyramids, in which the lateral planes of the one are set on the lateral edges of the other.

The different modes of describing crystals depend on the transitions that so often occur between them, by which one figure, owing to a succession of modifications, gradually passes into the other. Thus the cube, by the truncation of its angles, passes into the perfect octahedron. At first, the truncating planes on the angles of the cube are small, but become gradually larger and larger until they touch each other, when the crystal exhibits a form intermediate between that of the cube and the octahedron. If the truncating planes still increase in size, they become larger than those of the cube, and are now the principal planes of the figure, while those of the cube are alternating planes, and the whole represents an octahedron truncated on the angles. If the original planes of the cube, which now form truncating planes in the angles of the octahedron, become smaller and smaller, and at length entirely disappear, the perfect octahedron is produced.

The modifications that give rise to these transitions are the following.

1. *Alterations taking place in the proportional magnitude of the planes between themselves.*

Some planes increase in size, while others diminish, and thus one figure is changed into another. When the alternate lateral planes of the octahedron become larger, while the others diminish, a tetrahedron is formed, or the octahedron passes into the tetrahedron.

2. *Alterations in the angles under which the planes meet.* Thus the common dodecahedron, by the increasing obtuseness of its angles, at length passes into the cube.
3. The *convexity* of the faces of the crystals, which is sometimes occasioned by the division of the planes.
4. *By the newer or alternating planes becoming gradually larger at the expense of the original planes, which are at length totally obliterated.*

These changes are produced either by truncation, bevelment, or acumination; the transition of the cube into the octahedron, is an example of the first: the transition of the octahedron into the icosahedron, by the bevelment of the angles of the octahedron, of the second; and the third is exemplified by the transition of the tetrahedron into the rhomboidal or garnet-dodecahedron, by the acumination of each of the angles of the tetrahedron by three planes.

5. *By the aggregation of crystals.* Thus six-sided tables heaped on one another form six-sided prisms.

All the crystals that lie between two principal crystals, and form the transition of the one into the other, constitute what is called a *transition-suite.* These vary in extent, and sometimes they form circles, so that the last member of the suite passes into the first, or they form a straight line, and diverge into numerous branches.

Those mineral species that occur crystallized, are generally characterised by a particular suite of crystals, which does not occur in the other species. There are, however, mineral species very different from each other in their external characters, in which we meet with the same suite of crystals; and still more frequently do we meet with species that exhibit not the whole suite of crystals of another species, but a greater or smaller portion of it. Thus there is an extensive suite of crystals which extends from the icosahedron, through the dodecahedron, the cube, and the octahedron, into the tetrahedron, part of which we sometimes meet with in mineral species, but never the whole, only a larger or smaller portion of it.

That member of the suite of crystals of a mineral species, from which all the others originate or proceed, is named the *Fundamental Crystallization.* In those suites of crystals which form circles, it is often optional which of the figures we assume as the fundamental one; and in those which are disposed in lines, it is sometimes of little importance at which end we begin our description. Still we always select that crystallization which occurs the most frequently, and the most distinct in the species, and derive all the others from it.

In mineral species the crystals never appear isolated, but form a kind of progression, and pass gradually into each other. It follows from this important and highly interesting fact, that when a few crystals of a species are known, probably all the intermediate members of the series, which can be easily pointed out by crystallography, and which have not been found, may be expected to exist in nature, because the cause which produced the one part of the series may also have formed the others.

C. The Magnitude of Crystals.

This character is useful, not only in the description of varieties, but also in that of species, because in each mineral species the crystals appear to have a determinate range of magnitude. We have here to attend to the *absolute magnitude*, and also to the *relative magnitude*, of crystals.

Crystals, in regard to their *Absolute magnitude*, are divided into

α. *Uncommonly large*, when the crystal is two feet and upwards in length. The expression intimates that it is rare. Example, rock crystal.

β. *Very large*, from two feet to six inches in length. Examples, rock crystal, quartz, beryl, calcareous-spar, and felspar.

γ. *Large*, from six inches to two inches in length. It is a very frequent size. Examples, lead-glance, garnet, rock crystal, &c.

δ. *Middle-sized*, from two inches to half an inch. Examples of this magnitude are common, we shall only mention galena or lead-glance, iron pyrites, fluor-spar, calcareous-spar, and garnet.

ε. *Small*, from half an inch to the eighth of an inch. Examples, fluor-spar, calcareous-spar, &c.

ζ. *Very small*, from the eighth of an inch in length, until it is so minute as scarcely to be visible to the naked eye. Examples, native silver, grey copper-ore, spinel, &c.

η. *Microscopic*. When crystallized, but the form no longer distinguishable by the naked eye. Examples, gold, galena or lead-glance, &c.

In determining the *Relative magnitude* of crystals, we use the following terms.

α. In the prism.
- *aa*. For the length.
  - *Short* or *low*.
  - *Long* or *high*.
- *bb*. For the breadth and thickness.
  - *Broad*, when the breadth is greater than the thickness.
  - *Acicular* or *needle-shaped*, when the prisms are so thin that the planes are seen with difficulty.
  - *Capillary*, when the planes of the crystals are no longer visible.

β. In the pyramid.
- *aa*. For the length.
  - *Short* or *low*.
  - *Long* or *high*.
- *bb*. For breadth and thickness.
  - *Broad*.
  - *Lance-shaped*, allied to acicular.

γ. In the table.
- *aa*. For the length and breadth.
  - *Longish*, when one dimension of the lateral planes is greater than the others.
- *bb*. For the thickness.
  - *Thick* and *thin*.

δ. Crystals in which all the dimensions are nearly alike, are named *tessular*.

D. The Attachment of Crystals.

Werner understands by *attachment*, the connection of single crystals with massive minerals, and the aggregation of crystals together. According to the tabular view, the first distinction is into

A. *Solitary;* and this again into *loose*, *imbedded*, and *superimposed*.

α. *Loose*. Crystals are said to be loose, when they are not connected with any other mineral.

β. *Imbedded*. Crystals are said to be imbedded when they are completely enclosed in another mineral. They are crystallized on all sides, or are said to be all around crystallized, and must therefore have been formed at the same time with the mineral in which they are imbedded. We cannot conceive them to have been of anterior origin to the basis in which they are contained: for, on this supposition, we must conceive them to have remained suspended in space until the basis was formed around them. Nor can we admit them to be of posterior origin, because the crystals have impressed their form on the basis, and portions of the basis are sometimes contained in the crystals, and the crystals at their lines of junction, are occasionally intermixed with the basis. Examples of this we have in garnets imbedded in serpentine, or garnets in mica-slate.

γ. *Superimposed*. When crystals rest upon the surface of another mineral, and are firmly attached to it, they are said to be superimposed. No regular planes occur at their point of attachment; on the contrary, they take the impression of the kind of surface on which they rest. Hence it would appear, that probably they are often of posterior origin to the basis on which they rest.

The second distinction is into

B. *Aggregated*. Here there are two distinctions.

a. Where a determinate number of *crystals grow together in a determinate manner, and these differ*,

1. *With respect to number*.
   - i. *Pair wise* (twin crystals.)
   - ii. *Three together* (triple crystals.)
   - iii. *Four together* (quadruple crystals.)
2. *With regard to the manner of their intersection*.
   - i. *Penetrating one another*.
   - ii. *Intersecting one another*.
   - iii. *Adhering to one another*.

Twin crystals are formed by two crystals penetrating, intersecting, or adhering to one another. Of the *first* we have an example in felspar, where they penetrate one another in the direction of their thickness; in gypsum, where they penetrate one another in the direction of their breadth; and in calcareous-spar, where they penetrate one another in the direction of their length. Of the *second* we have an example in cross-stone, where the crystals intersect each other, and form a kind of cross, and have a common axis; and of the *third* in spinel, where the crystals adhere only by some of their planes.

Triple crystals, occur in spinel and calcareous-spar.

Quadruple crystals, occur rarely, as in tin-stone.

b. *Where there are many crystals together, but merely simply aggregated;* and these are either, 1. *On one another;* 2. *Side by side*, or adhering laterally to one another; and 3. *Promiscuous*.

The *first* occurs principally in tessular crystals, as in galena or lead-glance and fluor-spar. The *second* occurs in amethyst, where the pyramids or prisms are parallel among themselves. The *third* occurs principally in long and broad figures, as in tables and prisms. We have examples of it in grey ore of antimony, where very long and nearly needle-shaped crystals cross one another in different directions; also in tabular crystals, and this kind of tabular aggregation has much resemblance to the cellular external shape.

c. Where there are many crystals together, but doubly aggregated.

This kind of aggregation is distinguished from the foregoing by its forming groupes that exhibit shapes resembling bodies in common life.

i. *Scopiform* or *fascicular*. It is composed of a number of thin prismatic crystals, diverging from their point of attachment, and thus forming a kind of fasciculus or bundle. Examples, calcareous-spar and zeolite.

ii. *Manipular sheaf-like*. Consists of a number of crystals that diverge towards both ends, and are narrower in the middle, thus resembling a sheaf. It occurs in prismatic and tabular crystals. Examples, zeolite, calcareous-spar, and prehnite.

iii. *Columnar*. Consists of very long needle-shaped prisms, many of which are connected together in the direction of their length; and these columnar groupes sometimes cross one another in different directions. Examples, columnar heavy spar, and white-lead-spar.

iv. *Pyramidal*, is composed of many long prismatic crystals that are parallel to one another, but of which those in the middle are the highest, and the others decline on all sides, from the central one. Example, calcareous-spar.

v. *Bud-like*, is composed of low (generally) six sided pyramids, one of which is usually situated in the middle, and is surrounded by a number of others, whose extremities are directed towards one another. Here also many groupes occur together. Example, quartz.

vi. *Amygdaloidal*, is formed by tables disposed around each other, in such a manner as to form an amygdaloidal shape. Example, straight lamellar heavy spar.

vii. *Rose-like*, is composed of very thin six-sided tables, which are repeatedly curved, and so connected together that the groupe resembles a blown rose. It occurs in the variety of calcareous-spar called *rose-spar*, from Joachimsthal.

viii. *Globular*. Is composed of tables or cubes aggregated into a globular shape. Examples, iron pyrites, and curved lamellar heavy spar.

ix. *In rows*. When many crystals are superimposed on each other, in a straight direction, like the pearls in a necklace, they are said to be aggregated in rows. The flat three-sided pyramids of calcareous-spar, and the octahedrons of silver-glance or sulphuretted silver, afford examples of this kind of aggregation.

x. *Scalarwise*, in which many tessular crystals are arranged like steps of a stair. Example, cubes of corneous silver.

IV. *Extraneous External Shape.*

Extraneous external shapes of minerals are those derived from organic bodies. They are also named *Petrifactions*, and less properly *Fossils*. The particular study of these interesting forms belongs to geognosy, as the oryctognost views them only in a general way. In general, they are arranged in the order in which the species are described in the natural history of organic bodies, and are divided into petrifactions from the animal kingdom, and into those from the vegetable kingdom.*

A. Petrifactions from the Animal Kingdom.

a. Quadrupeds. The fossil remains of quadrupeds are generally found but little altered, and in single pieces, as bones, teeth, and horns; seldom in complete skeletons. The greater number of species found in this state appear to be extinct.†

b. Birds. The remains of birds, which are usually single bones, feet, claws, and bills, are very rare; they have been found in the vicinity of Mont Martre, near Paris, and in the limestone of Æningen and Pappenheim.

c. Amphibious Animals. Fossil remains of tortoises and crocodiles have been met with in different parts of Europe. Fossil tortoises occur in the Isle of Shepey in the Medway; and fossil remains of animals allied to the crocodile, are met with in the neighbourhood of Bath, in the cliffs on the Dorsetshire coast, and also on the coast of Yorkshire.

d. Fishes. Of these we find petrified, either the entire fish, skeletons, vertebræ, or teeth. Of the entire fish, instances have been observed in the copper or marl slate of the county of Mansfeld; and also in Oxfordshire, Gloucestershire, Leicestershire, Lincolnshire, Dorsetshire, and Kent;‡ of the skeletons in the limestone of Pappenheim; of the vertebræ in Shepey; of the teeth, particularly those of the shark, considerable quantities in the Island of Malta, and also in Kent and Isle of Shepey.

e. Insects. These are very rare. The only well authenticated instances of petrified fresh water insects, are the larvæ of libellulæ, found in the limestone of Pappenheim. Of sea insects, a very considerable variety have been discovered. Of the genus cancer, several distinct species have been found in the Isle of Shepey, in the Medway.

Insects inclosed in amber are not to be regarded as petrifactions, because they are dead bodies nearly unaltered.

f. Shells. Many genera of fossil shells are enumerated by authors. It is sufficient for our present purpose to remark, that these fossil remains are uncommonly numerous, and are for the most part of species which have never been found in a living state.

* In describing petrifactions, with the view of a complete history of the species, a more regular and comprehensive arrangement ought to be followed than that usually employed by naturalists. In a paper which Professor Jameson read before the Wernerian Society some years ago, he proposed and adopted the following arrangement, in describing a petrifaction from Sicily. 1. Description of the external aspect and internal structure. 2. Chemical characters, and chemical composition. 3. Geognostic situation. 4. Geographic situation. 5. Uses. 6. History, under which head he includes all that is known of the first discovery of the petrifaction, the names it may have had at different times, the different figures and descriptions of it published by authors, and other information of a miscellaneous nature.

† It may be remarked, that the fossil remains of the human species rarely occur; the only well-authenticated example of this kind being the human skeleton imbedded in an alluvial calcareous mass brought from Guadaloupe by Sir Alexander Cochrane, and now presented to the British Museum by Lord Melville; nor should the rarity of their occurrence excite our wonder, when it is recollected that human bones are looser in their texture, and more cellular than those of quadrupeds, and therefore much more liable to decomposition.

‡ Parkinson's *Organic Remains*, vol. iii. p. 249.

g. Crustaceous Animals. Of these, the most remarkable and abundant are the Echinites and Asterites.

h. Corals. Many different fossil genera and species of these bodies have been figured and described by naturalists, under the names Madreporites, Milleporites, Fungites, &c.

B. Petrifactions from the Vegetable Kingdom.

These are,

a. Impressions of plants and leaves. These occur very frequently, and appear to characterize particular formations. Thus, the impressions and casts of reeds and ferns appear to occur most frequently in the bituminous shale and slate-clay of the coal formation. Petrifactions of seeds and fruits also occur in sandstone and other rocks.

b. Transmuted wood, or *petrified wood.* It occurs in the form of trunks, branches, or roots. The wood is either petrified with an earthy mineral, as in wood-stone and wood-opal; with a metalliferous mineral, as in pyritical wood; or it is bituminous, as in the different kinds of brown-coal.*

II. *The External Surface.*

The external surface of minerals is either smooth, or more or less uneven. When the inequalities become so great as to affect the shape, they are no longer considered as characterizing a variety of surface, but as a variety of external form.

The following are the varieties of this character.

1. *Uneven.* This, of all the kinds of external surface, presents the greatest and most irregular elevations and depressions, yet they are not so considerable as to alter the external shape. Example, Surface of balls of calcedony.

2. *Granulated.* When the surface shews numerous small nearly similar roundish elevations, that appear like grains strewed over it, it is said to be granulated. It has a striking resemblance to shagreen.

3. *Rough.* This kind of surface is marked with small scarcely visible elevations, which we can hardly discover but by the feel. It has little or no lustre. Examples, Rolled pieces of common quartz and rock-crystal.

4. *Smooth.* Here there is no perceptible inequality, and the surface reflects more light than the preceding kinds of external surface. Examples, Fluor-spar, cubes of galena or lead-glance.

5. *Streaked.* This kind of surface is marked with line-like elevations. It is either *simply streaked* or *doubly streaked.*

A. *Simply streaked*, when the line-like elevations run but in one direction.

a. Longitudinally streaked. When the streaks are parallel with the length of the lateral planes. Example. Topaz.

b. Transversely streaked. When the streaks are parallel with the breadth of the lateral planes. Example, Rock-crystal.

c. Diagonally streaked. Where the streaks are parallel with the diagonal of the planes. We have an example of it in the garnet, where the streaks pass through the obtuse angle of the rhomboid.

d. Alternately streaked. When transverse and longitudinal streaks occur on alternate planes. Example, Cubic iron-pyrites.

B. *Doubly streaked*, when the streaks run in different directions. This is either

a. Plumiformly. When the streaks run obliquely towards a principal streak, like the disposition of the parts of a feather. We must be careful not to confound it with the plumose external shape. It occurs in the folia of Plumose native bismuth.

b. Reticularly. When the streaks either cross each other in a promiscuous manner, or under right angles, forming a kind of flat net-work. It occurs on the surface of silver-white cobalt.

6. *Drusy.* When a crystal is coated with a number of minute crystals of the same kind, so that the new surface acquires a scaly aspect, it is denominated drusy. Example, Common iron-pyrites.

III. *The External Lustre.*

Here we have to consider the *intensity* and the *sort* of lustre.

1. *The intensity of the lustre.* Of this there are five different degrees.

A. *Splendent.* A fossil is said to be splendent, when in full day-light (not in the sunshine) its lustre is visible at a great distance. The highest degree of this is termed *splecular splendent.* It generally occurs in minerals with a perfect foliated fracture. Example, Galena or lead-glance.

B. *Shining.* When a mineral at a distance reflects but a weak light, it is said to be shining. Example, Heavy spar.

C. *Glistening.* This degree of lustre is only observable when the mineral is near us, and at no greater distance than arm's length. Example, Porcelain jasper.

D. *Glimmering.* If the surface of a mineral, when held near to the eye in full and clear day-light, presents a very great number of small faintly shining points, it is said to be glimmering. In strong sunshine it exhibits a kind of play of colour. As an example of this degree of lustre, we may mention red hematite. It is divided into *metallic* and *non-metallic.*

E. *Dull.* When a mineral does not reflect any light, or is entirely destitute of lustre, it is said to be dull. Example, chalk.

2. *The sort of lustre.* Of the different sorts of lustre we cannot give any definition, but must rest satisfied with mentioning a few minerals which present these characters in the greatest perfection.

a. Metallic lustre, is always combined with opacity. It is divided into *perfect* and *imperfect.* The perfect occurs in native metals, the imperfect in tantalum ore.

b. Adamantine. Of this lustre there are two varieties, viz *metallic adamantine*, and *common adamantine.* White lead spar is an example of the first, and diamond of the second.

c. Pearly. Is divided into *common*, and *metallic-like.* Mica is an example of the first, and schiller spar of the second.

* The best English work on Petrifactions, is that of Mr. Parkinson, entitled "*Organic Remains of a Former World.*" It abounds in curious and important information, and is adorned and illustrated with numerous beautiful plates. Mr. Sowerby is publishing a useful work, entitled "*Mineral Conchology.*" And the valuable observations on Organic Remains, in the Transactions of the Geological Society of London, are further proofs of the general attention now bestowed on the natural history of petrifactions.

d. Resinous or *waxy*, as in pitchstone, yellow lead-spar, and tinstone crystals.

e. Vitreous or *glassy*, as in rock-crystal and topaz.

1. In determining the lustre of minerals, we ought to expose them to a strong light, but not to the direct rays of the sun. The specimens should not be handled, a practice too often followed, and which very soon alters the lustre, or adds a lustre to such as have none.

2. When different kinds of lustre occur in the same species, and pass into each other, a *lustre suite* is formed. The red silver affords an example of this. In some varieties the lustre is nearly perfect metallic; in others distinct adamantine; and other varieties are between metallic and adamantine; so that the whole forms a complete series or suite, where we cannot say where the one begins and the other ends.

II. THE ASPECT OF THE FRACTURE.

Here we have to observe the *lustre* of the fracture, the *fracture*, and the *shape of the fragments.*

IV. *The Lustre of the Fracture.*

The internal lustre, or the lustre of the fracture, presents the same varieties as the external lustre, and therefore requires no particular description.

V. *The Fracture.*

By fracture we understand the shape of those internal surfaces or planes of a mineral which are produced by breaking or splitting it. These surfaces are either continuous, when the fracture is said to be *compact*, or are composed of a number of line-like or foliated parts, termed *distinct concretions*, when the fracture is named *split* or *divided.*

A. *Compact Fracture.* There are six different kinds of compact fracture, viz. *splintery*, *even*, *conchoidal*, *uneven*, *earthy*, and *hackly*.

a. Splintery. When, on a nearly even surface, small wedge-shaped or scaly parts are to be observed, which adhere by their thicker ends, and allow light to pass through, we say that it is splintery. It sometimes passes into even. Examples, Ironstone and quartz.

b. Even, is that kind of fracture-surface which shows the fewest inequalities, and these inequalities are flat, and their boundaries never sharply marked; on the contrary, they run into each other imperceptibly. Minerals possessing this kind of fracture have generally a low degree of lustre and of transparency. It occurs in chrysoprase, calcedony, compact galena or lead-glance, compact red ironstone, and compact brown ironstone. It passes into large conchoidal and into splintery. Example, Lydian stone.

c. Conchoidal, is composed of concave and convex roundish elevations and depressions, which are more or less regular: when regular, they are accompanied with concentric ridges, as in many shells, and hence present a conchoidal appearance. Example, obsidian.

d. Uneven. This kind of fracture shows the most considerable elevations and depressions, and the elevations are usually angular and irregular. These elevations are denominated the *grain;* and, according to the size of the grain, the fracture is named *coarse-grained*, as in copper-pyrites; *small-grained*, as in copper-nickel; or *fine-grained*, as in arsenical pyrites.

This kind of fracture frequently occurs in opaque minerals having some lustre, and is more frequent in metallic minerals. It passes into small and imperfect conchoidal, and also into earthy.

e. Earthy. When the fracture surface shows a great number of very small elevations and depressions, which make it appear rough, it is called earthy. It is always associated with complete opacity and want of lustre, which latter character distinguishes it from the fine grained uneven fracture. It is peculiar to earthy minerals. It is distinguished into Coarse earthy and Fine earthy. It passes sometimes into even, and sometimes into uneven. Examples, Chalk, and clay ironstone.

f. Hackly. When the fracture surface consists of numerous small slightly bent sharp inequalities, which are sometimes only discoverable to the feel, it is said to be hackly. It occurs only in native malleable metals, and is, consequently, accompanied with metallic lustre and opacity. Examples, Native copper, and native silver.

These different kinds of compact fracture often run into each other, and frequently several occur together; in the latter case, the most prevalent fracture is that which is to be taken as the characteristic one.

B. *Split fracture.** Under this head we include what is called by some mineralogists, the *Structure of Minerals.*

Three different kinds of split fracture are enumerated by authors, viz. the *fibrous*, *radiated*, and *foliated.*

C. *Fibrous fracture.* In this kind of fracture the distinct concretions of which it is composed are so narrow, that the only magnitude which can be readily determined, by the naked eye, is the length; hence it is to be considered as composed of line-like parts. It is never dull; on the contrary, it is generally glimmering or glistening, seldom shining, and never splendent. It sometimes occurs in transparent minerals, but oftener in those which are only translucent, or even nearly opaque. The minerals in which it occurs are sometimes crystallized in capillary crystals. In the fibrous fracture we have to attend to the *thickness*, the *direction*, and the *position* of the fibres.

a. Thickness of the fibres.

α. Coarse fibrous, when the fibres are of considerable thickness, as in common fibrous quartz, common asbestus, and fibrous gypsum.

β. Delicate fibrous, when the fibres are narrower than in the preceding variety, and occasionally so delicate, as to be scarcely visible to the naked eye. Examples of delicate fibrous fracture occur in red hematite, and fibrous malachite; and of extremely

* This is the *gespaltenen Bruch* of the Germans; which I have translated *split fracture*, probably not a very appropriate translation, but I do not remember any less objectionable. The fibrous and radiated fractures are, more properly speaking, varieties of distinct concretions, and in this latter acceptation they are generally employed in the description of the species of this article.

delicate fibrous fracture, in calc-sinter and amianthus.

The coarse fibrous fracture is the link which connects the fibrous with the radiated fracture.

b. The *direction* of the fibres.

α. *Straight fibrous*, as in red hematite and fibrous malachite.

β. *Curved fibrous*, as in asbestus and fibrous gypsum.

c. The *position*.

α. *Parallel fibrous*, when the fibres, whether straight or curved, are parallel to each other, as in common asbestus, and fibrous gypsum.

β. *Diverging fibrous*, when the fibres proceed from a common centre, in different directions; and this is either,

i. *Stellular diverging*, when the fibres diverge in all directions, like the radii of a circle, as in brown hematite.

ii. *Fasicular* or *scopiform*, when the fibres diverge only on one side, so that the middle fibres are often longer than the lateral ones, as in malachite, fibrous zeolite, and reniform red hematite.

γ. *Promiscuous fibrous*, when the fibres cross each other in all directions, as in compact plumose antimony.

D. *Radiated fracture*. The distinct concretions in this kind of fracture have two discernible dimensions, namely, in length and breadth, and of these the fisst is the most considerable. Hence the fracture surface exhibits long and narrow fracture parts, which sometimes rest on each other, or are placed side by side. The lustre alternates from splendent to shining, and the transparency from translucent to opaque. The minerals in which it occurs are sometimes crystallised either in needles, or in broad prisms. In the radiated fracture, we have to attend to the *breadth*, *direction*, *position*, and *cleavage* of the rays, and the *aspect* of the surface of the rays.

a. *The breadth of the rays*.

α. *Uncommonly broad radiated*, when the breadth of the rays is more than one-fourth of an inch, as is sometimes the case with radiated grey antimony, and kyanite.

β. *Broad radiated*, when the breadth of the rays is less than the fourth of an inch, but not less than a line, as in common actynolite and mica.

γ. *Narrow radiated*, when the breadth is even less than in the preceding, also in actynolite.

b. *Direction of the rays*.

α. *Straight radiated*, which is very frequent, as in actynolite.

β. *Curved radiated*, which is rare. The curvature is either in the direction of the *breadth*, as in common actynolite, or in the direction of the length, as in kyanite.

c. *Position of the rays*.

α. *Parallel radiated*, as in grey antimony, and in common hornblende.

β. *Diverging radiated*.

i. *Stellular*, as in radiated red cobalt-ochre, or cobalt-bloom.

ii. *Scopiform*, as in radiated grey antimony, and radiated zeolite.

γ. *Promiscuous*, as in hornblende-slate, and grey antimony.

d. *Cleavage*, or *passage of the rays*.

a. *Single cleavage*.

b. *Double Cleavage*, as in hornblende. In general, the cleavage, of which a particular account will be given when treating of the foliated fracture, is imperfect, and we seldom can distinguish more than one variety of it, which is the single.

e. *The aspect of the rays surface*. The rays are either

α. *Smooth*, as in radiated grey antimony and actynolite.

β. *Streaked*, as in radiated grey manganese-ore and hornblende.

E. *Foliated fracture*. This kind of fracture is composed of folia or planes in which the length and breadth are nearly equal; which are shining or splendent, and superimposed on each other in various directions. It occurs in minerals possessing every degree of transparency, which are generally crystallised, and usually afford regular fragments. It is a more frequent fracture than either the radiated or fibrous.

In the foliated fracture we have to attend to the *size of the folia*—the *degree of perfection of the foliated fracture*—the *direction of the folia*—the *position of the folia*—the *aspect of the surface of the folia*—and the *passage of the folia* or *cleavage*.

a. *The size of the folia*. The size of the folia is determined by that of the distinct concretions; so that a mineral which is composed of large granular concretions, must have a large foliated fracture, or, of small granular concretions, a small foliated fracture. When a mineral with a foliated fracture is not composed of distinct concretions, but is one uniform undivided mass, the folia pass uninterruptedly through the whole extent of the mass, and afford the largest variety of foliated fracture.

b. *The degree of perfection of the foliated fracture*. This depends on the facility with which the folia are separated from each other by splitting on the lustre, and the smoothness of the fracture surface. Thus it is

α. *Highly perfect* or *specular splendent*, when the folia are perfectly smooth, and specular splendent, as in galena or lead-glance, yellow blende, transparent calcareous-spar, and selenite.

β. *Perfect foliated*, in which the folia are pretty smooth and shining, and sometimes splendent, as in mica and felspar.

γ. *Imperfect foliated*, when the folia are slightly uneven, or even rough, and the lustre lower than in the perfect foliated, as in fluor spar, and beryl.

δ. *Concealed foliated*, when the folia are separated from each other with difficulty, and the foliated fracture appears only in a few places of the fracture surface, as in rock-crystal.

c. *The direction of the folia*.

α. *Straight foliated*, as in selenite and calcareous-spar.

β. *Curved foliated*, which is either

i. *Spherical curved foliated*, when the folia are so bent, that they resemble either whole spheres, or segments of spheres, as in brown-spar and mica.

ii. *Undulating curved foliated*, when the folia are so laid over each other, that a transverse section gives a serpentine line, but the longitudinal one a straight line, as in mica.

iii. *Floriform foliated*, when the folia are variously curved, and the curvatures are arranged in a scopiform manner, as in galena or lead-glance.

iv. *Indeterminate curved foliated*, when the folia are irregularly or indeterminately curved, as in iron-mica or micaceous iron-ore, and mica.

d. *The position of the folia.*

α. *Common foliated*, when the folia extend throughout the whole mass, and cover each other completely, as in calcareous-spar, and most other minerals with a foliated fracture.

β. *Scaly foliated*, when the folia cover each other only partially in their arrangement, somewhat resembling the scales on a fish. It is divided into *large*, *small*, and *fine* scaly foliated, and occurs in mica.

e. *The aspect of the surface of the folia.* The foliated fracture is either

α. *Smooth*, as in calcareous-spar, and felspar; or *Streaked*, which is either

i. *Simply streaked*, and in the direction of the length, as in common hornblende.

ii. *Variously streaked*, as in iron-mica.

iii. *Plumosely streaked*, as in mica.

f. *The passage of the folia* or *cleavage.*

The cleavage is the number of determinate directions in which a mineral exhibits a foliated fracture, and according to which it can be split.

It is distinguished

α. *According to the number of the cleavages.*

i. *Single*, when it splits only in one direction, as in mica.

ii. *Twofold* or *double*, when it splits in two directions, as in felspar, hornblende, and tremolite.

iii. *Threefold* or *triple*, when it splits in three directions, as in calcareous-spar, rock-salt, and galena or lead-glance.

iv. *Fourfold* or *quadruple*, when it splits in four directions, as in fluor-spar, specular iron, or iron-glance and beryl.

v. *Sixfold*, when it splits in six different directions, as in blende and rock-crystal.

β. *According to the angle under which the cleavages intersect each other*; and these exhibit the following varieties.

i. In the *twofold cleavage*, the two folia or cleavages intersect each other *rectangularly*, as in felspar and hyacinth; or *oblique angularly*, as in hornblende.

ii. In the *threefold cleavage*, the folia intersect each other *rectangularly*, as in galena or lead-glance; *oblique*, yet *equiangularly*, as in calcareous-spar and sparry ironstone; *oblique* but *unequiangularly*, as in heavy-spar; and partly *rectangularly*, partly *oblique-angularly*, as in selenite.

iii. In the *fourfold cleavage*, all the cleavages are *equiangular* and *oblique angular*, as in fluor-spar, iron-glance, and diamond; or three cleavages are *equiangular* and *oblique-angular*, in a common axis, and are intersected by a fourth, which is horizontal and rectangular, as in beryl.

iv. In the *sixfold cleavage*, all the cleavages meet under *equal oblique angles*, as in rock-crystal; or three of the cleavages are *equiangular* and *oblique-angular*, in a common axis, which are obliquely intersected by three others, which also intersect the axis in an oblique direction. Example, Blende.

These angles of the various cleavages may also be more particularly measured by means of the goniometer.

D. *Slaty fracture.* This fracture, like the foliated, consists of plane-like portions, in which the length and breadth are nearly alike, but in which the thickness begins to be discernible. The fracture-surface is generally rough, with but little lustre. It is nearly allied to the foliated fracture, but is less perfect, and never occurs in regularly crystallised minerals, but always in those which are found in large masses, or in beds. Minerals with this fracture are generally opaque. This fracture is further distinguished according to *thickness*, *direction*, *perfection*, and *cleavage.*

a. *Thickness.*

a. *Thick slaty*, as in alum-slate, flinty-slate, and clinkstone.

b. *Thin slaty*, as in most of the varieties of clay-slate.

b. *Direction.*

a. *Straight slaty*, as in common clay-slate.

b. *Curved slaty*, which is either,

aa. *Indeterminate curved slaty*, as in some varieties of bituminous marl-slate.

bb. *Undulating curved slaty*, as in glossy alum-slate.

c. *Perfection.*

a. *Perfect slaty*, as in clay-slate.

b. *Imperfect slaty*, as in common flinty-slate.

d. *Cleavage.*

a. *Single cleavage*, which is the usual variety in clay-slate.

b. *Double cleavage*, rare, as in clay-slate.

2. *Where several fractures occur at the same time, their relative situation must be observed.*

A. *One including the other.*

In some minerals there occurs a double fracture, in which the one fracture is larger than the other, and includes it; the one, the larger fracture, is named the *fracture in the great*; the other, the lesser, the *fracture in the small*; thus, whet-slate has in the great a slaty fracture, but in the small a splintery fracture.

B. *One traversing the other.*

In other minerals, where the fracture also is double, but in which the length and breadth are different, that fracture which is in the direction of the length is named the *longitudinal fracture*; the other, in the direction of the breadth, the *transverse* or *cross fracture.* Thus, in topaz, there is a conchoidal longitudinal fracture, and a foliated transverse or cross fracture. But in tessular crystals, where the length and breadth are nearly alike, we use, in place of the term *longitudinal fracture*, *principal fracture*, and apply it to that fracture which occurs the most frequent in breaking a mineral; the other fracture, *the cross fracture.* Thus in blende, the principal fracture is foliated, with a sixfold cleavage; but the cross fracture is conchoidal; and in drawing slate, the principal fracture is slaty, and the cross fracture is earthy.

VI. *The shape of the Fragments.*

Fragments are those shapes which are formed when a mineral is so forcibly struck or split, that masses having surrounding fracture surfaces are separated from it.

The fragments are either *regular* or *irregular*.

1. *Regular fragments*, are inclosed in a certain number of regular planes, that meet under determinate angles. They occur only in such minerals as have a foliated fracture, with several cleavages. Each cleavage in these regular fragments, forms two opposite parallel planes, and the shape of the fragment depends on the number of these planes, and the magnitude of the angles under which they meet. Minerals with a twofold cleavage do not afford perfect regular fragments. The following are the varieties of regular fragments:

A. *Cubic*, which occur in minerals possessing a rectangular threefold cleavage, as galena or lead-glance and rock-salt.

B. *Rhomboidal* or *oblique-angular*, which occur in minerals having a threefold cleavage, as calcareous-spar. When two cleavages intersect each other obliquely, and are intersected rectangularly by a third, the fragments are oblique-angular in one direction, and rectangular in another, as in felspar and selenite. In calcareous-spar, the fragments are specular on every side; but in felspar, owing to the imperfect third cleavage, only on four sides.

C. *Trapezoidal*. Occur in foliated coal.

D. *Tetrahedral* or *three-sided pyramidal* and *octahedral*, occur in minerals having a fourfold cleavage, in which the folia meet under equal angles, as in fluor spar. *Three* and *six sided prismatic fragments* occur in minerals having a fourfold cleavage, in which three of the cleavages are placed under equal angles around a common axis, and are rectangularly intersected by the fourth, as in beryl.

E. *Dodecahedral*. Fragments of this form occur in minerals having a sixfold cleavage. Sometimes three of the cleavages are disposed around an axis, and are obliquely intersected with other three, as in blende; in other instances, all the six cleavages intersect each other under equal hexagon angles, and terminate in an apex, forming *double six-sided pyramidal fragments*, as in rock-crystal.

2. *Irregular fragments*.

These have no regular form. They occur in minerals with a single cleavage, and in all the varieties of compact fracture. The following are the different varieties:

A. *Cuneiform*, in which the breadth and thickness are much less than the length, and gradually and regularly diminish in magnitude from one end to the other. It occurs in minerals possessing a scopiform radiated fracture, as Cornish tin-ore, red-hematite, and radiated zeolite.

B. *Splintery*, in which the breadth and thickness are less considerable than the length, but without diminution of magnitude from one extremity to the other. It occurs in minerals having parallel fibrous and radiated fractures, as in asbestus and bituminous wood.

C. *Tabular*, in which the breadth and length are more considerable than the thickness, and the middle is frequently thicker than the sides, which indeed are sometimes thin and sharp. It occurs in minerals with a single cleavage, as mica, also in slaty minerals, as clay-slate, and there is occasionally a tendency to it in minerals with a conchoidal fracture, as flint.

D. *Indeterminate angular*, in which the length, breadth, and thickness are in general nearly alike, but the edges differ much in regard to sharpness, which gives rise to the following distinctions.

a. *Very sharp-edged*, as in obsidian and rock-crystal.

b. *Sharp-edged*, as in common quartz, pitch-stone, and jasper.

c. *Rather sharp-edged*, as in basalt and limestone.

d. *Rather blunt-edged*, as in pumice and copper-pyrites.

e. *Blunt-edged*, as in gypsum and steatite.

f. *Very blunt-edged*, as in fuller's earth and loam.

III. THE ASPECT OF THE DISTINCT CONCRETIONS.

Distinct Concretions are those portions into which certain minerals are naturally divided, and which can be separated from one another without breaking through the solid or fresh part of the mineral. They are separated from one another by natural seams, and frequently lie in different directions. When they are very much grown together, the natural seams are scarcely visible; in such cases, however, they can be distinguished by their different positions and resplendent lustre. They have been confounded with crystals and fragments, from both of which, as is evident from the preceding definition, they are completely different.

Here we have to consider, 1. The *shape of the distinct concretions* 2. The *surface of the distinct concretions*; and, 3. The *lustre of the distinct concretions.*

VII. *The Shape of the Distinct Concretions.*

Distinct concretions, in regard to shape, are distinguished into *granular*, *lamellar*, and *columnar*.

1. *Granular distinct Concretions.*

When the concretions are tessular, or have their length, breadth and thickness, nearly alike, they are said to be granular. It is the most frequent form of the distinct concretion. They are distinguished according to *shape* and *magnitude*.

A. In regard to *shape*, they are

a. *Round granular*, which is either

α *Spherical*, as in pea-stone and roe-stone.

β. *Lenticular*, as in red granular clay-iron stone.

γ. *Date-shaped*, which is of a longish round shape, as in quartz rock near Cullen in Banffshire, and at Prieborn in Silesia.

b. *Angulo-granular*, which is either,

α *Common angulo-granular*, as in galena or lead-glance, and is very frequent.

β. *Longish angulo-granular*, as in red hematite and zeolite.

B. In regard to *magnitude*, into

a. *Large granular*, in which the size exceeds that of a hazel nut, as in galena or lead-glance, blende, and zeolite.

b. *Coarse granular*, in which the size varies from the size of a hazel-nut to that of a pea, as in galena or lead-glance, blende, mica, and pea-stone.

c. *Small granular*, in which the size varies from that of a pea to that of a millet-seed, as in galena or lead-glance, pea-stone, roe-stone, and black blende.

2. *Lamellar distinct Concretions.*

In the lamellar distinct concretions, the length and breadth are nearly alike, and more considerable than the thickness. They occur frequently, but not so often as the granular concretions.

They are distinguished in regard to *direction* and *thickness*.

A. In regard to *direction*, they are

a. *Straight lamellar*, which is either,

α. *Quite straight*, as in straight lamellar heavy-spar, or

β. *Fortification-wise bent*, as in amethyst.

b. *Curved lamellar*, which is either,

α. *Indeterminate curved lamellar*, when it is not curved in any particular direction, as in specular iron-ore or iron-glance.

β. *Reniform curved lamellar*, as in red and brown hematite, and native arsenic.

γ. *Concentrical curved lamellar*, when they are disposed around a central point. It is divided into *spherical*, as in calcedony and basalt, and *conical*, as in calc-sinter and brown hematite.

B. In regard to *thickness*, into

a. *Very thick lamellar*, when the concretions are upwards of half an inch thick, as in amethyst, and galena or lead-glance.

b. *Thick lamellar*, when the thickness varies from half an inch to a quarter of an inch.

c. *Thin lamellar*, when the thickness varies from a quarter of an inch to a line, as in straight lamellar heavy-spar and calcedony.

d. *Very thin lamellar*, from that of a line, or the one-twelfth of a line, to the smallest thickness visible to the naked eye, as in straight lamellar heavy-spar, native arsenic, and specular iron-ore or iron-glance.

3. *Columnar or Prismatic distinct Concretions.*

In the columnar concretions, the breadth and thickness are inconsiderable in comparison of the length.

They are distinguished in regard to *direction*, *thickness*, *shape*, and *position*.

A. In regard to *direction*, they are,

a. *Straight columnar*, as in schorl and calcareous-spar.

b. *Curved columnar*, as in columnar clay iron-stone.

B. In regard to *thickness*, they are

a. *Very thick columnar*, when the thickness exceeds half an inch, as in amethyst and prase.

b. *Thick columnar*, from half an inch to a quarter of an inch, as in quartz and calcareous-spar.

c. *Thin columnar*, from half an inch to the twelfth of an inch, as in columnar clay iron-stone and schorl.

d. *Very thin columnar*, when it does not exceed the twelfth of a line, as in schorl. When the concretions become very minute, a transition is formed into the fibrous fracture.

C. In regard to *shape*, they are,

a. *Perfect columnar*, when the length is considerable, and the thickness uniform from one end to the other, as in calcareous-spar and schorl.

b. *Imperfect columnar*, when the concretions are in general short, and sometimes thick in the middle, sometimes at the extremities, as in amethyst and specular iron-ore or iron-glance. It passes into granular.

c. *Cuneiform columnar*, when the concretions become gradually narrower towards one extremity, as in calcareous-spar and quartz.

d. *Ray-shaped columnar*, when the columnar concretions are compressed, as in specular iron-ore or iron-glance. It passes into radiated.

D. According to the *position*, they are

a. *Parallel*, as in amethyst.

b. *Diverging*, as in schorl.

c. *Promiscuous*, as in calcareous-spar and arsenical-pyrites.

It may be remarked, that when the concretions occur very much on the great scale, as is the case in rocks of the trap formation, a slight alteration of terms is used. Thus, in place of *granular*, we say *massive*, *tabular* for *lamellar*, and always use *columnar*, never *prismatic*.

In several minerals, two varieties of distinct concretions, or different sizes of the same variety, occur together, either the one including the other, or the one traversing the other. Thus some varieties of schorl are composed of large granular concretions, and these, again, are formed of prismatic concretions; some varieties of straight lamellar heavy-spar, are composed of large granular concretions, and these, again, of thin and straight lamellar concretions; and peastone affords another example of the same kind of structure, it being composed of round granular concretions, and each of these of concentric curved lamellar concretions.

In other minerals we observe different kinds of distinct concretions intersecting each other, as in amethyst, where curved lamellar concretions intersect prismatic concretions, and in red and brown hematite, where granular concretions are intersected by lamellar concretions.

VIII. *The Surface of the Distinct Concretions.*

Distinct concretions exhibit the following varieties of surface.

Smooth, as in hematite and heavy-spar; *rough*, as in clay ironstone; *streaked*, which is either *longitudinally* streaked, as in schorl, *obliquely* streaked, as in calcareous-spar, or *transversely* streaked, as in amethyst; *uneven*, as in brown blende.

IX. *The Lustre of the Distinct Concretions.*

It is determined in the same manner as the external lustre.

V. THE GENERAL ASPECT.

Under this head we include those characters for the sight which are observed in minerals in general. These are, the *Transparency*, the *Streak*, and the *Soiling*.

X. *The Transparency.*

This character presents the five following degrees:

1. When a mineral, either in thick or thin pieces, allows the rays of light to pass through it so completely that we can clearly distinguish objects placed behind it, it is said to be transparent. It is either *simply transparent*, that is, when the body seen through it appears single, as in mica and selenite; or *duplicating*,

when the body seen through it appears double, as in calcareous-spar.

The distance of the two images is in proportion to the thickness of the specimens, and is very inconsiderable in thin pieces. The duplicating property, or double refracting power of calcareous spar, is observed by looking through two parallel planes; but in some other minerals it is observed by looking through two planes obliquely inclined on each other.

2. *Semi-transparent;* when objects can be discerned only through a thin piece, and then always appear as if seen through a cloud. It is the least frequent variety of this character, and occurs most frequently in siliceous minerals. Examples, calcedony, common and precious opal, and carnelian.
3. *Translucent.* When the rays of light penetrate into the mineral and illuminate it, but objects cannot be observed either through thick or thin pieces, it is said to be translucent. Examples, pitchstone, quartz, granular limestone, and massive fluor spar.
4. *Translucent on the edges.* When light shines through the thinnest edges and corners, or when the edges are illuminated in the same degree as the whole mineral in the immediately preceding variety of transparency, it is said to be translucent on the edges. Examples, hornstone, heliotrope, and compact limestone.
5. *Opaque.* When even on the thinnest edges of a mineral no light shines through, it is said to be opaque, as in chalk and coal.

XI. *The Opalescence.*

Some minerals, when held in particular directions, reflect from single spots in their interior a coloured shining lustre, and this is what is understood by opalescence.

It is distinguished into

A. *Common* or *simple opalescence*, when the lustre appears massive, in undivided rays, as in cat's-eye, and chrysoberyl.

B. *Stellular opalescence*, when the lustre appears in six rays, or in the form of a star, as in the variety of sapphire, named from that circumstance *star sapphire.* This phenomenon occurs principally in translucent minerals.

XII. *The Streak.*

By the streak, we understand the appearance which minerals exhibit when scratched or rubbed with a hard body, as a knife or steel. In some instances the colour of the mineral is changed; in others the lustre, and frequently neither colour nor lustre are altered.

The *streak*,

a. *In regard to colour*, is either
  α. *Similar* to that of the mineral, as in chalk and magnetic ironstone; or
  β. *Dissimilar*, as in specular iron ore or iron-glance, which has a steel-grey colour, but affords a cherry-red streak; wolfram, which has a greyish black colour, but a brownish red streak; and red orpiment, which has an aurora red colour, but affords an orange-yellow streak.

b. *In regard to lustre*, it remains
  α. *Unchanged*, as in chalk.
  β. *Is increased in intensity*, or *a shining or glistening lustre appears in minerals that otherwise have none.* Thus steatite, which is sometimes glimmering, becomes shining in the streak; and potter's clay, fuller's earth, and black and brown cobalt ochres, which have no lustre, become glistening or shining in the streak.
  c. *Is diminished in intensity*, or *altogether destroyed.* Thus, grey antimony-ore loses its lustre in the streak.

XIII. *The Soiling or Colouring.*

When a mineral taken between the fingers, or drawn across another body, leaves some particles, or a trace, it is said to *soil* or *colour.*

It is a character which occurs but in few minerals, and only in those which are soft and very soft. Minerals are said to

1. *Soil*, either
  A. *Strongly*, as chalk, drawing-slate, and reddle.
  B. *Slightly*, as graphite; or
2. *Do not soil*, as molybdena.
3. *Write*, as chalk, graphite, reddle, molybdena, and black chalk or drawing-slate.

Having now explained the External Characters which are observable by the sight, we proceed to describe those which are made known to us by the senses of Touch and Hearing.

V. CHARACTERS FOR THE TOUCH.

Here we have to observe, the Hardness, the Tenacity, the Frangibility, the Flexibility, the Adhesion to the Tongue, the Unctuosity, the Coldness, and the Weight.

XIV. *The Hardness.*

The degrees are

1. *Hard.* When a mineral either does not yield to the knife, or is very slightly affected by it, but affords sparks with steel, it is said to be hard. It is further distinguished according as it is more or less affected by the file.
  A. *Resisting the file*, or *hard in the highest degree*, when it does not yield to the file, but rather acts on it, as diamond, sapphire, and emery.
  B. *Yielding slightly to the file, and very slightly to the knife*, or *hard in a high degree*, as in garnet, flint, quartz and calcedony.
  C. *Yielding readily to the file, but with difficulty to the knife, or hard*, as porcelain-jasper, iron-pyrites, and felspar.
2. *Semihard.* When a mineral gives no sparks with steel, and yields more readily to the knife than the preceding, it is said to be semihard, as fluor-spar, and grey copper.
3. *Soft.* When a mineral is easily cut by the knife, but does not yield to the nail of the finger, it is said to be soft, as calcareous-spar, heavy-spar, serpentine, and galena or lead-glance.
4. *Very soft.* A mineral is said to be very soft, when it yields easily to the knife, and also to the nail of the finger, as gypsum, steatite, and chalk.

In our descriptions of minerals, it is useful to mention their relative hardness, which is ascertained by trying which will scratch the other, by drawing the sharp edge or angle of one on the flat surface of the other. It is, however, of consequence to know, that in crystallized minerals, the solid angles and edges of the primitive forms are very sensibly harder than the angles and edges of the derivative forms, or than the angles and edges produced by fracture, either of crystals or of massive varieties of the same species. This fact has been long known to diamond cutters, who always carefully distinguish between the *hard* and *soft* points of this gem, that is, between the solid angles belonging to the primitive octohedron, and those belonging to any of the modifications; the latter being easily worn down by cutting and rubbing them with the former*. Hauy, in determining the relative hardness, uses plates of calcareous-spar, glass, and quartz; but as it would be advantageous to have a more complete series of minerals for ascertaining these relative degrees of hardness, I insert the following Table of Minerals, arranged according to their hardness, the first being the hardest, the last the softest. We would recommend to mineralogists to provide themselves with polished pieces of these, and arrange them in a frame for use.

The following are the different degrees of hardness.

1. Expresses the hardness of	Talc.
2.	Gypsum.
3.	Calcareous spar.
4.	Fluor-spar.
5.	Apatite.
6.	Felspar.
7.	Quartz.
8.	Topaz.
9.	Corundum.
10.	Diamond.

Thus, if the hardness of a mineral is marked 7, it shows that it is equal to that of quartz. If the hardness is marked 7 5, it intimates that it is intermediate between that of quartz and the next number, 8, or topaz. By using still smaller numbers, more minute degrees of hardness might be expressed.

Observations. In examining the hardness of minerals, we must be careful to attend to the following circumstances:

1. Not to confound the real hardness of the mineral with accidental hardness; which latter is caused by the mixture of hard parts in soft minerals, and soft parts in hard minerals.

2. When minerals are composed of distinct concretions, which are not very closely joined together, we must not give the hardness of the aggregate for that of the mineral, because the hardness in such cases must be taken from that of the individual concretions.

3. And we must be careful that the mineral whose hardness we wish to ascertain, is not in a state of decomposition.

XIV. *The Tenacity.*

By tenacity is understood the relative mobility or the different degrees of cohesion of the particles of minerals. There is a series from the coherent and completely immoveable, to the coherent and moderately moveable, which latter is expressed by malleability, and is the greatest degree of the mobility of the particles observed among solid minerals. This series continues through different kinds of fluid minerals, and the greatest degree of the mobility of the particles is found in rock-oil. The degrees of tenacity are,

1. *Brittle.* A mineral is said to be brittle, when, on cutting it with a knife, it emits a grating noise, and the particles fly away in the form of dust, and leave a rough surface, which has in general less lustre than the fracture. In this degree of tenacity, the particles are completely immoveable. All hard, and the greater number of semihard minerals are brittle. Examples, quartz, heavy-spar, and grey copper.

2. *Sectile* or *mild.* On cutting minerals possessing this degree of tenacity, the particles lose their connection in a considerable degree, but this takes place without noise. The particles are coarser than in the brittle variety, and do not fly off, but remain on the knife. The lustre is increased on the streak. This degree of tenacity occurs in most of the soft and very soft minerals; and the only semihard mineral with this character is native arsenic. Examples, galena or lead-glance, copper-glance, graphite, and molybdena.

3. *Ductile.* Minerals possessing this degree of tenacity can be cut into slices with a knife, and extended under the hammer. The particles are more or less moveable among themselves, without losing their connection. Examples, native gold, native silver, and native iron.

XV. *The Frangibility.*

By frangibility is understood the resistance which minerals oppose when we attempt to break them into pieces or fragments. It must not be confounded with hardness Quartz is hard, and hornblende comparatively soft, yet the latter is much more difficultly frangible than the former. The degrees of frangibility are the following: 1. *Very difficultly frangible*, as in native malleable metals, in silver-glance, or vitreous silver, and fine granular hornblende. 2. *Difficultly frangible*, as hornstone and quartz. 3. *Not particularly difficultly frangible*, or *rather easily frangible*, as flint, calcedony, and copper-pyrites. 4. *Easily frangible*, as opal, calcareous-spar, and fluor-spar. 5. *Very easily frangible*, as straight lamellar heavy spar, galena, or lead-glance, and slate coal.†

XVI. *The Flexibility.*

This term expresses the property possessed by some minerals of bending without breaking. Flexible minerals are either *elastical flexible*, that is, if when bent they spring back again into their former direction, as mica; or *common flexible*, when they can be bent in different directions without breaking, and remain in the direction in which they have been bent, as molybdena, gypsum, talc, asbestus, and all malleable minerals.

XVII. *The Adhesion to the Tongue.*

This character occurs only in such minerals as possess the property of absorbing moisture, which causes them to adhere to the tongue. It occurs principally in soft and very soft minerals; it is not known in hard

* Vid. Bruckmann's Abhandlung von Edelsteinen, 4ter Aufl. s. 28. & 29. Mohs uber Hauy's Meionite, in Von Moll's Efermeriden der Berg und Huttenkunde 2ten Bandes, 1ste Lief, s. 3. Aiken's *Manual*, p. 5.

† Some earthy minerals, such as beryl, flint, and opal, when first extracted from their native repositories, are more difficultly frangible than after they have been exposed for some time to the influence of the atmosphere, owing to their containing in these situations a considerable portion of water, which, being a nearly incompressible fluid, renders the mineral more difficultly frangible than it is after exposure to the atmosphere, when the water has escaped, and the pores it occupied become filled with air, which is a highly compressible substance.—*Vide* Aikin, p. 9.

minerals, and there is but one instance of its occurrence in semihard minerals, that is, in the variety of semiopal called *oculus mundi.* The degrees of adhesion are, *strongly adhesive*, as meerschaum, and oculus mundi; *pretty strongly* adhesive, as bole, and potter's clay; *feebly adhesive*, as porcelain-earth, chalk, and tripoli; and *not at all adhesive*, as quartz and steatite.

XVIII. *The Unctuosity.*

Some minerals feel *greasy*, others *meagre;* and in order to distinguish the different degrees of greasiness, the following distinctions are employed.

1. *Very greasy*, as talc and graphite.
2. *Greasy*, as steatite and fuller's earth.
3. *Rather greasy*, as asbestus and polished serpentine.
4. *Meagre*, as cobalt.

The greasy and very greasy minerals are generally very soft and sectile, and become shining in the streak. Mica feels smooth, but not greasy; porcelain earth feels soft and fine, but not greasy.

XIX. *The Coldness.*

When different kinds of minerals, all having equally smooth surfaces, are exposed for some time to the same temperature, we find by feeling them that they possess different degrees of cold. To use this character with precision much practice is required; but those who have accustomed themselves to it are able, by the mere feel, to distinguish serpentine, gypsum, porphyry, alabaster, agate, &c. from one another, and can also distinguish artificial from true gems. It is, however, principally used in determining polished specimens. The different degrees mentioned are,

1. *Very cold.* Examples, the precious stones, mercury and agate.
2. *Cold.* Examples, Polished marble or limestone.
3. *Pretty cold.* Examples, Serpentine, and gypsum or alabaster.
4. *Rather cold.* Examples, Coal and amber.

XX. *The Weight.*

The degrees of the gravity of minerals, according to Werner, are the following:

1. *Swimming*, or *supernatant*, which comprehends all minerals that swim on water, and in which the specific gravity is under 1000, water = 1000. Examples, Mineral oil, mountain cork, and mineral agaric.
2. *Light*, in which the specific gravity varies from 1000 to 2000. Examples, Amber, sulphur, and black coal.
3. *Not particularly heavy*, or *rather heavy*, in which the specific gravity varies from 2000 to 4000. Examples, Quartz, flint, and calcedony.
4. *Heavy*, from 4000 to 6000. Examples, Heavy-spar, copper-pyrites, and iron-pyrites.
5. *Uncommonly heavy*, all minerals having a specific gravity above 6000. Examples, Native metals, as gold, silver, &c.; ores, as galena or lead-glance, tinstone, &c.

The first and second degrees, which comprehend the swimming and light minerals, contain all the inflammable minerals; the third, with a few exceptions, all the earthy minerals; the fourth, the greater number of metalliferous compounds; and the fifth, the native metals and a few ores, &c.

The preceding determinations answer very well for the general descriptions of species; but it renders them more complete, when we ascertain the specific gravity by means of the hydrostatic balance. See the article HYDRODYNAMICS, for the mode of conducting this experiment.

VI. CHARACTERS FOR THE HEARING.

XXI. *The Sound.*

The different kinds of sound that occur in the mineral kingdom are the following: 1. *A ringing sound*, which is a clear sound, as that of native arsenic, selenite, and rock-crystal. Specimens to possess this property in full perfection, should have one or two dimensions, as length and breadth, greater than the thickness: 2. *A grating sound*, which is a very weak rough sound, resembling that emitted by dry wood, or fresh burnt clay when rubbed, and is produced when the finger is drawn across certain minerals, as mountain cork and mealy zeolite: 3. *A creaking sound*, which is a harsh sharp sound, as that of natural amalgam, when pressed by the finger.

VII. CHARACTERS FOR THE SMELL.

Of this we can give no definition, and shall therefore illustrate it by the minerals in which it occurs.

It is observed, either when

1. *Spontaneously emitted*, in which case it is
   - *a. Bituminous*, as mineral oil and mineral pitch.
   - *b. Faintly sulphureous*, as natural sulphur.
   - *c. Faintly bitter*, as radiated grey antimony.
2. *After breathing on it*, in which a *clayey-like smell*, as in hornblende and chlorite, is produced.
3. *Excited by friction.*
   - *a. Urinous*, in stinkstone.
   - *b. Sulphureous*, in iron pyrites.
   - *c. Garlick-like*, or *arsenical*, in native arsenic and arsenic pyrites.
   - *d. Empyreumatic*, in quartz and rock crystal.

VIII. CHARACTERS FOR THE TASTE.

This character occurs principally in the saline class, for which it is highly characteristic.

The varieties of it are,

1. *Sweetish taste*, common salt.
2. *Sweetish astringent*, natural alum and rock butter.
3. *Styptic*, blue and green vitriol.
4. *Saltly bitter*, natural Epsom salt.
5. *Saltly cooling*, nitre.
6. *Alkaline*, natural soda.
7. *Urinous*, natural sal-ammoniac.

II. PARTICULAR GENERIC EXTERNAL CHARACTERS OF FRIABLE MINERALS.

The external characters of friable minerals form a particular Section in the System, because they exhibit varieties and kinds that do not occur in solid minerals, and many of the characters of solid minerals, such as fracture, distinct concretions, streak, hardness, and frangibility, and others, are wanting.

I. *The External Shape.*

In friable minerals there are but few external shapes. The five following kinds are all that have been hitherto described by naturalists.

1. *Massive*, as in porcelain earth, and scaly red and brown iron ores.

2. *Disseminated*, as in earthy azure copper, and blue iron earth.

3. *Thinly coating* or *incrusting*. It is analogous to the form in membranes. Examples, Copper-black, or black oxide of copper.

4. *Spumous*. When a friable mineral appears like froth resting on a solid mineral, as is sometimes the case with scaly brown iron ore.

5. *Dendritic*, also in scaly brown iron ore.

II. *The Lustre.*

It is determined in the same manner as in solid minerals; we have here, however, the following distinctions.

1. In regard to *Intensity*.
   A. *Glimmering*, which is either strong or feeble, as in scaly brown iron ore, and porcelain-earth.
   B. *Dull*, as in black cobalt ochre.
2. In regard to the *sort* of lustre.
   A. *Common glimmering*, as in scaly and brown iron ores.
   B. *Metallic glimmering*, as in scaly red and brown iron ores, and *Pearly glimmering*, as in earthy talc.

III. *The Aspect of the Particles.*

The particles of friable minerals appear in some instances like dust, so that we can with difficulty distinguish by the naked eye any dimensions; these are called *dusty particles*, and occur in cobalt crust, blue iron earth, and porcelain earth; in others, two dimensions can be observed, when they appear foliated, and these are called *scaly particles*, and occur in scaly brown and red iron ores, earthy talc, and chlorite earth.

IV. *The Colouring or Soiling.*

Friable minerals colour either strongly, as in scaly red and brown iron ores, and porcelain earth; or slightly, as in black cobalt ochre.

V. *The Adhesion to the Tongue.*

This character occurs only in those friable minerals which are cohering. It varies in intensity, being either feeble or strong.

VI. *The Friability.*

Friable minerals are either loose, that is, when the particles have no perceptible coherence, as in blue iron earth; or cohering, in which the particles are slightly connected together; they are either feebly cohering, as in porcelain earth, or strongly cohering, as in potter's clay.

III. PARTICULAR GENERIC EXTERNAL CHARACTERS OF FLUID MINERALS.

Fluid minerals possess fewer characters than friable minerals. The following four are all that occur.

1. *The Lustre* is either metallic, as in mercury; or resinous, as in rock oil. The lustre is always splendent.

2. *The Transparency.* The following are all the degrees necessary for the purposes of discrimination. 1. *Transparent*, as in naphtha. 2. *Troubled* or *turbid*, as in mineral oil; and, 3. *Opaque*, as in mercury.

3. *The Fluidity.* Here we have only two degrees to observe. 1. *Fluid*, as in mercury and naphtha. 2. *Viscid*, as is sometimes the case with mineral oil.

4. *The wetting*, by which we understand the wetting of the fingers when they touch the mineral. It is analogous to the soiling in solid and friable minerals. Mineral oil wets the finger, but mercury does not.

ON DESCRIBING MINERALS.

Most of the species exhibit many varieties of character, which are generally distributed throughout a number of individual specimens; hence it follows, that, in order to obtain a distinct conception of a species, we must examine not one, but many different specimens of it. The descriptions of the species may be executed in the following manner.

The following description may serve as an example of the mode of arranging the external characters.

Precious Garnet.

External Characters.—All the colours of this mineral are *deep-red*, which always inclines to blue; the principal colour is *columbine-red*, which passes into *cherry-red*, and *blood-red*, and it appears even to run into *brownish-red*, and *hyacinth-red*.

It rarely occurs massive, sometimes *disseminated*, in *angular pieces*, and in *lamellar concretions;* but most frequently in *roundish grains;* and *crystallized* in the following figures:

1. The *rhomboidal dodecahedron*, which is the fundamental figure.
2. The rhomboidal dodecahedron, *more or less deeply truncated on all the edges.* When the truncating planes become so large as to obliterate the original planes, there is formed the
3. *Leucite crystallization.*
4. *Rectangular four-sided prism*, acuminated on both extremities with four planes, which are set on the lateral edges.

The fundamental crystallization alternates from very large to very small; the others are middle-sized, small, and very small.

The crystals are *all around crystallized* and *imbedded.*

The *surface* of the grains is usually *rough, uneven*, or *granulated;* that of the crystals is almost always *smooth.*

Internally it alternates from *splendent* nearly to glistening, and the lustre is intermediate between *vitreous* and *resinous.*

The fracture is *more or less perfect conchoidal;* and sometimes *six fold cleavage.*

The fragments are indeterminate angular, and rather sharp-edged.

It alternates from *transparent* to *translucent.*

It is so hard as to scratch quartz.

It is rather difficultly frangible.

It is heavy.

Specific gravity, 4.230, Werner.

Werner recommends the more essential characters of the mineral to be printed in a different letter from that of the others, in order that they may more readily strike the eye,—a practice which is followed in the preceding description.

CHEMICAL CHARACTERS OF MINERALS.

The chemical characters of minerals are those we obtain by their complete analysis, and the changes induced on them by the action of the atmosphere, water, acids, and heat, by means of the blowpipe. In this article, we shall not enter on the various modes followed by chemists in the complete analysis of minerals, but confine ourselves to a short account of the chemical characters obtained by the other means just enumerated.

1. *Action of the Atmosphere.*

Many minerals, on exposure to the atmosphere, experience considerable changes in colour, lustre, hardness, or decay, fall in pieces, deliquesce, change into vitriol, &c. owing partly to the abstraction of the water, which enters as a constituent part into many species, partly to the absorption of water from the atmosphere, or to the oxidation of some of the constituent parts of the mineral.

2. *Action of Water.*

Water either forms a chemical combination with minerals, and completely dissolves them, as is the case with the mineral salts; or it acts by simply destroying their state of aggregation, when the mineral falls into small pieces with an audible noise, as is observed in bole: or it falls without noise into small pieces, which are soon diffused through the fluid, without either dissolving in it, or becoming plastic, as in fuller's earth; and some minerals, as unctuous clays, it renders plastic. Other minerals absorb water in greater or less quantity, by which their transparency, and also their colour, are changed.

3. *Action of Acids.*

Acids act powerfully on many different minerals, and are the principal agents employed in their complete analysis. When we wish, by means of acids, to obtain some obvious characters, the dilute muriatic acid is that which is generally employed. The native carbonates effervesce, and are soluble in it. In some, as in agaric mineral, calcareous-spar, and witherite, the effervescence is brisk, and the solution rapid; in others, as in dolomite, even when pulverised, the effervescence is feeble, and the solution slow. Some of the earthy minerals which contain silica, water and alkali, in a particular state of combination, as zeolite, if pulverised, and covered with an acid, are, in the space of a few hours, converted into a perfect jelly.

4. *Action of the Blowpipe.*

Common blowpipe.—The blowpipe is a tube of silver, copper, brass, or of glass, for delivering a continued stream of air. The stream being directed across a flame, turns it more or less from a vertical position, concentrating it at the same time, and occasioning a more powerful combustion. The air employed is generally either that of the atmosphere, or air which has been breathed: sometimes oxygen gas is made use of, and sometimes an inflammable gas, as the vapour of boiling alcohol. The continued stream of air is furnished by some apparatus, such as a pair of double bellows, a gazometer, a large bladder, or, what is most convenient of all, by blowing with the mouth.

Few persons, Mr. Aikin remarks, are able at first to produce a continued stream of air through the blowpipe, and the attempt often occasions a good deal of fatigue. The first thing to be done is, to acquire the habit of breathing easily, and without fatigue, through the nostrils alone; then to do the same when the mouth is filled and the cheeks inflated with air, the tongue being at the same time slightly raised to the roof of the mouth, in order to obstruct the communication between the mouth and the throat. When this has been acquired, the blowpipe may be put into the mouth, and the confined air expelled through the pipe by means of the muscles of the cheeks; as soon as the air is nearly exhausted, the expiration from the lungs, instead of being made through the nostrils, is to be forced into the cavity of the mouth; the communication is then instantly to be shut again by the tongue, and the remainder of the expiration is to be expired through the nostrils. The second, and all subsequent supplies of air to the blowpipe, are to be introduced in the same manner as the first. Thus, with a little practice, the power may be obtained of keeping up a continued blast for a quarter of an hour, or longer, without inconvenience. Much depends on the size of the external aperture of the blowpipe. If so large that the mouth requires very frequent replenishing, the flame will be wavering, and the operator will soon be out of breath; if, on the other hand, the aperture be too small, the muscles of the cheeks must be strongly contracted, in order to produce sufficient current, and pain and great fatigue of the part will soon be the consequence. An aperture, about the size of the smallest pinhole, will generally be found the most convenient, though, for particular purposes, one somewhat larger, or a little smaller, may be required.

Brooke's Blowpipe.

Mr. Brooke some time ago contrived a very simple and convenient blowpipe, of which the following description is given by Mr. Neuman.

"The instrument I have made consists of a strong plate-copper box, perfectly air-tight, three inches in width and height, and four in length, a condensing syringe to force air into the box, and a stop-cock and jet at one end of it to regulate the stream thrown out. The piston-rod of the condenser works through collars of leather in the cap, which has an aperture in the side, and a screw connected with a stop-cock, which may again communicate with a jar, bladder, or gazometer, containing oxygen, hydrogen, or other gases. This communication being made, and the condenser being worked, any air that is required may be thrown into the box and propelled through the jet on the flame.

"The use of the instrument is very simple. By a few strokes of the piston, the air is thrown into the chamber, and forms a compressed atmosphere within. When the cock is opened, the air expanding, issues out with great force, in a small but rapid stream, which, when directed on the flame of a lamp, acts as the jet from a common blowpipe, but with more precision and regularity. The force of the stream of air is easily adjusted by opening more or less the small stop-cock; and I have found, that, with a moderate charge, it will remain uniform for twenty minutes; opening the stop-cock, or the use of the syringe, will immediately raise it to its first strength.

These blowpipes are very portable, not liable to injury, and answer, I believe, the expectations of all who have tried them, and I have made many of them for different persons. The whole instrument, with a lamp adapted to it, packs up in a small box not more than six inches in length, and four inches in width and height, and there is space enough left for other small articles. I have fitted up boxes rather larger in size, with a selection of tests and other useful articles, in addition to the blowpipe, and in this state they form complete mineralogical travelling cabinets."

Fuel for the Blowpipe.

The fuel for the lamp is oil, tallow, or wax; and of these the wax is the best, the oil the worst. The wick should neither be snuffed too high nor too low, and should be a little bent at its summit *from* the blast of the pipe. The flame, while acted on by the blowpipe, will consist of two parts, an outer and inner: the latter will be of a pale blue colour, converging to a point at the distance of about an inch from the nozzle; the former will be of a yellowish colour, and will converge less perfectly. The most intense heat is just at the point of the blue flame. The white flame consists of matter in a state of full combustion, and oxygenates substances immersed in it: the blue flame consists of matter in a state of imperfect combustion, and therefore partly deoxygenates metallic oxides which are placed in contact with it.

Supports for minerals exposed to the Blowpipe.

Various substances are employed for supporting the mineral, when undergoing the action of the blowpipe. These are of two kinds, combustible and incombustible. The combustible support, used chiefly for ores, is charcoal. The closest grained and soundest pieces of charcoal, of elder or lime-tree, are to be selected; or a support may be made of well pulverised and heated charcoal and gum tragacanth. The gum should be dissolved in water, and powder of charcoal added to it, until it becomes very viscid, when it is to be formed into parallelopipeds, and slowly dried. The incombustible supports are metal, glass, and earth; in the use of all which, one general caution may be given, to make them as little bulky as possible. The best metallic support is platina, because it is infusible, and transmits heat to a less distance, and more slowly, than other metals. A pair of slender forceps of brass, pointed with platina, is the best support for non-metallic minerals, which are not very fusible; for the fusible earthy minerals, and for the infusible ones when fluxes are used, leaf-platina will be found the most convenient. It may be folded like paper into any form, and the result of the experiment may be obtained, simply by unfolding the leaf in which it was wrapped up. Glass supports, are slender glass tubes, on the extremity of which the mineral to be examined is cemented by heating. Earthen supports are, either of small pieces of kyanite, or, when a kind of cuppellation is to be performed, they are made of bone-ash, in order to absorb the litharge, and other impurities.

The size of the specimens to be used in our experiments, depends in some measure on the magnitude of the flame to which they are exposed. In a blowpipe having an aperture not larger than a fine pin, the piece ought not to be so large as a pea. A good deal also depends on the fusibility of the mineral; for, if it is very fusible, a much larger piece may be used than when it is difficultly fusible: in the one case, it may be the size of a pea: in the other, it should not exceed that of a pin's head. The heat first applied to investigate the properties of mineral substances should be very low, not exceeding that which exists a little the outside even of the yellow flame. At this temperature the phosphorescence is best extricated, and decrepitation for the most part takes place, the fusible inflammables begin to melt, and the metallic and most other mineral salts lose their water of crystallization. The yellow flame will raise a mineral to a tolerably full red heat; and it is the temperature best fitted for roasting all the metallic ores. In the still higher degree of heat produced at the point of the interior blue flame, although some minerals still continue refractory, and undergo but little change of any kind, yet the greater part are very sensibly altered. Some, as pearlstone, enlarge very considerably in bulk at the first impression of the heat, but are with difficulty afterwards brought to a state of fusion: others are melted only on the edges and angles; and in some, a complete fusion takes place.

Fluxes for Minerals exposed to the Blowpipe.

In examining earthy minerals with the blowpipe, no fluxes are required; whereas to most of the metallic ores fluxes will be found at almost all times a very useful and often a necessary addition. The ores of the difficultly reducible metals, such as manganese, cobalt, chrome, and titanium, are characterised by the colours which the oxides give to glass. In all these cases, therefore, glassy fluxes must be largely made use of, both to dissolve the earthy matter with which the oxides are generally combined, and to furnish a body, with little or no colour of its own, which may receive, and sufficiently dilute, the inherent colour of the oxide. When the object is not only to dissolve the oxide, but at the same time to retain it at a high state of oxidation, the flux employed should be either nitre, or a mixture of this with glass of borax, or, still better, nitrous borax, formed by dissolving common borax in hot water, neutralizing its excess of alkali by nitrous acid, then evaporating the whole to dryness, and, lastly, hastily melting it in a platina crucible. For an active, and at the same time non-alkaline flux, boracic acid may be used, or neutral borate of soda; and where a slight excess of alkali is required, or at least does no harm, common borax by itself, or mixed with a little cream of tartar, when a strong reducing flux is required, may be had recourse to. For coloured glasses, the proper support is leaf-platina, but for reductions, charcoal. In the latter case, the ore, previously roasted, if it contain either sulphur or arsenic, is to be pulverised, and accurately mixed with the flux; a drop of water being then added to make it cohere, it is to be formed into a ball, and deposited in a shallow hole in the charcoal, being also covered with a piece of charcoal, if a high degree of heat is required. In the easily reducible metals, a bit of the ore being placed in the charcoal, and covered with glass of borax, will, in the space of a few seconds, be melted by the blowpipe, and converted into a metallic globule, imbedded in a vitreous scoria. In all cases where a metallic globule is obtained, it should be separated from the adhering scoria, and examined as to its malleability, and other external characters; being then placed a second time on the charcoal, but without flux, it is to be brought to the state of a gentle ebullition, during which, the surface being oxygenated, will exhale a heavy vapour, that condenses on the blowpipe, or falls down on the charcoal in the form of a powder, or of specular crystals, from the colour and other characters of which the nature of the metal may probably be ascertained. If any suspicion is entertained of a portion of silver or of gold being mixed with the oxydable metal, the button must be placed on an earthen support, and there brought to a full melting heat: by degrees, the oxydable metal will become scorified, and will entirely sink into the support, leaving on the surface a bright bead of *fine metal*, if any such was contained in the alloy; but the proportion of this last being generally very small, and the entire mass of the alloy often not exceeding a large shot, it is not unfrequently necessary to have recourse to the magnifying glass, to be fully convinced of the presence or absence of the fine metal.*

PHYSICAL CHARACTERS OF MINERALS.

Physical characters are those derived from physical phenomena originating from the mutual action of minerals and other bodies. They are highly curious in a general view, but are seldom useful in the discrimination of minerals, as they occur in but few species, and in these rare cases the same physical properties are met with in very different species. The principal physical characters which occur among minerals, are Electricity, Magnetism, and Phosphorescence.

1. *Electricity.*

It is well known that there are two kinds of electricity; the one named *positive* or *vitreous*, and the other *negative* or *resinous*.

Electricity can be excited in minerals in three different ways,—by friction, by heating, or by communication with an electrified body. The greater number of minerals which are capable of becoming electrical, acquire this property by friction. Earthy, saline, and metallic minerals, in this way become positively electrified. Some minerals by this process become very easily and powerfully electric, while others become electric with difficulty, and exhibit but faint traces of it. A few minerals become electric by heating, and these belong to the number that also exhibit electrical properties by friction. It has been ascertained, that these minerals have at least two points, of which the one is the seat of positive, and the other that of negative electricity. To these points, which are always placed in two opposite parts of the mineral, Hauy gives the name of *electric poles*. For a full account of the pyro-electricity of minerals, see the article ELECTRICITY.

The third mode of exciting electricity in minerals, or that by communication, occurs only in minerals which are in a pure metallic state.

2. *Magnetism.*

Very few minerals are magnetic; it is a character which occurs principally in ores of iron, or in such minerals as contain a portion of metallic iron, or iron in the state of black oxide. A good many minerals, after exposure to the blow-pipe, become magnetic.

3. *Phosphorescence.*

Some minerals, when rubbed or heated emit in the dark a more or less shining light, are said to be phosphorescent. Thus, yellow blende, when scratched with a hard body, emits a strong light. When two pieces of quartz are forcibly struck against each other, both become luminous; and fluor-spar, and other minerals, when heated, become phosphorescent. For a full account of phosphorescent minerals, by Dr. Brewster, see the *Edinburgh Philosophical Journal*, vol. i. p. 383.

Geognostical and Geographical Characters.

These characters are derived from the geognostical relations and geographical distribution of the species. In another article we shall show that simple minerals are not irregularly distributed throughout the crust of the earth. On the contrary, that particular species very often occur together, and in the same formation; that some species are met with in nearly all the formations of rocks, others in only a few members of the series, while some are confined to a particular rock; and that certain beds and formations are characterized by the simple minerals they contain. In their geographical distribution, numerous interesting relations will be pointed out, of the grouping of particular species in limited tracts of country; of the wider range of others through whole regions; and of the distribution of species, according to distance from the equator, and particular meridians.

Mohs' Crystallography.

The preceding details make us acquainted with those characters which are used in *describing* minerals; but in the following arrangement considerable use is made of the primitive forms, as ascertained by Professor Mohs. According to his view, every simple form, from which other simple forms are derived, is named a *fundamental form*; and the class of figures derived from that fundamental form, *a system of crystallizations.* The fundamental forms are four in number, and, consequently, also the systems of crystallization. These fundamental forms are, the *rhomboid*, *pyramid with a square base*, *oblique four-sided prism*, and *hexahedron* or *cube*; and the systems of crystallizations derived from these, are denominated *rhomboidal. pyramidal, prismatic*, and *tessular*. Connected with the rhomboids there are series of *scalene six-sided pyramids*; and the series both of rhomboids and of the scalene pyramids are terminated by *regular six-sided prisms*, which are distinguished from each other by their positions. The pyramids with square bases form series; and their limiting form, or last member of the series, is the *rectangular four-sided prism*. Each pyramid with a square base has *depending* on it three *scalene eight-sided pyramids*; and the limiting forms of these scalene eight-sided pyramids are *unequiangular eight-sided prisms*. The oblique four-sided prism has depending on it numerous oblique based pyramids, and oblique prisms. The hexahedron has depending on it the *regular octahedron*, including the *tetrahedron*, the *rhomboidal dodecahedron*, and the *icositetrahedron*. The forms that arise from the hexahedron produce among themselves various combinations; but they admit into them no form, *which is either a rhomboid, or a four-sided pyramid with a square base, or an oblique four-sided pyramid, or can be derived from any of these figures.* The rhomboid, the four-sided square-based pyramid, and the

* These Observations on the action of the Blowpipe are taken from Mr. Aikin's Manual, p. 35.

four-sided oblique-based pyramid, are forms which cannot by any means be derived from each other; hence the *four groups* of simple forms, as well as their combinations, must each be altogether distinct from the rest; and hence arises a correct and natural division of all *possible* crystallizations, which is of great utility in mineralogy. An interesting sketch of Mohs' Views in Crystallography, is given in the *Edinburgh Philosophical Journal*, vol. iii. p. 154. Fig. 10. Plate CCCXCVI. represents the *rhomboid;* Fig. 30, *Pyramid with square base;* Fig. 6, *Oblique four-sided prism;* Fig. 3, *Hexahedron* or *cube;* Fig. 9, *Tetrahedron;* Fig. 2, *Pentagonal Dodecahedron;* and Fig. 35, the *Tetragonal isositetrahedron.*

The nomenclature of the species used is nearly that of Mohs, and is founded on the primitive forms of the minerals, on the nature of their cleavage, or on the position of the bevelment.

According to Mohs, as already mentioned, all the regular forms in the mineral kingdom are reducible to some one of four great systems or groups, named Rhomboidal, Pyramidal, Prismatical, and Hexahedral or tessular, including octahedron, cube octahedron, rhomboidal dodecahedron, &c. Thus, in the genus Corundum, there are three species in which the primitive forms are the octahedron, rhomboid, and prism; and hence these are named octahedral corundum, rhomboidal corundum, and prismatic corundum. In the genus Zeolite, there are seven species; one of these is named Prismatoidal zeolite, because the cleavage is prismatoidal; another is named Axifrangible, because one of its most striking characters is its axifrangible cleavage. In the genus Augite, one species is named Oblique-edged augite, because the edge formed by the meeting of the bevelling planes, on the extremities of the crystal, is placed obliquely to the axis of the prism; another species is named Straight-edged augite, because the edge formed by the bevelling planes on the extremity, is straight or perpendicular to the axis of the prism.

In the generic characters, the number of axes of the crystals is given. But it will be inquired, what is here understood by axis. When the section of a simple figure, as a rhomboid or cube, affords, by means of a plane which does not pass through its centre, a regular, or equi-angular or equi-lateral figure, or one in which such a figure can be inscribed, the straight line, which stands perpendicular on the middle point of the figure, and passes through the centre of the figure, is an *axis.* If we take a hexahedron, and place it in such a situation that two only of its planes are horizontal, and the others vertical, every section of it, with a horizontal plane, will afford a square; and the vertical line, which stands perpendicular on the middle point of the square, and passes through the centre of the figure itself, will be an axis. Bring the same hexahedron in such a situation, that one of its solid angles is above, and another vertically under it. The section with a horizontal plane will be an equilateral triangle or equi-angular hexagon, and the straight line perpendicular on the middle point of this plane, and through the centre of the figure, an axis. Lastly, if we place the hexahedron in such a situation, that four of its edges are horizontal, and the others are equally inclined towards the horizontal plane, all the sections but two will be longish rectangles, and the straight line, perpendicular on the middle point, and through the centre of the figure, is an axis.—The kind of axis is determined by the figure of the section, and one and the same figure may contain not only many, but also axes of different kinds. That axis in which the form of the section is triangular, or in which a triangle can be inscribed by connecting some of its angles by straight lines, is named a *rhomboidal axis,* because it occurs in the rhomboid; when the form of the section is a square, the axis is named *pyramidal,* because it occurs in the pyramid with square bases; and when the form of the section is rhomboidal, the axis is named *prismatic,* because it occurs in the oblique double four-sided prism, which is a member of the prismatic series. In the Tabular View, the Diamond is said to have *many axes,* because its primitive figure, the octahedron, has rhomboidal axes that pass through the centre of the planes, pyramidal axes that pass through the angles, and six subordinate axes that pass through the middle point of the edges. Zircon is said to have one axis, because its primitive figure belongs to the pyramidal system, in which there is only one principal axis. Topaz has three axes, because it belongs to the prismatic series, in which there are three principal axes.

II. SYSTEM OF ARRANGEMENT.

Three modes of arranging simple minerals have been employed by naturalists: in the first, they are arranged according to their chemical composition; in the second, in conformity with their external characters; and in the third, both methods are conjoined. The pure chemical method is desirable in a system of chemistry: the mixed method, from its unsatisfactory nature, should be banished from mineralogical science; while that founded on external characters, or what has been called the Natural History Method, ought to be adopted as the only true and scientific plan for the purposes of natural history and practical utility. The natural history method is followed in the present article, and the arrangement is that of Professor Mohs of Freyberg. Dr. Walker, the former Professor of Natural History in the University of Edinburgh, taught mineralogy according to the natural history method. Professor Jameson, his successor, has frequently done the same; and we find, from the introduction to the third edition of his *System of Mineralogy,* that he now abandons the mixed method, and adopts the natural history method.

The following is a tabular view of the plan of arrangement followed of the genera and species now to be described.

CLASS I.

ORDER I. GAS.

Genus 1. Marsh gas. Sp. 1. Carburetted.
2. Sulphuretted.
3. Phosphuretted.

Genus 2. Meteoric gas. Sp. 1. Pure gas or atmospherical air.

ORDER II. WATER.

Genus 1. Meteoric water. Sp. 1. Pure water.
2. Sea water. 1. Common.

ORDER III. ACID.

Genus 1. Carbonic acid. Sp. 1. Æriform.
2. Muriatic acid. 1. Æriform.

3. Sulphuric acid.	1. Æriform.
	2. Fluid.
4. Boracic acid.	1. Scaly.
Genus 5. Arsenic acid.	1. Octahedral.

ORDER IV. SALINE MINERALS.

Genus 1. Natron.	Sp. 1. Prismatic.
2. Nitre.	1. Prismatic.
3. Glauber salt.	1. Prismatic.
4. Alum.	1. Octahedral.
5. Epsom salt.	1. Prismatic.
6. Vitriol.	1. Rhomboidal.
	2. Prismatic.
	3. Pyramidal.
7. Sal ammoniac.	1. Octahedral.
8. Rock salt.	1. Hexahedral.
9. Borax.	1. Prismatic.

CLASS II.

ORDER I. HALOIDE.

Genus 1. Gypsum.	Sp. 1. Axifrangible or common.
	2. Prismatic or anhydrite.
2. Cryolite.	1. Pyramidal.
3. Alum-stone.	1. Rhomboidal.
4. Fluor.	1. Octahedral.
5. Apatite.	1. Rhomboidal.
6. Limestone.	1. Prismatic or arragonite.
	2. Rhomboidal or calcareous spar, &c.
	3. Short axed. Dolomite and rhomb spar in part.
	4. Long axed. Rhomb spar in part.

ORDER II. BARYTE.

Genus 1. Red manganese.	Sp. 1. Rhomboidal.
2. Sparry iron.	1. Sparry iron.
3. Calamine.	1. Prismatic.
	2. Rhomboidal.
4. Tungsten.	1. Pyramidal.
5. Baryte.	1. Di-prismatic or Strontianite.
	2. Rhomboidal or Witherite.
	3. Prismatic or common.
	4. Axifrangible or celestine.
6. Lead spar.	1. Di-prismatic or white lead spar.
	2. Rhomboidal, or green and brown lead spar.
	3. Prismatic, or red lead spar.
	4. Pyramidal, or yellow lead spar.
	5. Tri-prismatic, or lead vitriol.

ORDER III. KERATE.

Genus 1. Corneous silver.	Sp. 1. Hexahedral.
2. Corneous Mercury.	1. Pyramidal.

ORDER IV. MALACHITE.

Genus 1. Copper green.	Sp. 1. Common.
2. Malachite.	1. Prismatic, or blue copper.
	2. Acicular, or common malachite.
Genus 3. Olivenite.	Sp. 1. Prismatic, or phosphate of copper.
	2. Di-prismatic, or lenticular copper.
	3. Acicular.
	4. Hexahedral, or cube ore.
4. Emerald-copper.	1. Rhomboidal.

ORDER V. MICA.

Genus 1. Copper mica.	Sp. 1. Prismatic.
2. Uran mica.	1. Pyramidal.
3. Cobalt mica.	1. Prismatic or red cobalt.
4. Antimony mica.	1. Prismatic or red antimony.
5. Blue iron, or iron mica.	1. Prismatic.
6. Graphite.	1. Rhomboidal.
7. Mica.	1. Rhomboidal, including mica, chlorite, talc, &c.
8. Pearl mica.	1. Rhomboidal.

ORDER VI. SPAR.

Genus 1. Schiller spar.	Sp. 1. Prismatic, or green diallage.
	2. Slaty, including bronzite and common schiller spar.
	3. Labrador, or hyperstene.
	4. Gerader, or anthophyllite.
Genus 2. Kyanite.	Sp. 1. Prismatic.
3. Spodumene.	1. Prismatic.
4. Prehnite.	1. Prismatic.
5. Datolite.	1. Prismatic.
6. Zeolite.	1. Dodecahedral, or leucite.
	2. Hexahedral, or analcime.
	3. Rhomboidal, or chabasite.
	4. Pyramidal, or cross-stone.
	5. Di-prismatic, or Laumonite.
	6. Prismatic, or mesotype.
	7. Prismatoidal, or stilbite.

Zeolite.	Sp. 8. Axifrangible, or apophyllite.
7. Felspar.	Sp. 1. Rhomboidal or nepheline.
	2. Prismato-pyramidal, or meionite.
	Sp. 3. Prismatic, or common.
	4. Pyramidal, or scapolite.
8. Augite.	Sp. 1. Oblique-edged, including common augite, diopside, &c.
	2. Straight-edged, including hornblende, actynolite, and asbestus.
	3. Prismatoidal, or epidote.
	4. Prismatic, or tabular spar.
9. Azure spar.	Sp. 1. Prismatic, including azurite and Hauyne.
	2. Prismatoidal, or blue spar.

ORDER VII. GEM.

Genus 1. Boracite.	Sp. 1. Octahedral.
2. Andalusite.	1. Prismatic.
3. Corundum.	1. Octahedral, or spinel.
	2. Rhomboidal. Oriental ruby and sapphire.
	3. Prismatic, or chrysoberyl.
4. Diamond.	1. Octahedral.
5. Topaz.	1. Prismatic.
6. Emerald.	1. Rhomboidal.
	2. Prismatic, or euclase.
7. Quartz.	1. Rhomboidal.
	2. Indivisible.
8. Axinite.	1. Prismatic.
9. Chrysolite.	1. Prismatic.
10. Tourmaline.	1. Rhomboidal.
11. Garnet.	1. Pyramidal, or Vesuvian.
	2. Dodecahedral, including precious garnet, &c.
	3. Prismatic, or grenatite.
12. Zircon.	1. Pyramidal.
13. Gadolinite.	1. Prismatic.

ORDER VIII. ORE.

Genus 1. Titanium ore.	Sp. 1. Prismatic, or sphene.
	2. Prismato-pyramidal, including rutile, iserine, and menachanite.
	3. Pyramidal, or octahedrite.
2. Red copper ore.	1. Octahedral.
3. Tin ore.	1. Pyramidal or tin-stone.
4. Wolfram, or scheel ore.	1. Prismatic.
5. Tantalum ore.	1. Prismatic.
6. Uranium ore.	1. Indivisible.
7. Cerium ore.	1. Indivisible.
8. Chrome ore.	1. Prismatic.
9. Iron ore.	1. Octahedral, or magnetic ore.
	2. Rhomboidal, red iron-ore, or iron-glance.
	3. Prismatic, or brown iron-ore.
10. Manganese ore.	1. Prismatic, or grey and black manganese ores.

ORDER IX. NATIVE METALS.

Genus 1. Arsenic.	Sp. 1. Native.
2. Tellurium.	1. Native.
3. Antimony.	1. Dodecahedral, or native antimony.
	2. Octahedral, including antimonial and arsenical silver.
4. Bismuth.	Sp. 1. Octahedral.
5. Mercury.	1. Dodecahedral, or amalgam.
	2. Fluid.
6. Silver.	1. Hexahedral.
7. Gold.	1. Hexahedral.
8. Platina.	1. Native.
9. Iron.	1. Octahedral.
10. Copper.	1. Octahedral.

ORDER X. PYRITES.

Genus 1. Nickel pyrites.	Sp. 1. Prismatic, or copper nickel.
2. Arsenical pyrites.	1. Prismatic.
	2. Di-prismatic.
3. Cobalt pyrites.	1. Hexahedral, or silver-white cobalt.
	2. Octahedral, or tin-white and grey cobalt.
4. Iron pyrites.	1. Hexahedral.
	2. Prismatic.
	3. Rhomboidal.
5. Copper pyrites.	1. Octahedral, or yellow copper pyrites.
	2. Tetrahedral, including grey and black copper pyrites.

ORDER XI. GLANCE.

Genus 1. Copper glance.	Sp. 1. Rhomboidal.
2. Silver glance.	1. Hexahedral.
	2. Rhomboidal.
3. Lead glance, or galena.	1. Hexahedral.
4. Black tellurium.	1. Prismatic.
5. Molybdena.	1. Rhomboidal.
6. Gold glance.	1. Prismatic.
7. Bismuth glance.	1. Acicular.
	2. Prismatic.
8. Antimony glance.	1. Prismatoidal, or grey antimony.
	2. Axifrangible, or Bournonite.
	3. Prismatic.

ORDER XII. BLENDE.

Genus 1. Manganese blende.	Sp. 1. Prismatic.
2. Zinc blende, or garnet blende.	1. Dodecahedral.
3. Antimony blende.	1. Prismatic, or red antimony.
4. Ruby blende.	1. Rhomboidal, or red silver.
	2. Prismato-rhomboidal, or cinnabar.

ORDER XIII. SULPHUR.

Genus 1. Sulphur.	Sp. 1. Hemi-prismatic, or ruby-sulphur, or red orpiment.
	2. Prismatoidal sulphur, or yellow orpiment.
	3. Prismatic, or common sulphur.

CLASS III.

ORDER I. RESIN.

Genus 1. Honey-stone.	Sp. 1. Pyramidal.
2. Mineral resin.	1. Yellow or amber.
	2. Black, including mineral oil and mineral pitch.

ORDER II. COAL.

Genus 1. Coal.	Sp. 1. Brown coal.
	2. Black coal.
	3. Glance coal.

When we wish to determine the species to which any mineral belongs, by means of the preceding system, we first ascertain either its primitive form or cleavage, and afterwards the hardness and specific gravity. We next compare these characters with those in the Classes, Orders, Genera, and Species; and if a species in any of the genera possesses the same characters, our mineral is to be considered as belonging to that species.

If the form or cleavage cannot be ascertained, our determination of the species will not be so satisfactory or certain. Thus, suppose we meet with a variety of iron pyrites, in which neither form nor cleavage can be detected, but of which the hardness and specific gravity are known; and that the hardness is 6, and the specific gravity 4.9. If we compare these characters with those of the Classes, Orders, Genera, and Species, we shall find that the only genus to which they apply, is *iron pyrites*. But these characters will not enable us to determine the species with absolute certainty, because the essential character of every species depends on the primitive form. They will, however, show that the mineral is iron pyrites, even that it is not rhomboidal iron pyrites; but they will not enable us to decide whether it is hexahedral or prismatic iron pyrites. In other cases, the species can be determined without knowing the primitive form; but still, the determination is not so certain as when that form is known. Thus, suppose we meet with a species of magnetic iron ore, which we find, by inspection, cannot be either the rhomboidal or prismatic species, but which agrees in hardness and specific gravity with the octahedral species, we can say that it very probably is a variety of octahedral magnetic ore. But there may be a fourth species of this genus not in the system, having the same hardness and specific gravity as the octahedral, but with a different primitive form; and we cannot be certain that our mineral does not belong to that species. When the primitive form is known, all doubt vanishes. In compound minerals, it is very often impossible to determine the external form. In such cases, a knowledge of the cleavage is of infinite importance. But when neither form, nor hardness, nor specific gravity, can be determined, the system cannot be advantageously used; for the principal characters on which it depends are wanting. Amianthus, which is a variety of straight-edged augite, (hornblende,) occurs in crystals so very minute, that they cannot be determined either by the eye or the microscope, and of course the cleavage is not visible. These crystals are flexible, and their hardness not capable of being determined. Their surface is so considerable in comparison of their mass, that they float on water, although they have a considerable specific gravity. It is remarked, that in other varieties of straight-edged augite, the crystals become thicker, then lose their flexibility, but are still too small for allowing the hardness to be ascertained; others, again, are thicker, but still, owing to their minuteness, the dimensions of the form cannot be measured; these sink in water, scratch gypsum, but break on calcareous spar. At last, in other varieties, the form is discernible by the cleavage, and the hardness is equal to 5 and 6. and the specific gravity equal to 3.0. These, on examination, prove to be straight-edged augite. What these are, so are all the preceding varieties, and also amianthus. It is by pursuing this mode of examination, that we are able to refer such substances as amianthus to their true place in the system. Other minerals, again, which occur in an earthy state, can only be referred to their true place in the system by tracing them in connection with compact minerals, which stand in connection with others having a crystallised structure. Thus porcelain earth can be traced to compact felspar, and this to foliated felspar; or it can be traced immediately to foliated felspar, and in this way its true place is ascertained. Other earths, and loosely aggregated minerals, as many clays, cannot be referred to any species; these, therefore, are determined in an empirical way; and we may use the blowpipe, acids, and other means, for obtaining a knowledge of their properties. These bodies are more properly objects of geological curiosity, and of economical value, than interesting to the mineralogist.

The nomenclature of the species used in the present arrangement, is founded on the primitive forms of the minerals, on the nature of their cleavage, or on the position of the bevelment.

According to Mohs, all the regular forms in the mineral kingdom are reducible to some one of four great systems or groups, named rhomboidal, pyramidal, prismatical, and hexahedral or tessular, including octahedron, cube, rhomboidal dodecahedron, &c. Thus, in the genus corundum, there are three species, in which the primitive forms are the octahedron, rhomboid, and prism; and hence these are named, octahedral corundum, rhomboidal corundum, and prismatic corundum. In the genus zeolite, there are seven species; one of these is named prismatoidal zeolite, because the cleavage is prismatoidal; another is named axifrangible, because one of its most striking characters is its axifrangible cleavage. In the genus augite, one species is named oblique-edged augite, because the edge formed by the meeting of the bevelling planes, on the extremities of the crystal, is placed obliquely to the axis of the prism; another species is named straight-edged augite, because the edge formed by the bevelling planes on the extremity, is straight or perpendicular to the axis of the prism.

CLASS I.

If solid, there is a sensible taste. No bituminous smell. Specific gravity under 3.0.

Order I. GAS.

Æriform. Not acid. Sp. gr. = 0.0001.—0.0014.

Genus I. MARSH GAS.

Smell. More or less respirable. Sp. gr. = 0,0001.—0,0014.

This genus contains three species, viz. 1. Carburetted marsh gas. 2. Sulphuretted marsh gas. 3. Phosphuretted marsh gas.

1. Carburetted marsh gas, or carburetted hydrogen. Empyreumatic smell. Sp. gr. = 0,0008.

Geognostic Situation.—This gas rises from marshes and volcanoes. It is also met with in great quantities in coal-mines, forming the *fire-damp* of miners.

2. Sulphuretted marsh gas, or sulphuretted hydrogen. Smell of rotten eggs. Taste nauseous and bitter.

Hydrogen 6.244. Sulphur 93.756 = 100. *Berzelius.*

Geognostic Situation.—It rises from sulphureous springs, also from marshy places, and is met with in mines.

3. Posphuretted marsh gas, or posphuretted hydrogen. Smell of putrid fish. Taste bitter.

Geognostic Situation.—It rises from marshy and other places where organic substances are in a state of decomposition.*

Genus II. METEORIC GAS.

Without smell or taste. Perfectly respirable. Sp. gr. =0.001.—0.0013—

1. Pure meteoric gas, or atmospheric air. Respirable, without smell or taste.

Geognostic Situation —Forms the atmosphere which surrounds the earth.

Order II. WATER.

Fluid. Tasteless, or with sensible taste and smell. Sp. gr. = 1 1—1,0269.

Genus I. METEORIC WATER.

Without smell or taste.

1. Pure. Without smell or taste.

This is common rain, river, and spring water. Mineral waters are to be considered as accidental varieties of pure meteoric water.

Genus II. SEA WATER.

Sensible taste and smell.

1. *Common.* Bitter nauseous taste and disagreeable smell.

Order III. ACIDS.

If solid, is feebly acid. If the Sp. gr. is = 3 and more, it is sweetish astringent. Sp. gr. =0.0015—3.7.

Genus I. CARBONIC ACID.

Spiritus Letalis, *Plin.* Gas Sylvestre, Spiritus Sylvestris, *Paracelsus* and *Van Helmont.* Fixed air, *Black.*

Taste acid. Sp. gr. =0.0018.

1. *Æriform.* Is gaseous.

Geognostic and Geographic Situations.—It occurs in considerable quantities in marshy places, rises from certain acidulous waters, and abounds in many caves, as in that of Del Cane near Naples, and of Aubenas in Ardèche.

Genus II. MURIATIC ACID.

Smell of saffron and strong acid taste. Not respirable. Sp. gr. =0.0023.

1. *Æriform.* In the gaseous form.

Geognostic Situation.—Emanates from volcanoes, &c.

Genus III. SULPHURIC ACID.

If æriform, the smell is sulphureous, and it is not respirable; if fluid it is strongly acid to the taste. Sp. gr. =0,0025—1.5.

1. Æriform. Sp. gr. =0.0025.

Geognostic Situation.—It rises from volcanoes, and sometimes in considerable quantity.

2. *Fluid.* Fluid. Sp. gr. =1.4—1.5.

Geognostic and Geographic Situations.—It is observed trickling from the roofs of caves in Ætna; near Aix, in Savoy, and in various places in Italy. Also in some situations in America, and in the island of Java.

Genus IV. BORACIC ACID.

Solid. Sp. Gravity under 3.0.

1. *Scaly.* It occurs in scaly crusts. It tastes first sourish, or subacid, then bitter and cooling, and lastly sweetish.

Geognostic and Geographic Situation.—It is found on the edges of hot springs, near Sasso, in the territory of Florence, and also in Volcano, one of the Lipari islands.

Genus V. ARSENIC ACID.

Solid. Specific gravity above 3.

1. *Octahedral.* Cleavage octahedral. Taste sweetish astringent. Sp. gr. =3.6—3.7.

External Characters.—Its colours are reddish-white, snow-white, yellowish-white, and milk-white. It occurs massive, in thin crusts, stalactitic, small reniform, and botryoidal; and frequently in delicate capillary shining crystals, which are scopiformly or stellularly aggregated. Its lustre is shining and silky, and pearly. It is very soft, passing into friable.

Chemical Character.—Is soluble in water.

Geognostic and Geographic Situation.—It occurs as a secondary formation in veins, as at Andreasberg in the Hartz, where it is accompanied with native arsenic, red silver, galena, and red orpiment.

Order IV. SALTS.

olid. Not acid, but subacid. Sp. gr.=.

* Hydrogen gas, in a pretty pure state, forms the material of the perpetual fires of some countries, and might here be introduced as a distinct species of marsh gas.

Genus I. NATRON.

Cleavage prismatic. Taste sharp and alkaline. H.=. Sp. gr. =1.4.

1. Prismatic Natron.—*Jameson.*

Prism =129° 60°? Cleavage not accurately ascertained.

This species is divided into two subspecies, viz. Common natron and radiated natron.

First Subspecies.

Common Natron, *Jameson.*—Gemeines Natron, *Werner.*

Description.—External Characters.—Colours, yellowish and greyish-white; also smoke grey and cream-yellow. When fresh, it is compact, sometimes granular, sometimes radiated, vitreous and glistening, and more or less translucent: when weathered, it is in loose, dull, opaque parts.

Chemical Characters.—It effervesces with acids. It is easily soluble in water, and its solution colours blue vegetable tinctures green. It is very fusible before the blowpipe.

Constituent Parts.

Egyptian Natron.		*Bohemian Natron.*		*Natron of Hungary.*	
Dry sub-carbonate of Soda,	32.6	Carbonate of Soda, -	89.18	Carbonate of Soda, -	14.2
Dry Sulphate of Soda, -	20.8	Carbonate of Lime, -	7.44	Muriate of Soda,	22.4
Dry Muriate of Soda, -	15.0	Carbonate of Magnesia, -	1.35	Sulphate of Soda, -	9.2
Water, -	31.6	Extractive matter. -	2.03	Earthy residuum,	9.2
				Water, -	45.0
	100.0		100.00		100.0
Klaproth, Beit. b. iii. s. 80.		*Reuss.* Min. b. iii. s. 5.		According to *Lampadius.*	

Geognostic Situation.—It occurs as an efflorescence on the surface of soil,—on decomposing rocks of particular kinds,—on the sides and bottoms of lakes that become dry during the summer season,—also on the walls and bottoms of caves,—and dissolved in the water of lakes and springs. In Hungary, according to Ruckert and Pazmand, there are so many natron lakes, that 50,000 quintals of soda could be obtained from them annually. In some places of the same country, it effloresces on the surface of the soil, heath, &c. It abounds in the natron lakes of Egypt.

Geographic Situation.—Europe.—It occurs in Bohemia, Hungary, Switzerland, in the Phlegrean Fields, Monte Nuovo, near Naples, and Mount Ætna in Sicily.

Africa.—It occurs in considerable quantity in Egypt.

Asia.—In the vicinity of Smyrna, and the ancient city of Ephesus; in Bengal; near Bombay; Persia; Natolia; district of Ochotsk, in the government of Irkutsk; and in the Crimea.

America.—Dissolved in the lakes of Mexico.

Second Subspecies.

Radiated Natron, *Jameson.*—Strahliches Natron, *Klaproth.*

External Characters.—Colours greyish and yellowish white. Occurs in crusts, in radiated distinct concretions, and crystallized in capillary or acicular crystals, which are aggregated on one another. The lustre is glistening and vitreous. It is translucent.

Chemical Characters.—Same as those of common natron.

Constit. Parts.—Water of crystallization, 22.50
Carbonic acid, . 38 00
Pure soda, . . 37.00
Sulphate of soda, . 2 50—100.00
Klaproth, Beit. b. iii. s. 87.

Geognostic and Geographic Situations.—Mr. Bagge, Swedish Consul at Tripoli, gives the following information respecting this interesting subspecies of natron. "The native country of this natron, which is there called *Trona*, is the province Sukena, two days journey from Fezzan. It is found at the bottom of a rocky mountain, forming crusts, usually the thickness of a knife, and sometimes, although rarely, of an inch, on the surface of the earth. It is always crystalline: in the fracture it consists of cohering, longish, parellel, frequently radiated crystals, having the aspect of unburnt gypsum. Besides the great quantity of trona which is carried to the country of the Negros and to Egypt, fifty tons are annually carried to Tripoli. It is not adulterated with salt. The salt-mines are situated on the sea-shore; but the trona occurs twenty-eight days journey up the country." According to the accounts of Mr. Barrow, it would appear also to occur in the district of Tarka, in Boshieman's Land, in Southern Africa.

Uses.—It is principally employed in the manufacture of glass and soap, in dyeing, and for the washing of linen. It is sometimes purified before it is used, but more frequently (particularly that from Egypt) it is used in its natural state.

Genus II. NITRE.

Three axes. Cleavage, prismatic. Taste, cooling and saline. Hardness = 2.0. Specific gravity = 1.9, 2.0.

1. Prismatio Nitre, *Jameson.*—Prismatisches Natürlicher Saltpeter, *Mohs.* Natürlicher Salpeter, *Werner.*

Prism = . Cleavage prismatic, and in the direction of the smaller diagonal of the prism.

Description.—External Characters.—Colours greyish-white, yellowish-white, and snow-white. Occurs in flakes, crusts, and in capillary prismatic crystals. Dull, glimmering, or shining, and the lustre vitreous. Alternates from translucent to transparent. Brittle, and easily frangible.

Chemical Characters.—Deflagrates when thrown on hot coal.

Constituent Parts.—The natural nitre of Molfetta, according to Klaproth: Nitrate of potash, 42.55
Sulphate of lime, 25.45
Carbonate of lime, 30.40
Muriate of Potash? 0.20
Loss, . . 1.40
——100.00
Klaproth, Beit. b. i. s. 320.

Geognostic Situation.—It is usually found in thin crusts on the surface of soil, and sometimes also covering the surface of compact limestone, chalk, and calc-tuff. In many countries it germinates in certain seasons out of the earth, and when this earth is accumulated in heaps, so as to expose a large surface to the atmosphere, it is found to produce it annually.

Geographic Situation.—Europe.—It is found in great quantities in many plains in Spain; very abundantly in the plains of Hungary, the Ukraine and Podolia; and also in France and Italy.

Asia.—Nitre is very abundant in India; also in Persia; and in the valley between Mount Sinai and Suez, in Arabia.

Africa.—This salt is abundant in Egypt; also at Ludamar, in the interior of Africa; and in the Karoo Desart. to the east of the Cape of Good Hope.

America.—The nitre used for the manufacture of gunpowder in the United States of America, is obtained from an earth collected in the limestone caves of Kentucky. Nitre effloresces in considerable abundance on the soil near Lima; and in Tucuman in South America.

Uses.—In Hungary, Spain, Molfetta, and the East Indies, considerable quantities of natural nitre are collected; but the greatest proportion of that used in commerce, is obtained by working artificial nitre beds. These consist of the refuse of animal and vegetable bodies, undergoing putrefaction, mixed with calcareous and other earths. Its principal use is in the fabrication of gunpowder: it is also used in medicine, and many of the arts.

Genus III.—GLAUBER SALT.

Three axes. Cleavage prismatic. Taste first cooling, and then saline and bitter. Hardness = . Sp. gravity 2.2, 2.3.

1. Prismatic Glauber Salt, *Jameson.*—Prismatisches Glauer Salz, *Mohs.* Natürliches Glauber Salz, *Werner.*

Prism unknown. Cleavage not accurately ascertained.

External Characters.—Its colours are greyish and yellowish white; seldom snow or milk white. It occurs in the form of mealy efflorescences; in crusts; seldom stalactitic, small botryoidal, reniform; in small and fine granular distinct concretions; and crystallized in prisms, which are often acicular. Internally it is shining, and the lustre is vitreous. The fracture is conchoidal, or uneven. The fragments are indeterminately angular, and blunt edged. It is brittle, and easily frangible.

Chemical Characters.—Before the blowpipe, it is affected in the same manner as Epsom salt, but its solution does not, like that of Epsom salt, afford a precipitate with an alkali.

Constituent Parts.—Natural Glauber Salt of Eger, according to Reuss, (Chemische-medicinische Breschreibung des Kaiser Franzens Bades, Dresden, 1794), contains

Sulphate of Soda,	67.024
Carbonate of Soda,	16.333
Muriate of Soda,	11.000
Carbonate of Lime,	5.643——100

Geognostic Situation.—It occurs, along with rock-salt and Epsom salt, on the borders of salt lakes, and dissolved in the waters of lakes; in efflorescences on moorish ground; also on sandstone, marl-slate, and old and newly built walls.

Geographic Situation.—*Europe.*—It occurs in Germany, France, Hungary, Spain, and Italy.

Asia.—It occurs on the banks, and in the water of many Siberian salt-lakes; neighbourhood of the Lake Baikal; the desert plains of Iset, Ischem, and Barebyn.

Africa.—Egypt.

Uses.—It is used as a purgative medicine; and in some countries as a substitute for soda, in the manufacture of white glass.

Genus IV. ALUM.

Many axes. Cleavage tessular. Taste sweetish, astringent and acidulous. Hardness = 2.0,25. specific grav. = 1.7, 1.8.

1. Octahedral Alum, *Jameson.* Octaedrisches Alaun, *Mohs.* Natürlicher Alaun, *Werner.*

Crystallized in tubes and octahedrons. Cleavage octahedral.

External Characters.—Colours yellowish and greyish-white. Occurs as a farinaceous efflorescence, stalactitic, in delicate curved and parallel fibrous concretions. The varieties with fibrous concretions have a pearly lustre; others are glistening and vitreous. When the fracture can be observed, it is conchoidal.

Chemical Characters.—It is soluble in from sixteen to twenty times its weight of water. It melts easily by means of its water of crystallization; and by continuance of the heat, it is converted into a white spongy mass.

Constituent Parts.—

	Natural Alum of Freinwald.
Alumina,	15.25
Potash,	0.25
Oxide of iron,	7.50
Sulphuric acid, and water,	77.00—100.00

Klaproth, Beit. b. iii. s. 103.

Geognostic Situation.—It generally occurs as as efflorescence on aluminous minerals, as alum-slate, alum-earth, alum-stone, aluminous coal, aluminous-slate-clay, and bituminous shale, and also encrusting lavas.

Geographic Situation.—*Europe.*—It occurs as an efflorescence on the surface of bituminous-shale and slate-clay at Hurlet, near Paisley; also encrusting alum-slate near Moffat, in Dumfriesshire; Ferrytown of Cree, in Galloway; and at Whitby, in Yorkshire. On the Continent of Europe, it is met with in many places, as in the alum-slate rocks near Christiania in Norway; in coal-mines in Bohemia; also in Austria, Bavaria, Hungary, Italy, and the Islands of Stromboli, Milo, &c. in the Mediterranean Sea.

Africa.—In Egypt.

America.—In Real del Monte in Mexico, on a porphyritic stone.

Uses.—It is employed as a mordant in dying; also in the manufacture of leather and paper; as a medicine; for preserving animal substances from putrefaction; and it is sometimes mixed with bread, in order to give it a whiter colour.

* Rock-Butter (*a.*)—Bergbutter, *Werner.*

External Characters.—Colours yellowish-white, yellowish-grey, cream-yellow, straw-yellow and pale sulphur-yellow. Occurs massive, and tuberose. Internally strongly glimmering, and resinous. Fracture straight foliated. Fragments blunt-edged. Translucent on the edges. Feels rather greasy. Easily frangible.

Constituent Parts.—It is alum, mixed with alumina and oxide of iron.

Geognostic Situation.—It oozes out of rocks that contain alum, or its constituents, as alum-slate, bituminous-shale impregnated with iron-pyrites, or alum-earth.

Geographic Situation.—It occurs at the Hurlet alum-work, near Paisley; oozing out of rocks of alum-slate in the island of Bornholm, in the Baltic; at Muskau in

Upper Lusatia; Saalfeld in Thuringia; and, according to Pallas, in aluminous rocks on the banks of the river Jenisei, in Siberia.

Genus V. EPSOM SALT.

Three axes. Cleavage prismatic. Taste bitter and saline. Hardness = . spec. grav. =

1. Prismatic Epsom Salt, *Jameson.*—Prismatisches Bitter Salz, *Mohs.*—Natürlicher Bitter Salz, *Werner.*

Prism. = 90°. Cleavage very perfect, according to one of the diagonals.

External Characters.—Colours snow-white, greyish-white, yellowish-white, sometimes ash-grey, and smoke-grey. Occurs in farinaceous crusts, flakes, small botryoidal, reniform, and crystallized. Prisms acicular and capillary. The farinaceous variety is dull, the others shining, glistening, and pearly. Varies from transparent to opaque. Brittle, and easily frangible.

Chemical Characters.—Before the blowpipe, it dissolves very easily by the assistance of its water of crystallization, but it is difficultly fusible. Its solution gives a precipitate with lime-water.

Constituent Parts.—The constituent parts of purified Epsom salt, the sulphate of magnesia of chemists, are, according to

	Bergmann.	*Kirwan.*
Sulphuric Acid, .	33.0	29.46
Magnesia, . . .	19.0	17.00
Water of Crystallization,	48.0—100.0	53.54—100.00

Geognostic and Geographic Situations.—It occurs as an efflorescence at Hurlet, near Paisley, along with natural alum; and sometimes effloresces on old walls.

Uses.—When purified, it is used as a purgative medicine; and it is valued by chemists on account of the magnesia which can be obtained from it.

Genus VI. VITRIOL.

One and three axes. Cleavage rhomboidal, pyramidal, and prismatic. Taste astringent. H. =
Sp. gr. = 1.9—2.2.

1. Rhomboidal Vitriol, or Green Vitriol, *Jameson*—Rhomboedrisches Vitriol Salz, *Mohs.* Eisen Vitriol, *Werner.*

Rhomboid = 81°.23′. Cleavage same, or = *r*. H = 2. Sp. gr. = 1 9, 2.0.

Description.—Colours emerald, apple, and verdigris green, and sometimes grass-green: on exposure to the weather, it becomes straw-yellow, cream-yellow, ochre-yellow, and yellowish-brown. Occurs pulverulent, massive, disseminated, stalactitic, tuberose, botryoidal, reniform, in fibrous distinct concretions, and crystallized. Shining, both externally and internally, and the lustre is vitreous, with exception of the fibrous varieties, which are pearly. Fracture flat conchoidal. Alternates from semi-transparent to opaque. Refracts double.

Chemical Character.—Before the blow-pipe, on charcoal, it becomes magnetic, and colours glass of borax green.

Constituent Parts.—	Oxide of iron	25 7
	Sulphuric acid	28.9
	Water .	45.4—100.0
		Berzelius.

Geognostic and Geographic Situations.—It is always associated with iron pyrites, by the decomposition of which it is formed. Occurs in several coal mines in this country, and in many iron and coal mines on the continent of Europe, and also in America and Asia.

Uses.—It is employed to dye linen yellow, and wool and silk black; in the preparation of ink; of Berlin-blue; for the precipitation of gold from its solution; and sulphuric acid can be obtained from it by distillation. The residue of the latter process (colcothar of iron) is used as a red paint, and, when washed, for polishing steel.

2. Prismatic vitriol, or blue vitriol, *Jameson.* Prismatisches Vitriol-Salz, *Mohs.* Kupfervitriol, *Werner.*

Prism = 124° 2′. Cleavage the same. Hardness = 2.5. Sp. gravity = 2.1, 2.2.

External Characters.—Common colour dark sky-blue, which sometimes approaches to verdigris-green. By exposure to the air it becomes yellow. It occurs massive, disseminated, stalactitic, dentiform, and crystallized. Externally and internally it is shining and vitreous. The fracture is conchoidal. The fragments are rather sharp-edged. It is translucent.

Chemical Characters.—When a portion of it is dissolved in water, and spread on the surface of iron, it immediately covers it with a film of copper.

Constituent Parts.—	Oxide of copper	32.13
	Sulphuric acid	31.57
	Water .	36.30—100.00
		Berzelius.

Geognostic and Geographic Situations.—It occurs, along with copper pyrites, in Pary's mine in Anglesea; and also in the copper-mines in the county of Wicklow in Ireland.

Uses.—It is used in cotton and linen printing; and the oxide separated from it is used by painters.

3. Pyramidal vitriol, or white vitriol, *Jameson.* Pyramid = 120° 90′. Cleavage unknown. Hardness =
Sp. gravity = 2.

External Characters.—Colours greyish, yellowish reddish, and greenish-white. It occurs massive, stalactitic, reniform, botryoidal, in crusts; also in radiated, fibrous, and granular distinct concretions; and crystallized. It is shining, translucent, brittle, and easily frangible.

Chemical Characters.—It intumesces before the blowpipe, but does not phosphoresce; it dissolves in 2.285 parts of boiling water.

		From Rammelberg.	Ditto.
Constit. Parts—	Oxide of Zinc	27.5	21.739
	Oxide of manganese	0 5	6.522
	Sulphuric acid	22.0 }	71.739
	Water .	56.0 }	
		100.0	100

Klaproth, Beit. b. v. s. 196. *Herz.* Archiv. b. iii. s. 537.

Geognostic and Geographic Situations.—It occurs in repositories that contain blende, and appears to be formed by the decomposition of that mineral. It occurs at Holywell in Flintshire; and it is said also in Cornwall.

Uses.—It is used as a medicine; is employed in great quantities by varnishers to make oil drying; and a fine white colour named *Zinc-white*, which is more durable than white-lead, is prepared from it. To prepare this colour, the salt is dissolved in water, and the white oxide, which is the zinc-white, is precipitated from it by means of potash or chalk.

*Red vitriol, or sulphate of cobalt, *Jameson*.—Kobaltvitriol, *Werner*

External Characters.—Colour flesh-red, inclining to rose-red. Occurs coralloidal, stalactitic, in crusts; also in granular distinct concretions. Surface rough, and longitudinally furrowed. Dull, and seldom shining on the surfaces of the distinct concretions, and the lustre is pearly. Fracture earthy. Fragments blunt-edged. Opaque. Affords a yellowish-white streak. Easily friable, and brittle. Taste styptic.

Chemical Characters.—Its solution affords, with carbonate of potash, a pale-bluish precipitate, which tinges borax of a pure blue colour.

Constituent Parts.—Oxide of cobalt	38 71	
Sulphuric acid	19 74	
Water .	41 55	—100.00

Kopfe, in Journal fur di Chemie. Physik et Mineralogie. b. vi. Heft 1. 1808, s. 157.

Geognostic and Geographic Situations.—It occurs in mining-heaps in Biber, along with lamellar heavy-spar, earthy cobalt, and grey cobalt; and it has been also found in the Leogang at Salzburg.

Genus VII. SAL AMMONIAC.

Many axes. Cleavage tessular. Taste sharp and urinous. Hardness=1.5—2. sp. gravity, 1.5.—1.6.

1. Octahedral Sal Ammoniac, *Jameson*.—Octaedrisches Salmiac Salz, *Mohs*. Natürlicher Salmiack, *Werner*.

Tessular. Cleavage octahedral.

This species is divided into two subspecies, viz. Volcanic sal ammoniac, and conchoidal sal ammoniac.

First Subspecies.

Volcanic Sal Ammoniac, *Jameson*.—Vulcanischer Salmiak. *Karsten*.

External Characters.—Colours yellowish and greyish-white; pearl-grey and smoke-grey; wine-yellow; sometimes apple-green, sulphur-yellow, and brownish-black. Occurs in efflorescences, crusts, stalactitic, small botryoidal, tuberose, corroded, also in granular concretions, and caystallized figures. Crystals small and very small; and lateral planes usually smooth. Externally dull or glistening; internally shining and vitreous. Alternates from transparent and opaque. Slightly ductile and elastic.

Chemical Characters.—When moistened, and rubbed with quicklime, it gives out a pungent ammoniacal odour.

	Sal Ammoniac of Vesuvius.
Constituent Parts.—Muriate of ammonia,	99 5
Muriate of soda	0.5—100.0

Klaproth, Beit. b. iii. s. 91.

Geognostic Situation.—As its name implies, it is a volcanic production, occurring in the fissures, or on the surface of volcanic, or pseudo-volcanic rocks.

Geographic Situation.—*Europe*.—It occurs in the vicinity of burning beds of coal, both in Scotland and England. It is found in the island of Iceland. On the continent it is met with at Solfatara, Vesuvius, Ætna, the Lapari Islands, and Tuscany.

Asia.—Thibet, Persia, and the Isle of Bourbon.

America.—In volcanic districts both in North and South America.

Second Subspecies.

Conchoidal Sal Ammoniac, *Jameson*.—Muschlicher Salmiak, *Karsten*.

External Characters.—Colour greyish-white. Occurs in angular pieces. Surface is uneven. Externally glimmering; internally shining and vitreous. Fracture nearly perfect conchoidal. Fragments indeterminate angular. Semi-transparent or transparent. Malleable. Soft. Light. Taste pungent and urinous.

Constituent Parts.—Muriate of ammonia	97.50
Sulphate of ammonia	2.50—100.

Klaproth, Beit. b. iii. s. 94.

Geognotsic and Geographic Situations.—This mineral is said to occur, along with sulphur, in rocks of indurated clay or clay-slate, in the country of Bucharia.

Uses.—This salt is used for a variety of purposes. Great quantities of artificial sal ammoniac are annually exported from this country to Russia, where it appears to be used by dyers. It is employed by copper-smiths, to prevent the oxidation of the surface of the metals they are covering with tin. It renders many metallic oxides volatile, and is frequently used to separate metals from each other.

* Mascagnine, or Sulphate of Ammonia.—Mascagnin, *Karsten*.

External Characters.—Colours yellowish-grey, lemon-yellow. Occurs in meally crusts, or stalactitic. Internally dull or glistening. Fracture uneven or earthy. Semi-transparent or opaque. Taste sharp and bitter.

Chemical Characters.—It is easily soluble in water; partly volatilised by heat; and becomes moist on exposure to the air.

Constituent Parts.—It is a compound of ammonia, sulphuric acid, and water.

Geognostic and Geographic Situations.—It occurs among the lavas of Ætna and Vesuvius; in the Solfatara by Puzzæolo; in the lagunes, near Siena in Tuscany; and on the bottom of a hot spring in Dauphiny.

Genus VIII. ROCK-SALT.

Steinsalz, *Werner* and *Mohs*.

Many axes. Cleavage tessular. Taste saline. Hardness=2.0—2.5. Sp. gravity=2.1, 2.2.

1. Hexahedral Rock-Salt, *Jameson*.—Hexaedrisches Steinsalz. *Mohs*.

Tessular. Cleavage hexahedral.

This species is divided into two subspecies, viz. rock-salt and lake-salt.

First Subspecies.

Rock-Salt. Steinsalz, *Werner*.

This subspecies is divided into two kinds, viz. Foliated rock-salt and fibrous rock-salt.

First Kind.

Foliated Rock-Salt, *Jameson*. Blättriches Steinsalz, *Werner*.

External Characters.—Its most common colours are white and grey. Of white, it occurs greyish, yellowish, and milk-white; but it seldom approaches to snow-white. Of grey, ash, smoke, and pearl-grey. From pearl-grey it passes, though rarely, into flesh, blood, and brick red. Still seldomer do we observe the white varieties marked with Berlin, azure, violet, or lavender blue spots or patches. It is said also to occur ochre-yellow, wine-yellow, and emerald-green. It occurs massive, disseminated, in minute veins, in crusts, plates, and stalactitic ; also in distinct concretions, which are large, coarse, small, and fine angulo-granular, and these sometimes incline to prismatic.* On the fresh fracture shining or resplendent, lustre resinous. Fracture conchoidal. Fragments cubic. In general it is strongly translucent, sometimes semi-transparent and transparent. Feels rather greasy. Rather brittle, and easily frangible.

Second Kind.

Fibrous Rock-Salt, *Jameson.* Fasriges Steinsalz, *Werner.*

External Characters.—Colours greyish, yellowish, and snow white ; from these it passes into ash and smoke grey ; more rarely it is marked with stripes of flesh red, violet, sky, and Berlin blue. Occurs massive and dentiform ; also in distinct concretions, which are coarse and fine, and straight and curved fibrous. Internally it is shining and glistening, and the lustre is resinous. The fragments are splintery. Strongly translucent, verging on semi-transparent. In other characters it resembles the preceding kind.

Chemical Characters.—It decrepitates briskly when exposed to the action of the blow-pipe, or when laid on burning coals.

		Cheshire Rock-Salt.
Constituent Parts.—	Muriate of soda	$983\frac{1}{4}$
	Sulphate of lime	$6\frac{1}{2}$
	Muriate of magnesia	$0\frac{3}{16}$
	Muriate of lime	$0\frac{1}{16}$
	Insoluble matter	10—1000.0

Henry, *Philosophical Transactions* for 1810, pt. i. p. 97.

Geognostic Situation.—It occurs in transition rocks in Switzerland, and in secondary rocks in Germany, England, and South America.

Geographic Situation.—*Europe.*—The principal deposite of salt in this island is that in Cheshire, where there are several beds that vary in thickness from four feet to upwards of one hundred and thirty feet, and alternate with clay and marl, which contain compact, foliated, granular, and radiated gypsum. Rock-salt also occurs at Droitwich in Worcestershire ; and in Germany, France, Hungary, and Spain.

Africa.—Besides the great beds of this mineral found in Europe, it is also very extensively distributed in other quarters of the globe. In the northern part of Africa, on both sides of the Atlas Mountains, vast quantities of rock-salt occur. In the valley of Egarement there are beds of rock-salt resting on gypsum. Mr. Horneman, on his journey from Cairo to Ummosogeir, discovered a plain on the summit of the chain of limestone mountains that bound the desert of Lybia to the north, consisting of a mass of rock-salt, spread over so large a tract of surface, that in one direction no eye could reach its termination, and its width he computed at several miles. To the south-east of Abyssinia, there is a plain of rock-salt four days journey across, whence all that country is supplied.† At Tegazza, and in several other places in Sahara, very large beds of pure rock-salt occur under strata of different kinds of solid rock ; and beds of salt appear at Darfur, and in the country of Congo.

Asia.—There is a considerable mine of rock-salt twenty versts from Jena-Tayerska, in the desert between the Volga and the Uralian Mountains; another named Iletzki near Astracan ; and there are several others in Siberia.‡ Salt mines are worked in that part of China which borders on Tartary. At Teflis, Tauris, and other places in Persia, there are great masses of rock-salt; and we are informed, that in the desert of Caramania, and also in Arabia, rock-salt is so abundant, and the atmosphere is so dry, that the inhabitants use it for building houses. The Island of Ormuz, situated in the mouth of the Persian Gulf, is principally composed of rock-salt. Rock-salt is one of the mineral productions of the valley of Cashmere ; and in the province of Lahore, in India, there is a hill of rock-salt equal to that of Cordona ; the salt of this hill is cut into dishes, plates, and stands for lamps.

America.—Rock-salt is found in vast quantity on the elevated deserts of Peru, where it is very hard, and has usually a violet colour ; also in the Cordilleras of New Granada, at the height of 2000 toises. It occurs in considerable quantity in Upper Louisiana ; and great masses of it have been found at the junction of the stream of Atha-pus-caou with the Atha-pus-caou lake ; and in California.

New Holland.—According to Governor Hunter, it is found in considerable quantity on the east coast of New Holland.

Uses.—Its uses are very various and important. We make use of it daily as a seasoning for our food : vast quantities are employed for the preservation of animal flesh, butter, &c. ; it is also used in the manufacture of earthen ware, soap-making, and in many metallurgic operations. It affords muriatic acid and soda by certain chemical processes. It is sometimes employed in its crude state, but is more commonly purified.

Second Subspecies.

Lake-Salt, *Jameson.*—Seesalz, *Werner.*

External Characters.—Colour greyish-white. Occurs in coarse and small roundish grains. Internally shining or glistening, and the lustre resinous. Fracture is imperfect foliated. In other characters it agrees with the other subspecies.

Geognostic and Geographic Situations.—It is found on the bottoms and sides of salt-lakes. In Europe, Asia, and also in Africa and America.

CLASS II.

Tasteless. Specific gravity above 1.8.

Order I.—HALOIDE.

No metallic lustre. Streak not changed in the colour.

Cleavage.—If in the direction of a four-sided prism, the hardness is equal to four and less : if axifrangible and prismatoidal, the hardness and specific gravity are below 3. Hardness ranges from 1.5 to 5. If the hardness is less than 2.5, the specific gravity will be 2.4 and

* Some authors describe rock-salt in globular and columnar concretions.

† Bruce mentions, that in some parts of Abyssinia, cubic pieces of rock-salt pass as current coin.

‡ Pallas speaks of rock-salt in the neighbourhood of the river Jaik, which is sometimes so hard as to snap the pick-axes made use of in quarrying it.

less. Specific gravity ranges from 2.2 to 3.2. If less than 2.4, the hardness will be 2.4, and less.

Genius. I.—GYPSUM.

Three axes . Cleavage prismatic. Hardness =1.5—3.5. Sp. gr. =2.2—3.0.

1. Axifrangible Gypsum, *Jameson*.—Axentheilendes Gyps-Haloide, *Mohs*.

Prism =113° 8′. Cleavage perpendicular to the axis, or axifrangible. Hardness =1.5—2.0. Sp. gr. =2.2 2.4.

This species contains six subspecies, viz. Sparry Gypsum or Selenite, Foliated Granular Gypsum, Compact Gypsum, Fibrous Gypsum, Scaly Foliated Gypsum, and Earthy Gypsum. *Montmartrite.

First Subspecies.

Sparry Gypsum or Selenite, *Jameson*.—Fraueneis, *Werner*.

External Characters.—Colours smoke-grey, greyish-white, snow-white, greenish-white, and yellowish-white, and also wax-yellow, pale ochre-yellow, and yellowish-brown. Sometimes dark-brown, owing to intermixed stinkstone. Some varieties display iridescent colours. Occurs massive, coarsely disseminated, also in distinct concretions, which are large and coarse granular, and sometimes inclining to thick lamellar; and crystallized. The following are some of the secondary figures:

1. Six-sided prism. 2. Lens. 3. Twin-crystals. These are either formed by two lenses, which are attached by their faces, or by two six-sided prisms pushed into each other in the direction of their breadth, in such a manner, that the united summits at one extremity form a re-entering angle, but at the other a salient angle, or four-planed acumination. When two such twin-crystals are pushed into each other in the direction of their length, a 4. Quadruple crystal is formed.

Lateral planes of the prism sometimes smooth, sometimes longitudinally streaked, and shining; the convex terminal faces, and lens, are rough and dull. Internally, lustre splendent and pearly. Cleavage threefold; the most distinct cleavage perpendicular to the axis of the prism; the other two parallel with the lateral planes of the primitive prism. Cleavages generally straight, and sometimes curved. Fragments rhomboidal, in which two of the sides are smooth and splendent, and four are streaked and shining. Alternates from semi-transparent to transparent, and in the latter case is observed to refract double. Sectile. Very easily frangible. In thin pieces flexible, but not elastic.

Chemial Characters.—Exfoliates before the blowpipe, and, if the flame is directed towards the edge of the folia, it melts into a white enamel, which, after a time, falls into a white powder.

Constituent Parts.—Lime,	. .	33.9
	Sulphuric Acid	43.9
	Water . .	21.0
	Loss, . .	2.1—100.0

Bucholz, in Gehlen's Journ. b. v. s. 158.

Geognostic Situation.—Occurs principally in the secondary or flœtz gypsum formation, in thin layers: less frequently in rock-salt; more rarely as a constituent part of metalliferous veins; but in considerable quantity in that deposite known in the south of England under the name of Blue or London Clay. Crystals of this substance are daily forming in gypsum hills, in old mines, and in mining heaps.

Geographic Situation.—It is not unfrequent in the blue clay in the south of England, as at Shotover Hill, near Oxford, and occurs in the secondary gypsum around Paris.

Uses.—At a very early period, before the discovery of glass, selenite was used for windows; and we are told, that, in the time of Seneca, it was imported into Rome from Spain, Cyprus, Cappadocia, and even from Africa. It is used for the finest kind of stucco, and the most delicate pastil colours. When burnt, and perfectly dry, it is used for cleansing and polishing precious stones, work in gold and silver, and also pearls.

Second Subspecies.

Foliated Granular Gypsum, *Jameson*.—Blættrigger Gyps, *Werner*.

External Characters.—Most common colours white, grey, and red; seldomer yellow, brown, and black. Occurs massive, also in granular and prismatic distinct concretions. Sometimes crystallized in small conical lenses, in which the surface is rough. Lustre passes from shining through glistening to glimmering, and is pearly. Has the same cleavage as selenite. Fragments very blunt edged. Translucent. Sectile, and very easily frangible.

Constituent Parts.—Lime,	.	32
	Sulphuric Acid,	30
	Water .	38—98 *Kirwan*.

Geognostic Situation.—It occurs in beds in primitive rocks: in a similar repository in transition clay-slate; but most abundantly in beds in rocks of the secondary or flœtz class.

Geographic Situation.—It occurs in Cheshire and Derbyshire; at the Segeberg, near Kiel; and at Lunebürg, where it contains crystals of boracite, and sometimes of quartz; and in many other parts of Europe.

Uses.—The foliated and compact subspecies of gypsum, when pure, and capable of receiving a good polish, are by artists named simply *Alabaster*, or, to distinguish them from calc-sinter, or what is called calcareous alabaster, *Gypseous Alabaster*. The finest white varieties of granular gypsum are selected by artists for statues and busts: the variegated kinds are cut into pillars, and various ornaments, for the interior of halls and houses; and the most beautiful variegated sorts are cut into vases, columns, plates, and other kinds of table furniture. Those varieties that contain imbedded portions of selenite, when cut across, exhibit a beautiful iridescent appearance, and are named *Gypseous Opal*. In Derbyshire, and also in Italy, the very fine granular varieties are cut into large vases, columns, watch-cases, plates, and other similar articles. Both subspecies are used in agriculture. Much difference of opinion has prevailed among agriculturists with respect to the uses of gypsum. It is said to have been very advantageously employed in America, and also in the county of Kent; but it has failed in most of the other counties of England, though tried in various ways, and for different crops. When peat-ashes contain a considerable portion of gypsum, they may be advantageously employed as a top-dressing for cultivated grasses, on such soils as contain little or no sulphate of lime. The pure white varieties of granular gypsum are used as ingredients in the composition of earthen-ware and porcelain; and the glaze or enamel with which porcelain is covered, has the purest gypsum, or even selenite, as one of its ingredients. Its most important use is in the preparation of *stucco.*

Third Subspecies.

Compact Gypsum, *Jameson.*—Dichter Gyps, *Werner.*

External Characters.—Colours white, grey, blue, red, and sometimes honey-yellow. Occurs massive. Generally dull, seldom feebly glimmering. Fracture fine splintery, passing on the one side into even, on the other into fine-grained uneven. Fragments indeterminate angular, and blunt-edged. Translucent on the edges.

Chemical Characters.—All the different varieties of gypsum, when exposed to heat, are deprived of their water of crystallization, become opaque, fall into a powder, which, when mixed with water, speedily hardens on exposure to the air. They are difficultly fusible before the blowpipe, without addition, and melt into a white enamel: when heated with charcoal, they are converted into sulphuret of lime.

Constituent Parts.—Lime,	.	34
Sulphuric acid,		48
Water,	.	18—100 *Gerhard.*

Geognostic Situation.—Occurs in beds, along with granular gypsum, selenite, and stinkstone, in the flœtz or secondary class of rocks.

Geographic Situation.—Occurs in the Campsie Hills; Derbyshire; Ferrybridge in Yorkshire; and Nottinghamshire.

Fourth Subspecies.

Fibrous Gypsum, *Jameson.*—Fasriger Gyps, *Werner.*

External Characters.—Principal colours white, grey, red, and yellow. Occurs massive, and dentiform; also in fibrous distinct concretions, which are parallel, generally straight, and sometimes curved. Lustre passes from glistening, through shining to splendent, and is pearly. Fragments are long splintery. Translucent.

Constituent parts.—Lime,	. .	33.00
Sulphuric Acid,		44.13
Water,	. .	21.00—98.13

Bucholz, N. Allg. Journ. d. Chem. b. v. H. ii. s. 160.

Geognostic Situation.—It occurs along with the other subspecies of this species.

Geographic Situation.—It occurs in red sandstone, near Moffat; in red clay, on the banks of the Whitadder in Berwickshire; in Dunbartonshire; also in Cumberland, Yorkshire, Cheshire, Worcestershire, Derbyshire, Somersetshire, and Devonshire.

Uses.—When cut *en cabochon*, and polished, it reflects a light not unlike that of the cat's-eye, and is sometimes sold as that stone. It is also cut into necklaces, ear pendents, and crosses; and in this form it is also sold for a harder mineral, the Fibrous Limestone, or even imposed on the ignorant for that variety of felspar named Moonstone.

Fifth Subspecies.

Scaly Foliated Gypsum, *Jameson.*—Schaumgyps, *Werner.*

External Characters.—Colours yellowish-white and snow-white. Occurs massive and disseminated; also in distinct concretions, which are small and scaly granular. Internally glistening and pearly. Fracture small scaly foliated. Fragments indeterminate angular, and blunt-edged. Opaque, or translucent on the edges. Sectile, and easily frangible.

Geognostic and Geographic Situations.—It occurs with selenite and compact gypsum at Montmartre, near Paris, in that formation of gypsum named by Werner the third or yellow flœtz gypsum formation

Sixth Subspecies.

Earthy Gypsum, *Jameson.*—Gyps-erde, *Werner.*

External Characters.—Colour yellowish-white, which passes into yellowish-grey, and sometimes inclines to snow-white. Composed of fine scaly or dusty particles, which are more or less cohering. Feebly glimmering. Feels meagre, and rather fine. Soils slightly. Light.

Geognostic Situation.—It is found immediately under the soil, in beds several feet thick, resting on gypsum, and also in nests or cotemporaneous masses imbedded in it.

Geographic Situation.—It is found in Saxony, Switzerland, Salzburg, and Norway.

*Montmartrite.—Chaux sulphatée calcarifere, *Lucas & Huay.* Gypsum of Montmartre.

External Characters.—Colour yellowish. Occurs massive, but never crystallized. Soft. Effervesces with nitric acid.

The Montmartrite is composed of gypsum and carbonate of lime. This carbonate is converted into quicklime in the furnace, and thus a kind of mortar is formed: it is on this account, that the *plaster* made of this mineral may be used in work exposed to the weather; while that of pure gypsum, on exposure, soon yields to the action of rain. The montmartrite contains about—

Sulphate of Lime,	83
Carbonate of Lime,	17—100

II. Prismatic Gypsum, or Anhydrite, *Jameson.*—Prismatisches Gyps-Haloide, *Mohs.*—Muriacit, *Werner.*

Prism=100° 8′. Three cleavages, perpendicular to each other. Hardness=3.0—3.5. Specific gravity=2.7—3.0.

It is divided into five subspecies, viz. Sparry Anhydrite, Scaly Anhydrite, Fibrous Anhydrite, Conchoidal Anhydrite, Compact Anhydrite. *Vulpinite. *Glauberite.

First Subspecies.

Sparry Anhydrite, or Cube-Spar, *Jameson.*—Wurfelspath, *Werner.*

External Characters.—Chief colour white, which passes on the one side into blue, and on the other into red. Occurs massive; also in distinct concretions, which are thin and straight lamellar, collected into others which are large granular. Sometimes crystallized in the following figures.

1. Rectangular four-sided prism: it is sometimes so low as to appear as a four-sided table. 2. Broad six-sided prism. 3. Eight-sided prism. 4. Broad rectangular four-sided prism, acuminated on the extremities with four planes, which are set on the lateral edges, and the apex of the acumination deeply truncated.

Externally shining or splendent, and pearly: internally splendent and pearly. Fragments cubical. Fracture conchoidal. Alternates from transparent to strongly translucent, and refracts double. Brittle, and very easily frangible.

Chemical Characters.—When exposed to the blowpipe, it does not exfoliate, and melt like gypsum, but becomes glazed over with a white friable enamel.

	From Bern.	From Tyrol.
Constit. Parts. Lime	40	41 75
Sulphuric Acid,	60	55.00
Muriate of Soda,		1.00
	100	97.75
	Hauy, Traité, t. iv. p. 349.	*Klaproth*, Beit. b. iv. s. 235.

Geognostic and Geographic Situations.—It is sometimes met with in the gypsum of Nottinghamshire. In the salt-mines of Hall in the Tyrol, and in other countries.

Second Subspecies.

Scaly Anhydrite, *Jameson.*—Anhydrite, *Werner.*

External Characters.—Colours white, smalt-blue, and rarely grey. Occurs massive, and in small granular concretions. Lustre splendent and pearly. Cleavage imperfect and curved. Fragments not particularly blunt-edged. Translucent on the edges. Easily frangible.

Constituent Parts.—Lime, 41.75
Sulphuric Acid, 55.00
Muriate of Soda, 1.00—97.75
Klaproth, Beit. b. iv. s. 235.

Geognostic and Geographic Situations.—It is found in the salt-mines of Hall in the Tyrol, 5088 feet above the level of the sea.

Third Subspecies.

Fibrous Anhydrite, *Jameson.*—Fasriger Muriacit, *Werner.*

External Characters.—Colours red; also blue and grey. Occurs massive, and in coarse fibrous concretions, which are straight or curved, and sometimes stellular. Internally glimmering and glistening, and pearly. Fragments long splintery. Translucent on the edges, or feebly translucent. Rather easily frangible.

Geographic Situation.—It is found in the salt-mines of Berchtesgaden, and at Ischel in Upper Austria, at Hall in the Tyrol, Salz on the Neckar, Carinthia, and Tiede near Brunswick.

Uses.—The blue varieties are sometimes cut and polished for ornamental purposes.

Fourth Subspecies.

Convoluted Anhydrite, *Jameson.*—Gekröstein, *Werner.*

External Characters.—Colour dark milk-white. Occurs massive; also in distinct concretions, which are thick lamellar, and intestinally convoluted or contorted, and these are again composed of others which are thin prismatic. Internally glistening or glimmering, and the lustre pearly. Fracture small and fine splintery. Fragments indeterminate angular, and rather sharp-edged. Translucent on the edges, or translucent.

Constituent Parts.—Lime, 42.00
Sulphuric Acid, 56.50
Muriate of Soda, 0.25—98.75
Klaproth, Beit. b. iv. s. 233.

Geognostic and Geographic Situations.—It occurs in the salt-mines of Bochnia and at Wieliczka in Poland.

Observations.—It was first described as a variety of compact heavy spar, and is by many named *Pierre de Tripes*, from its convoluted concretions.

Fifth Subspecies.

Compact Anhydrite, *Jameson.*—Dichter Muriacit, *Werner.*

External Characters.—Colours bluish-white, and tile-red. Sometimes with spotted delineations. Occurs massive; also in granular distinct concretions. Feebly glimmering, or dull. Fracture small splintery, passing into even and flat conchoidal. Fragments more or less sharp-edged. Alternates from translucent to translucent on the edges.

Constituent Parts.—Lime, 41.48
Sulphuric Acid, 56 28
Water, 0.75—100.00
Rose, in Karsten's Tabellen.

Geognostic and Geographic Situations.—It occurs in beds in the salt mines of Austria and Salzburg; and also in secondary gypsum, on the eastern foot of the Hartz mountains.

*Vulpinite.

External Characters.—Colour greyish-white, and veined with bluish-grey. Occurs massive. Internally splendent. Fracture foliated. Fragments rhomboidal. Occurs in granular distinct concretions. Translucent on the edges. Brittle. Easily frangible.

Chemical Characters.—It melts easily before the blowpipe into a white opaque enamel; and becomes feebly phosphorescent when thrown on glowing coals.

Constituent Parts.—Sulphate of Lime, 92.0
Silica, 8.0—100.0
Vauquelin. in Bulletin des Sciences de la Société Philomatique, N. 9.; Journal de Physique, t. xlvii. p. 101.; Journal des Mines, N. xxxiv.

Geognostic and Geographic Situations.—It occurs along with granular foliated limestone, and is sometimes associated with quartz, and occasionally with sulphur. It is found at Vulpino in Italy.

Uses.—1. It takes a very fine polish, and is employed by the statuaries of Bergamo and Milan for making slabs, chimney-pieces, &c. It is known to artists by the name *Marmo bardiglio di Bergamo*. 2. It was first particularly noticed by Fleuriau.

*Glauberite.—Glauberite, *Brongniart.*

External Characters.—Colours greyish-white, and wine-yellow. Occurs crystallized, in very low oblique four-sided prisms, the lateral edges of which are 104° 28′ and 75° 32′, and in which the terminal planes are set on obliquely. Crystals occur singly, or in groups. Lateral planes transversely streaked; the terminal planes smooth. Shining. The fracture parallel with the terminal planes and edges is foliated; in other directions it is conchoidal. Softer than calcareous spar. Transparent. Brittle. Specific gravity 2.700.

Chemical Characters.—It decrepitates before the blowpipe, and melts into a white enamel. In water it becomes opaque, and is partly soluble.

Constituent Parts.—Dry Sulphate of Lime, 49.0
Dry Sulphate of Soda, 51.0
100.0
Brongniart. J. des Mines, t. xxiii. p. 17.

Geognostic and Geographic Situations.—It is found imbedded in rock-salt at Villaruba, near Ocana in New Castile, in Spain.

Observations.—It was brought from Spain to Paris by M. Dumeril, and first analyzed and described by Brongniart.

Genus II.—CRYOLITE.

Eis-Haloide, *Mohs.*

One axis. Cleavage pyramidal. One perpendicular cleavage, and other two less perfect. Hardness =2.5—3.0. Specific gravity =2.9—3.

1. Pyramidal Cryolite, *Jameson.*—Pyramidales Eis-Haloide, *Mohs.*

Pyramid unknown. The most perfect cleavage is parallel with the terminal planes of a rectangular four-sided prism; another less distinct, parallel with the diagonals of a rectangular four-sided prism; and a third, still less perfect, parallel with the planes of the pyramid.

External Characters.—Colours pale greyish-white, snow-white, yellowish-brown, and yellowish-red. Occurs massive, disseminated, and in straight and thick lamellar distinct concretions. It is shining, inclining to glistening, and the lustre is vitreous, inclining to pearly. Fracture uneven. Fragments cubical or tabular. Translucent. Brittle, and easily frangible.

Chemical Characters.—It becomes more translucent in water, but does not dissolve in it. It melts before it reaches a red heat, and when simply exposed to the flame of a candle. Before the blowpipe, it at first runs into a very liquid fusion, then hardens, and at length assumes the appearance of a slag.

Constit. Parts.—		
Alumina,	24.0	21.0
Soda,	36.0	32.0
Fluoric Acid, and Water,	40.0	47.0
	100.0	100.0
	Klaproth, Beit. b. iii. s. 214	*Vauquelin*, Hauy, Traié. t. ii. p. 400.

Geognostic and Geographic Situations.—This curious and rare mineral has been hitherto found only in West Greenland, and but in one place of that dreary and remote region, viz. the Fiord or arm of the sea named Arksut, situated about thirty leagues from the colony of Juliana Hope, where it occurs in two thin layers in gneiss.

Genus III. ALUM-STONE.

Thon Haloide, *Mohs.* Alaunstein, *Werner.*

One Axis. Cleavage rhomboidal. Hardness =5.0. Sp. gr. =2.4.—2.6.

1. Rhomboidal Alumstone, *Jameson.*—Rhombœdrishes Thon Haloide, *Mohs.*

Rhomboid unknown. The most distinct cleavage parallel with the sides of a rhomboid; another, less distinct, parallel with the terminal plane of a six-sided prism.

External Characters.—Colours white, pale flesh-red, and more rarely pearl-grey and bluish-grey. Sometimes several of these colours occur together in spotted, striped, and veined delineations. Occurs massive, sometimes porous, or nearly vesicular, with the walls lined with small crystals. Internally it is dull, or feebly glimmering. Fracture coarse, small grained uneven, which passes into splintery, earthy, and flat conchoidal. Fragments indeterminate angular, and rather sharp-edged. Feebly translucent on the edges. Brittle and easily frangible.

Constituent Parts.

		Alumstone from Tolfa.	Hungarian Alumstone.
Alumina,	43.92	19.00	17.50
Silica,	24.00	56.50	62.25
Sulphuric Acid,	25.00	16.50	12.50
Potash,	3.08	4.00	1.00
Water,	4.00	3.00	5.00
		99.00	98 25
	Vauquelin.	*Klaproth*, Beit. b. iv. s. 252	*Klaproth*, Id. s. 256.

Geognostic and Geographic Situations.—It occurs at Tolfa, near Civita Vecchia, in nests, kidneys, and small veins, in a flœtz or secondary rock. The Hungarian varieties are found in beds at Bergszaz and Nagy-Begany, in the country of Beregher, in Upper Hungary.

Uses.—Alum is obtained from this mineral, by repeatedly roasting it, then lixiviating it, and crystallizing the solution thus obtained.

Genus IV. FLUOR.

Many axes. Cleavage octahedral. Hardness = 4.0. Sp. gr. = 3.0, 3.1.

This genus contains but one species, viz. Octahedral Fluor.

1. Octahedral Fluor, *Jameson.*—Flus, *Werner.* Octaedrisches Flus Haloide, *Mohs.*

Tessular. Cleavage octahedral. Hardness = 4.0.

It is divided into three subspecies, Compact Fluor, Foliated Fluor, and Earthy Fluor.

First Subspecies.

Compact Fluor, *Jameson.*—Dichter Flus, *Werner.*

External Characters.—Colours greenish-grey, greenish-white, brownish-red, mountain-grey, and greenish-black. Occurs massive. Externally and internally dull, or feebly glimmering. Fracture even, passes on one side into small splintery, on the other into flat conchoidal. Fragments rather sharp-edged. More or less translucent. Brittle, and easily frangible.

Chemical Characters.—The chemical characters are those of the following subspecies.

Geognostic and Geographic Situations.—It is found in veins, associated with fluor-spar, at Stolberg, in the Hartz.

Second Subspecies.

Foliated Fluor, *Jameson.*—Flus-Spath, *Werner.*

External Characters.—Most common colours white, yellow, green and blue, seldomer red, grey, brown, and least frequently black. Colours of all degrees of intensity, and sometimes pieces occur spotted or striped. Green cubes occur with blue angles, &c. Some colours, as sky-blue, fade by keeping, particularly in warm places. Occurs massive, disseminated, also in distinct concretions, which are large, coarse, small, and fine granular, sometimes straight prismatic, which are traversed by others that are thick and fortification-wise curved lamellar. Striped colour delineation in the direction of these concretions. It occurs crystallized, in the following figures:

1. Cube. 2. Cube, truncated on all the edges. 3. The rhomboidal or garnet dodecahedron. 4. Cube, with truncated angles. 5. Octahedron, or regular double four-sided pyramid. 6. Cube, with bevelled edges.

7. Cube, in which all the angles are acuminated with three planes, which are set on the lateral planes. 8. Cube, in which all the angles are acuminated with six planes, which are set on the lateral planes.

Cubes vary from very large to very small; the other crystals are only small and middle sized. Crystals generally placed on one another, and form druses; but are seldom single. Surface smooth and splendent, or drusy and rough, as in the rhomboidal dodecahedron, and some octahedrons. Internally the lustre is specular-splendent, or shining and vitreous. Fragments octahedral or tetrahedral. Alternates from translucent to transparent, and refracts single. Is brittle, and easily frangible.

Chemical Characters.—Before the blowpipe it generally decrepitates, gradually loses its colour and transparency, and melts, without addition, into a greyish-white glass. When two fragments are rubbed against each other, they become luminous in the dark. When gently heated, or laid on glowing coal, it phosphoresces, (particularly the sky-blue, violet-blue, and green varieties,) partly with a blue, partly with a green light. When brought to a red-heat, it is deprived of its phosphorescent property. The violet-blue variety from Nertschinsky, named *Chlorophane*, when placed on glowing coals, does not decrepitate, but soon throws out a beautiful verdigris-green and apple-green light, which gradually disappears as the mineral cools, but may be again excited, if it is heated; and this may be repeated a dozen of times, provided the heat is not too high. When the chlorophane is exposed to a red-heat, its phosphorescent property is entirely destroyed. Pallas mentions a pale violet blue variety spotted with green, from Catharinenburg, which is so highly phosphorescent, that, when held in the hand for some time, it throws out a pale whitish light; when placed in boiling water, a green light; and exposed to a higher temperature, a bright blue light. When sulphuric acid is added to heated fluor-spar, in the state of powder, a white penetrating vapour (the fluoric acid) is evolved, which has the property of corroding glass.

Constituent Parts.

	Northumberland.	Gersdorf.	Gersdorf.
Lime	67.34	67.75	65.0
Fluoric Acid	32.66	32.25	35.0
	100 00	100.00	100.0
	Thomson, in Wern. Mem. vol. i. p. 11.	*Klaproth*, Beit. b. iv. s. 365.	*Richter*, Uber die Neuren Gegnest. v. Chem. b. iv. s. 25.

Geognostic Situation.—It occurs principally in veins that traverse primitive, transition, and sometimes secondary rocks; also in beds, associated with other minerals; in kidneys in secondary limestone; and in drusy cavities in trap-rocks.

Geographic Situation.—*Europe.* Fluor-spar is a rare mineral in Scotland, having been hitherto found only in four places, viz. near Monaltree in Aberdeenshire, where it is contained in a small vein of galena or lead-glance which traverses granite; in gneiss in Sutherland; in secondary porphyry near the village of Gourock in Renfrewshire; and in the island of Papa Stour, one of the Shetland islands, in small quantity, in a trap-rock. It occurs much more abundantly in England, being found in all the galena veins that traverse the coal formation in Cumberland and Durham; in great quantities, and often associated with galena, in veins or kidneys, in secondary or flœtz limestone, in Derbyshire; and it is the most common vein-stone in the copper, tin, and lead veins that traverse granite, clay-slate, &c. in Cornwall and Devonshire.

Uses.—On account of the variety and beauty of its colours, its transparency, the ease with which it can be worked, and the high polish it receives, it is cut into vases, pyramids, and other ornamental articles. The largest masses, and most beautiful varieties for use, are found in Derbyshire, and it is in that county that all the ornamental articles of fluor-spar are manufactured. It is also used by the metallurgist, as a flux for ores, particularly those of iron and copper; and hence the name *fluor* given to it. The acid it contains has been employed in the way of experiment for engraving upon glass.

Third Subspecies.

Earthy fluor, *Jameson.*—Erdiger Fluss, *Karsten.*

External Characters.—Colours greyish white, and violet-blue, and sometimes so deep as almost to appear black. Occurs generally in crusts, investing some other mineral. Dull. Earthy. Friable, passing into very soft.

Constituent Parts.—It is said to be a compound of Lime and fluoric acid.

Geognostic and Geographic Situations.—It occurs in veins, along with fluor-spar, at Beeralston in Devonshire; in limestone, along with fluor-spar and arragonite, in Cumberland.

Genus V.—APATITE.

One axis. Cleavage rhomboidal. Hardness $=5$ 0. Sp. gravity $=3.1$, 3.2.

1. Rhomboidal apatite, *Jameson.*—Rhomboedrischer Flus Haloide, *Mohs.*—Apatit, *Werner.*

Di-rhomboid $=131°$ 49′, 109° 28′. The most perfect cleavage is parallel with the terminal planes of a six-sided prism; another, less distinct, parallel with the sides of a regular six-sided prism. Hardness $=5.0$.

This species is divided into three subspecies, viz. Foliated Apatite, Conchoidal Apatite, and Lamellar Apatite.

First subspecies.

Foliated apatite, *Jameson.*—Geminer Apatite, *Werner.*

External Characters.—Its most frequent colour is white; from greenish-white it passes into mountain-green, celandine-green, light-green, emerald-green, and olive-green. It occurs also red and blue. Sometimes it is pale wine-yellow, and yellowish-brown. Frequently several of these colours occur in the same piece. It sometimes occurs massive and disseminated, also in distinct concretions, which are large and small angulo-granular, and sometimes thin and straight lamellar; generally crystallized. Its secondary figures are the six-sided prism, and six-sided table, variously modified by truncations, bevelments, and acuminations. The crystals are small, very small, and middle-sized; and occur sometimes single, sometimes many irregularly superimposed on each other. The lateral planes are seldom smooth, generally longitudinally streaked; the truncating and acuminating planes are smooth. Externally it is splendent or shining; internally glistening, and the lustre is resinous. Fracture intermediate between uneven and imperfect conchoidal. Fragments indeterminate angular, and rather sharp-edged. Generally translucent; seldom nearly transparent, when it refracts single. Brittle, and easily frangible.

Physical Characters.—It becomes electric by heating, and also by being rubbed with woollen cloth.

Chemical Characters.—When thrown on glowing coals, it emits a pale grass-green phosphoric light. It dissolves very slowly in the nitric acid, and without effervescence. It gradually loses its colour, when heated before the blowpipe, but its lustre and transparency are heightened. It is infusible without addition.

Constituent Parts.	Lime . . .	55
	Phosphoric Acid, and trace of Manganese	45—100

Klaproth, Bergm. Journ. 1788, b. i. s. 269.

Geognostic Situation.—It occurs in tin-stone veins, and also imbedded in talc.

Geographic Situation.—*Europe.*—It occurs in yellow foliated talc, and, along with fluor-spar, in the mine called Stena-Gwyn, in St. Stephen's, in Cornwall, also at St. Michael's Mount, Godolphin-bal in Breage, also in Cornwall; and in various districts on the continent of Europe.

America.—It occurs in grains or hexahedral prisms in granite, near Baltimore, in Maryland; in granite and gneiss, along with beryl, garnet, and schorl, at Germantown in Pennsylvania; in iron-pyrites at St. Anthony's Nose, in the Hudson in New York; in granite, at Milford hills, near New Haven in Connecticut; and at Topsham in Maine, in granite.

Second Subspecies.

Conchoidal Apatite or Asparagus Stone, *Jameson.*—Muschlicher Apatit, *Hausmann.* Spargelstein, *Werner.*

External Characters.—Colours green and wine-yellow, bordering on orange-yellow. Also sky-blue, greenish and yellow-grey, and clove-brown. Sometimes massive and disseminated, also in distinct concretions, which are large granular; but most frequently crystallized, and in the following figures:

1. Equilateral, longish, six-sided prism, acuminated with six planes, which are set on the lateral planes. 2. The same figure, truncated on the lateral edges of the prism.

Crystals middle-sized, small, and very small; sometimes longitudinally streaked, and sometimes traversed by cross rents. Externally crystals splendent and vitreous: internally shining, and resinous. Fracture small and imperfect conchoidal. Fragments rather blunt-edged. Alternates from transparent to translucent. In other characters agrees with the foliated apatite.

Chemical Characters.—Some varieties of this subspecies do not phosphoresce when exposed to heat.

Constituent Parts.

Apatite from Utö.		From Zillerthal.	
Phosphate of Lime,	92 00	Lime, . .	53.75
Carbonate of Lime,	6.00	Phosphoric Acid,	46 25

Manganese a trace.	——		*Klaproth*, Beit. b. iv. s. 197.
	99 50		
	Klaproth, Beit. b. v. s 181.		

Geognostic and Geographic Situations.—*Europe.*—It occurs, imbedded in gneiss, near Kincardine in Ross-shire; also in beds of magnetic ironstone, along with sphene, calcareous-spar, hornblende, quartz, and augite, at Arendal in Norway.

America.—Imbedded in granite at Baltimore; in gneiss at Germantown; and in mica-slate in West Greenland.

Third Subspecies.

Phosphorite, *Jameson.* Phosphorit, *Werner.*

This Subspecies is divided into two Kinds, viz. Common Phosphorite, and Earthy Phosphorite.

First Kind.

Common Phosphorite, *Jameson.* Gemeiner Phosphorit, *Karsten.*

External Characters.—Colour yellowish-white, sometimes approaching to greyish-white. Occasionally spotted pale ochre-yellow, and yellowish-brown. Occurs massive, and in distinct concretions, which are thin and curved lamellar. Surface uneven and drusy. Dull or glistening. Cleavage imperfect curved, and generally floriform. Fracture uneven. Fragments indeterminate angular, and rather blunt-edged. Opaque, or feebly translucent on the edges.

Chemical Characters.—It becomes white before the blowpipe, and, according to Proust, melts with difficulty into a white-coloured glass. When rubbed in an iron mortar, it emits a green-coloured phosphoric light; and the same effect is produced when it is pounded and thrown on glowing coals.

Constituent Parts.—	Lime, ...	59 0
	Phosphoric Acid, .	34.0
	Silica, ...	2.0
	Fluoric Acid, . .	2.5
	Muriatic Acid, .	0.5
	Carbonic Acid, .	1.0
	Oxide of Iron, .	1.0—100.0

Pelletier, Journal des Mines, N. 166.

Geognostic and Geographic Situations.—It occurs in crusts, and crystallized, along with apatite and quartz, at Schlackenwald, in Bohemia, but most abundantly near Leigrosan, in the province of Estremadura, in Spain, where it is sometimes associated with apatite, and forms whole beds, that alternate with limestone and quartz.

Second Kind.

Earthy Phosphorite, *Jameson.* Erdiger Phosphorit, *Karsten.*

External Characters.—Colours greyish-white, greenish-white, and pale greenish-grey. Consists of dull dusty particles, which are partly loose, partly cohering, and which soil slightly, and feel meagre and rough.

Chemical Characters.—It phosphoresces when laid on glowing coals.

	Earthy Phosphorite from Marmarosch.	
Constituent Parts.—	Lime, ...	47 00
	Phosphoric Acid,	32.25
	Fluoric Acid, .	2.50
	Silica, ...	0.50
	Oxide of Iron, .	0.75
	Water, ...	1.00
	Mixture of Quartz and Loam. . .	11.50—95 50

Klaproth, Beit. b. iv. s. 373.

Geognostic and Geographic Situations.—It occurs in a vein, in the district of Marmarosch in Hungary.

Genus VI. LIMESTONE.

Kalk-Haloide. *Mohs.*

One and three axes. Cleavage di-prismatic; rhomboidal. Hardness ranges from 3.0 to 4.5. Sp. gr. = 2.5 — 3.2.

This genus contains four species, viz. 1. Prismatic or Arragonite. 2. Rhomboidal, or calcareous spar. 3. Short-axed, including dolomite and several varieties of rhomb-spar. 4. Long-axed. Rhomb-spar in part.

I. Prismatic Limestone, or Arragonite, *Jameson.* Prismatischer Kalk-Haloide, *Mohs.* Arragon, *Werner.*

Vertical prism = 115° 56′; horizontal prism in the direction of the shorter diagonal 109° 28′. The cleavage is the same, but most distinct in the direction of the smaller diagonal of the vertical prism. Hardness = 3.5, — 4.0. Sp. gr. = 2.6, — 3.0.

This species is divided into two subspecies, viz. Common Arragonite, and Coralloidal Arragonite.

First Subspecies.

Common Arragonite, *Jameson.* Gemeiner Arragon, *Werner.*

External Characters.—Colours white, grey, green, and violet-blue. In some crystals, green and blue colours occur together, and sometimes also grey. Occurs massive, and in distinct concretions, which are thick, thin, and very thin prismatic, and sometimes scopiformly diverging. It is frequently crystallized.

The following are some of its secondary figures:

1. Irregular six-sided prism, frequently with four lateral edges of about 116°, and two of 128°; or with three lateral edges of 128°, two of 116°, and one of 104°. These are formed by the grouping of several oblique four-sided prisms, bevelled on the extremities. Sometimes this prism is so flat, that it appears like a table.
2. Six-sided table.

    When, on the contrary, the long six-sided prism becomes acicular, there is formed

3. Long, and generally acicular double six-sided pyramids.

The crystals are middle-sized and small; they are generally attached by their terminal planes, seldomer by their lateral planes; sometimes imbedded, and are to be observed intersecting each other. Lateral planes of the crystals sometimes smooth, more frequently more or less deeply streaked or grooved. Terminal planes seldom smooth, generally uneven and rough, and sometimes also deeply notched. External lustre varies from dull to shining, and is vitreous: internally shining and glistening, and vitreous, inclining to resinous. Fracture small and imperfect conchoidal, passing into uneven. Fragments indeterminate angular, and rather sharp-edged; in the prismatic varieties splintery. Translucent, passing into semi-transparent, and refracts double. Brittle, and easily frangible.

Chemical Characters.—If we expose a small fragment to the flame of a candle, it almost immediately splits into white particles, which are dispersed around the flame. This change takes place principally with fragments of transparent crystals, fragments of the other varieties becoming merely white and friable. Fragments of calcareous-spar, when placed in a similar situation, undergo no alteration. Completely soluble, with effervescence, in the nitric and muriatic acids.

Constituent Parts.

From Molina in Arragon.

Carbonate of Strontian, .	3.9662	
Hydrate of Iron, . . .	0.7060	
Water of Crystallization, .	0.3000	99.5489

Stromeyer, in Gilbert's Annalen der Physik, xiv. 217. October, 1813.

Geognostic and Geographic Situations.—*Europe.* It occurs along with galena in the lead mines of Leadhills, and in secondary trap-rocks in different parts of Scotland. It is one of the many interesting minerals met with in the secondary trap-rocks of the island of Iceland, and in the trap-rocks of the Department of the Puy de Dome, of Caupenne near Dax, and at Bastanes in Bearn, all in France.—*America.* It is found in the trap-rocks in Kannioak in North Greenland, and in the Haasen Island, also in North Greenland. Specimens of it have been met with at Guanaxuato in Mexico, but not in Peru.—*Asia.* It occurs in the trap-rocks of Van Diemen's Land, and in the neighbouring islands.—*Africa.* It is enumerated amongst the simple minerals contained in the trap or lava rocks of the isle of Bourbon.

Second Subspecies.

Coralloidal Arragonite.—*Jameson.*

External Characters.—Its most frequent colours are varieties of white. It occurs massive, reniform, tuberose, coralloidal, imperfect globular; in distinct concretions, which are fibrous, generally straight, seldom curved, and stellular and scopiform; sometimes also in reniform curved lamellar, and large angulo-granular concretions. Lustre glimmering, or glistening and pearly. Fracture fine splintery. Fragments wedge-shaped and splintery. Translucent, or translucent on the edges. In other characters, agrees with the preceding subspecies.

Geognostic and Geographic Situations.—It is found in Dufton Fell in Cumberland, also in the iron mines of Stiria and Carinthia, and at St. Marié aux Mines.

II. Limestone, *Jameson.*—Rhomboedrischer Kalk-Haloide, *Mohs.*

Rhomboid = 105° 5′. The most perfect cleavages are in the direction of the faces of the primitive rhomboid: less perfect in the direction of a flatter rhomboid; a third still less perfect, which is parallel with the planes of a six-sided prism; and a fourth, the most imperfect, which is parallel with the terminal planes of the six-sided prism. Hardness = 3.5. Sp. gr. = 2.5, — 2.8.

This species is divided into twelve subspecies, viz. 1. Foliated Limestone; 2. Compact Limestone; 3. Chalk; 4. Agaric Mineral; 5. Fibrous Limestone; 6. Calc-Tuff; 7. Peastone; 8. Slate-Spar; 9. Aphrite; 10. Lucullite; 11. Marl; 12. Bituminous Marl Slate.

First Subspecies.

Foliated Limestone, Jameson.—Blättriger, Kalkstein, *Werner.*

This subspecies is divided into two kinds, viz. Calcareous-spar, and Foliated Granular Limestone.

First Kind.

Calcareous-spar, or Calc-spar, *Jameson.*—Kalkspath, *Werner.*

External Characters.—Its colours are white, grey, red, blue, green, yellow, yellowish-brown, and greyish-black. White and grey varieties occur more frequently in the massive; yellow, green, and red, in those which are crystallized. White-coloured transparent varieties are often iridescent. It occurs massive, disseminated, globular, botryoidal, reniform, tuberose, stalactitic, tubular, cellular, and curtain-shaped; also in distinct concretions, which are large coarse, rarely small, angulo-granular; sometimes very thick, thick and thin, prismatic, generally wedge-shaped prismatic; always straight; sometimes parallel, sometimes scopiform prismatic; and these are intersected by lamellar concretions, which are fortification-wise bent, and very frequently crystallized. The suite of crystallizations of calcareous-spar far exceeds in extent that of any other mineral hitherto discovered.* The principal varieties are by Werner, according to his method, brought under three classes or subdivisions, which not only form series amongst themselves, but are connected together in such a manner, that the last member of the third class joins with the first member of the first class, and thus the whole forms a very beautiful returning series. Each of these divisions have their characteristic crystalline form, viz. The first an *acute double six-sided pyramid;* the second an *equiangular six-sided prism*, (including the six-sided table;) and the third a *rhomboid* or *three-sided pyramid.*

I. *Acute six-sided Pyramid.*

When perfect, it is always acute, and two and two lateral planes meet under obtuser angles than the others. It is generally obliquely streaked, but the streaks run from the acute towards the obtuse edges.

It occurs,

A. Single.

B. Double. The lateral planes of the one set obliquely on the lateral planes of the other, so that the edge of the common base forms a zig-zag line.

These pyramids occur either perfect, or in the following varieties:

1. The apex acuminated with three planes, which are set on the obtuse lateral edges. These are parallel with the cleavage.
2. The apex flatly acuminated with three convex faces, which are set on the acute lateral edges. The convexity is in the direction of the axis of the double pyramid.
3. The angles on the common base of the double pyramid truncated, thus forming a transition into the six-sided prism.
4. The acute lateral edges of the double pyramid sometimes truncated, and either with straight and smooth planes, or with convex and uneven planes.
5. Twin-crystal.

The double six-sided pyramids apparently pushed into each other in the direction of their length, in which they are either

(1.) *Unchanged* in position, when the acute edges rest on the obtuse edges; or they are

(2.) *Turned around* one-sixth of their periphery, so that obtuse edges are set on obtuse edges, and acute edges on acute edges; and the alternate angles on the common base have broken re-entering angles; or the angles on the common basis are truncated, and thus a transition is formed into the next following principal form.

II. *Equiangular six-sided Prism.*

It is equiangular, but generally with alternate broad and narrow lateral planes. It originates from the pyramid No. 3.; and hence it presents the following varieties:

1. The equiangular six-sided prism, acutely acuminated with six planes, of which two and two meet under obtuse angles, and each is set obliquely on the lateral edges. Sometimes the acute acuminating edges are truncated, or they are bevelled, and the edges which the bevelling planes make with the broad lateral planes, truncated.
2. In other varieties, the apices of the acuminations are more or less deeply truncated, and sometimes so deeply, that the acuminating planes appear as truncating planes on the angles of the prism.
3. The preceding figure, in which the six-planed acumination is *flatly acuminated* with three planes, which are set on the acute edges of the six-planed acumination.
4. Six-sided prism *acutely acuminated* with three planes which are set on the alternate lateral planes. The apex of the acumination is sometimes more or less deeply truncated. Sometimes the truncation is so deep, that the remains of the acuminating planes appear as truncations on the alternate terminal edges. In other varieties the prism becomes so short, that the acuminating planes meet and form an acute double three-sided pyramid.
5. When the planes of the flat three-planed acumination N° 3. increase so much that those of the six-planed acumination disappear, a six-sided prism is formed, *flatly acuminated* with three planes, which are set on the alternate lateral planes in an unconformable position. When the prism disappears, there is formed an obtuse double three-sided pyramid.

   These prisms are often pyramidally aggregated.
6. When the prism becomes very low, it may be viewed as an equiangular six-sided table, which is sometimes aggregated in a rose-like form.
7. Sometimes the six-sided prism is truncated on the lateral edges, and thus forms a twelve-sided prism. The prisms are aggregated in a pyramidal, manipular, scopiform, and tabular manner.

III. *Three-Sided Pyramid.*

It is divided, according to the magnitude of the summit-angle, into the following varieties:

1. *Very obtuse three-sided pyramid*, nearly tabular. It is sometimes aggregated in a rose-like form.
2. *Flat three-sided pyramid*, in which the lateral planes of the one are set on the lateral edges of the other. The angles on the common basis are sometimes truncated, and frequently the apices of the pyramid are more or less deeply truncated. When the truncation

* Romé de Lisle enumerates 26 varieties of calcareous-spar—Haüy above 150—and Bournon 642. Many more might be described.

on the apices is very deep, the crystal appears as a six-sided table, in which the terminal planes are set on alternately oblique.

3. *Acute three-sided pyramid.* This form very nearly resembles the cube.

It would extend this description too much, were we to attempt to give an account of every variety of form exhibited by these crystals; and besides, we have already enumerated the principal ones. The crystals occur of various magnitudes, as large, small, and very small. The lateral planes of the prisms and pyramids are generally shining, splendent, and smooth; the acuminating planes frequently streaked or drusy, seldom granulated. Sometimes it occurs in extraneous external forms of shells, &c. Internally it is generally specular splendent, or shining, sometimes glistening, and the lustre is vitreous, which inclines sometimes to resinous, and more rarely to pearly. Fracture perfect conchoidal. Fragments indeterminate angular, and rather sharp-edged, or they are rhomboidal. Occurs transparent, semi-transparent, and occasionally only translucent. It refracts double.* Brittle, and very easily frangible.

Chemical Characters.—It is infusible before the blow-pipe, but it becomes caustic, losing by complete calcination about 43 per cent.; effervesces violently with acids.

Constituent Parts.

	Stromeyer, Gilbert's Annalen for 1813, p. 217.	*Philips*, Phil. Mag. xiv. 290.	Gehl. *Bucholz*, Journ. iv. 412.	*Stromeyer*, Gilbert's An. for 1813, p. 217.

Geognostic Situation.—It never occurs in mountain-masses, but venigenous in almost every rock, from granite to the newest secondary formation.

An interesting geognostic character of calcareous-spar, is the uniformity of its crystallizations in particular districts. Thus, in the mines of Derbyshire, the acute six-sided pyramid and its congenerous forms are the most frequent and abundant; at Schneeberg in Saxony, and in the Upper Hartz, the prevailing forms are the regular six-sided prism and table; while in the mines of Freyberg, the most frequent forms are the regular six-sided prism, acuminated with three planes, set on the lateral planes, and the flat double three-sided pyramid.

Geographic Situation.—This mineral is so common in every country, as to render any account of its geographic distribution unnecessary.

Second Kind.

Granular Foliated Limestone, *Jameson.*—Blättriger Körniger Kalkstein, *Werner.*

External Characters.—Its most common colour is white, grey, red, yellow, and green. Has generally but one colour; sometimes, however, it is spotted, dotted, clouded, striped, and veined. Occurs massive, and in angulo-granular distinct concretions. Internally alternates from shining to glistening, and glimmering; lustre intermediate between pearly and vitreous. Fracture foliated, but sometimes inclines to splintery. Fragments indeterminate angular, and rather blunt-edged. More or less translucent. Brittle, and easily frangible.

Chemical Characters.—It generally phosphoresces when pounded, or when thrown on glowing coals. It is infusible before the blow-pipe. It dissolves with effervescence in acids.

Constituent Parts.—	Lime,	.	56.50
	Carbonic Acid,		43.00
	Water,	.	0.50—100

Bucholz, in Neuen Journal der Chem. iv. s. 419.

Geognostic Situation.—This mineral occurs in beds, in granite, gneiss, mica slate, clay-slate, syenite, greenstone, grey-wacke, and rarely in some of the secondary rocks.

Geographic Situation.—This mineral occurs in all the great ranges of primitive rocks that occur in Europe, and in such as have been examined in Asia, Africa, and America.

Uses.—All the varieties of this subspecies may be burnt into quicklime; but it is found, that in many of them, the concretions exfoliate and separate during the volatilization of their carbonic acid, so that by the time when they are rendered perfectly caustic, their cohesion is destroyed, and they fall into a kind of sand,—a circumstance which will always render it improper to use such varieties in a common kiln. But the most important use of this mineral is as marble. These marbles have been known from a very early period; and ancient statuaries have immortalised their names, by the masterpieces of art which they have executed in them. Of the ancient marbles, the most celebrated are those of Paros, Pentelicus, and Carrara. Marbles of different descriptions occur in Scotland, England, and Ireland, as appears from the following enumeration.

Scottish Marbles.

The Marbles of this part of Great Britain have hitherto been but little attended to, although it is highly probable that many valuable varieties occur in the different primitive and transition districts. At present, we shall mention a few of the best known varieties.

1. *Tiree Marble.*—Of this marble there are two varieties, viz. the Red and White.

a. Red Tiree Marble.—This is one of the most highly prized of the Scottish marbles. Its colours are red, of various tints, such as rose-red and flesh-red; also reddish-white; its lustre is glimmering; and the fracture is minute foliated, accompanied with splintery. It is very faintly translucent, or only highly translucent on the edges. It is always intermixed with different other earthy minerals, that add to its beauty, and give it a peculiar appearance. The most frequent of the imbedded minerals is common hornblende; the others are pale-green sahlite, blackish-brown mica, and green chlorite. In some varieties the hornblende is so abundant, that at first sight they might be confounded with syenite: in others, where nearly the whole mass is of hornblende, it would be considered as a variety of hornblende rock.

b. White Tiree Marble.—Its colours are greyish-

* The double refracting power of calcareous-spar was first observed by Erasmus Bartholin.

white and bluish-white: it contains scales of mica, and crystals or grains of common hornblende; which latter, when minutely diffused, give the marble a green or yellowish-green colour, and, when very intimately combined with the mass, form beautiful yellowish-green spots.

2. *Iona Marble.*—Its colours are greyish-white and snow-white. Its lustre is glimmering, and fracture minute foliated, combined with splintery. It is harder than most of the other marbles. It is an intimate mixture of limestone and tremolite; for if we immerse it in an acid, the carbonate of lime will be dissolved, and the fibres of tremolite remain unaltered. It is sometimes intermixed with steatite, which gives it a green or yellow colour, in spots. These yellow or green-coloured portions receive a considerable polish, and have been erroneously described as nephritic stone, and are known also under the name of *Iona* or *Icolmkill Pebbles.* The marble itself does not receive a high polish: this, with its great hardness, have brought it into disrepute with artists. Several of the varieties of Iona marble are dolomite.

3. *Skye Marble.*—In the Island of Skye, in the property of Lord Macdonald, there are several varieties of marble, deserving of attention, inclosed in porphyry, sandstone, and trap-rocks. One variety is of a greyish inclining to snow-white colour: another greyish-white, veined with ash-grey; and a third is ash-grey, or pale bluish-grey, veined with lemon-yellow or siskin-green. Dr. M'Culloch has described other varieties; and more minute details are expected from his promised work on the "Geology of the Hebrides."

4. *Assynt.*—The following varieties of marble, found in Sutherland, have been introduced into commerce by Mr. Joplin of Gateshead.

a. White marble, which acquires a smooth surface on the polisher, but remains of a dead hue, like the marble of Iona: hence its uses as an ornamental marble are much circumscribed.

b. White mottled with grey, and capable of receiving a high polish, and is not deficient in beauty.

c. Grey-coloured, and highly translucent and crystalline, and capable of being applied to the purposes of ornament in sepulchral sculpture.

d. Dove-coloured, compact, translucent, and receiving a good polish.

e. Pure white, and translucent, and capable of being used in plain ornaments; but too translucent for sculpture.

f. White, with irregular yellow marks, from being intermixed with serpentine. It is very compact.

g. White variety, with layers of slate-spar.

5. *Glen Tilt Marble.*—The limestone of Glen Tilt, first mentioned by Dr. Macknight, in his description of that valley, has of late attracted the notice of the Duke of Athole, through the suggestion of Dr. M'Culloch. The marbles are white and grey, and veined or spotted with yellow or green: they vary in the size of the grain or concretion, and also in the degree and kind of polish they receive.

6. *Marble of Ballichulish.*—This marble is of a grey or white colour, and is very compact. It may be raised in blocks of considerable size.

7. *Boyne Marble.*—Its colours are grey or white, and it receives a pretty good polish.

8. *Blairgowrie Marble.*—Mr. Williams, in his Natural History of the Mineral Kingdom, mentions a beautiful saline marble, of a pure white colour, which occurs near Blairgowrie in Perthshire, not far from the road side. According to him, it may be raised in blocks and slabs, perfectly free of blemishes, and in every respect fit to be employed in statuary and ornamental architecture.

9. *Glenavon Marble,*—is of a white colour, and the concretions are large granular. It is mentioned by Williams as a valuable marble; but he adds, that its situation is remote, and difficult of access.

English Marbles.

Hitherto but few marbles of granular foliated limestone have been quarried in England; the greater number of varieties belonging to the flœtz or secondary limestone. One of the most remarkable of the English marbles of the present class, is that of Anglesea, named *Mona Marble*, which is not unlike the *Verde Antico.* Its colours are greenish-black, leek-green, and sometimes purple, irregularly blended with white; but they are not always seen together in the same piece. The white part is limestone: the green shades are said to be owing to serpentine and asbestus. The Black Marbles found in England, are varieties of Lucullite.

Irish Marbles.

The Black Marbles of Ireland, now so generally used by architects, are Lucullites. In the county of Waterford, different kinds of marble are known; thus at Toreen, there is a fine variegated sort, of various colours, viz. chesnut-brown, white, yellow, and blue, and which takes a good polish: a grey marble, beautifully clouded with white, susceptible of a good polish, has been found near Kilcrump, in the parish of Whitechurch, in the same county. At Loughlougher, in the county of Tipperary, a fine purple marble is found, which, when polished, is said to be beautiful. Smith describes several variegated marbles in the county of Cork; but whether these, and others now enumerated as Irish marbles, are granular limestone, I cannot discover, as I have neither met with good descriptions of them, nor seen any specimens. Thus, he mentions one with a purplish ground, and white veins and spots, found at Churchtown; a bluish and white marble from the same place; and several fine ash-coloured varieties, as that of Castle Hyde, &c. The county of Kerry affords several variegated marbles, such as that found near Tralee. Marble of various colours is found in the same county, in the islands near Dunkerron, in the river of Kenmare: some are purple and white, intermixed with yellow spots; and some beautiful specimens have been seen, of a purple colour, veined with dark-green.

Second Subspecies.

Compact Limestone, *Jameson.*—Dichter Kalkstein, *Werner.*

This Subspecies is divided into three kinds, viz. Common Compact Limestone, Blue Vesuvian Limestone, and Roe-stone.

First Kind.

Common Compact Limestone, *Jameson.*—Gemeiner Dichter Kalkstein, *Werner.*

External Characters.—Most frequent colour grey, greyish-black, yellow, and red. Frequently exhibits veined, zoned, striped, clouded, and spotted coloured delineations; and sometimes also black and brown coloured arborisations. It very rarely exhibits a beautiful play of colours, caused by intermixed portions of pearly shells. Occurs massive, corroded, in large plates, rolled masses, and in various extraneous external shapes, of univalve, bivalve, and multivalve shells, of corals, fishes, and more rarely of vegetables, as of ferns and reeds. Internally dull, seldom glimmering, which is owing to intermixed calcareous-spar. Fracture small and fine splintery, which sometimes passes into large and flat conchoidal, sometimes into uneven, inclining to earthy, and it occasionally inclines to straight and thick slaty. Fragments indeterminate angular, more or less sharp-edged, but in the slaty variety they are tabular. Generally translucent on the edges, sometimes opaque. In general rather softer than granular foliated limestone. Brittle, and easily frangible. Streak generally greyish-white.

Specific gravity, Splintery, 2.600, 2.720, *Brisson.* Opalescent Shell Marble, 2.673, *Leonhard.*—2.675, *Werner.*

Chemical Characters.—It effervesces with acids, and the greater part is dissolved; and burns to quick-lime, without falling to pieces.

Constituent Parts.

Simon, Gehlen's Jour. iv. s. 426.		*Simon*, Ib.		*Simon*, Ib.		*Bucholz*, Ib.	

Geognostic Situation.—This mineral occurs in vast abundance in nature, principally in secondary formations, along with sandstone, gypsum, and coal; but in small quantity in primitive mountains.

Geognostic Situation.—It abounds in the sandstone and coal formations, both in Scotland and England; and in Ireland, it is a very abundant mineral in all the districts where clay-slate and red sandstone rocks occur. On the Continent of Europe, it is a very widely and abundantly distributed mineral; and forms a striking feature in many extensive tracts of country in Asia, Africa, and America, as will be particularly described in the Geognostic part of this article.

Uses.—When compact limestone joins to pure and agreeable colours, so considerable a degree of hardness that it takes a good polish, it is by artists considered as a Marble; and if it contains petrifactions mineralized, it is named *shell* or *lumachella*, and *coral* or *zoophytic marble*, according as the organic remains are testaceous or coralline*. In one particular variety of lumachella or shell marble, found at Bleiberg in Carinthia, the shells and fragments of shells, which belong to the nautilus tribe, are set in a brown coloured basis, and reflect many beautiful and brilliant pearly inclining to metallic colours, principally the fire-red, green, and blue tints. It is named *opalescent* or *fire marble*. Another lumachella marble from Astracan, contains, in a reddish-brown basis, pearly shells of nautili, that reflect a very brilliant gold-yellow colour. In some compact marbles, the surface presents a beautiful arborescent appearance, and these are naturally *arborescent* or *dendritic marbles*. Such as those of Papenheim in Bavaria.

The *Florentine Marble*, or *Ruin Marble*, as it is sometimes called, is a compact limestone. It occurs on the Po and the Arno, and is worked into various articles at Florence. To the same compact limestone may be referred the variety called *Cottam Marble*, from being found at Cottam, near Bristol. It resembles in many respects the landscape marble.

In different parts of Scotland, compact limestone is cut and polished as marble: this was the case in the parish of Cummertrees in Dumfriesshire,—in Cambusland parish, in Lanarkshire,—in Fifeshire, &c. In England, many compact limestones are cut and polished as marbles; such are the limestones of Derbyshire, Yorkshire, Devonshire, Somersetshire, and Dorsetshire. It is sometimes used as a building stone, and, in want of better materials, for paving streets, and making highways. When, by exposure to a high temperature, it is deprived of its carbonic acid, and converted into quicklime, it is used for mortar; also by the soap-maker, for rendering his alkalies caustic; by the tanner, for cleansing hides, or freeing them from hair, muscular substance, and fat; by the farmer, in the improvement of particular kinds of soil; and by the metallurgist, in the smelting of such ores as are difficultly fusible, owing to an intermixture of silica and alumina.

Second Kind.

Blue Vesuvian Limestone, *Jameson.*—Blauer Vesuvischer Kalkstein, *Klaproth.*

External Characters.—Colour dark bluish-grey, partly veined with white. Externally it appears as if it had been rolled; and the surface is uneven. Fracture fine earthy, passing into splintery. Is opaque. Affords a white streak.

Const. Parts.—Lime,		58.00
	Carbonic Acid,	28.50
	Water, which is somewhat ammoniacal,	11.00
	Magnesia,	0.50
	Oxide of Iron,	0.25
	Carbon,	0.25
	Silica,	1.25—99.75

Klaproth, Beit. b. v. s. 96.

From this analysis, it appears, that the vesuvian limestone differs remarkably in composition from common compact limestone. In common compact limestone, 100 parts of lime are combined with at least 80 parts of carbonic acid; whereas in the vesuvian limestone, 100 parts of limestone are not combined with more than 50 parts of carbonic acid. Secondly, In common limestone, independent of the water which adheres to it accidentally, as far as we know, there is no water of composi-

* The name *marmor* is derived from the Greek μαρμαιρειν, *to shine*, or *glitter*, and was by the ancients applied, not only to limestone, but also to stones possessing agreeable colours, and receiving a good polish, such as gypsum, jasper, serpentine, and even granite and porphyry.

tion; but in the vesuvian limestone there are 11 parts of water of composition.

Geographic Situation.—This remarkable limestone is found in loose masses amongst unaltered ejected minerals in the neighbourhood of Vesuvius.

Observations.—It is known to some collectors under the name *Compact Blue Lava* of Vesuvius; and is sometimes employed by artists in their mosaic work, to represent the sky.

Third Kind.

ROESTONE, or OOLITE *Jameson**.—Roogenstein, *Werner.*

External Characters.—Colours brown and grey. Occurs massive, and in distinct concretions, which are round granular; the larger are composed of fine spherical granular, and sometimes of very thin concentric lamellar concretions. Internally dull. Fracture of the grains fine splintery; but of the mass round granular in the small, and slaty in the large. Fragments in the large blunt-edged. Is opaque. Rather brittle, and very easily frangible. Sp. gr. 2.6829, 2.6190, *Kopp.*—2.585 *Breithaupt*

Chemical Characters.—It dissolves with effervescence in acids.

Geognostic Situation.—It occurs along with red sandstone, and *lias* limestone.

Geographic Situation.—This rock, which, in England, is known under the names Bath-stone, Ketton-stone, Portland-stone, and Oolite, extends, with but little interruption, from Somersetshire to the banks of the Humber in Lincolnshire. On the Continent of Europe, it occurs in Thuringia, the Netherlands, the mountains of Jura, and in other countries.

Uses.—The Oolite, or Roestone, particularly that of Bath and Portland, is very extensively employed in architecture; it can be worked with great ease, and has a light and beautiful appearance; but it is porous, and possesses no great durability, and should not be employed where there is much carved or ornamental work, for the fine chiselling is soon effaced by the action of the atmosphere. On account of the ease and sharpness with which it can be carved, it is much used by the English architects, who appear to have little regard for futurity. St. Paul's is built of this stone, also Somerset-House. The Chapel of Henry VIII. affords a striking proof of the inattention of the architects to the choice of the stone. All the beautiful ornamental work of the exterior had mouldered away in the short comparative period of 300 years. It has recently been cased with a new front of Bath-stone, in which the carving has been correctly copied: from the nature of the stone, we may predict, that its duration will not be longer than that of the original. Both Portland and Bath-stone varies much in quality. In buildings constructed of this stone, we may frequently observe some of the stones black, and others white. The black stones are those which are more compact and durable, and preserve their coating of smoke: the white stones are decomposing, and presenting a fresh surface, as if they had been recently scraped. Roestone is also used as a manure, but when burnt into quicklime, the marly varieties afford rather an indifferent mortar; but those mixed with sand a better mortar.

THIRD SUBSPECIES.

CHALK, *Jameson.*—Kreide, *Werner.*

External Characters.—Colour yellowish-white, sometimes passes to greyish-white and snow-white. It is sometimes marked with yellowish-grey. Occurs massive, disseminated, in crusts, and in extraneous external shapes. Is dull. Fracture coarse and fine earthy. Fragments blunt-edged. Opaque. Writes and soils very much. Soft, and sometimes very soft. Rather sectile, and easily frangible. Adheres slightly to the tongue. Feels very meagre, and rather rough. Specific gravity, 2.252 *Muschenbroeck.*—2.315, *Kirwan.*—2.657 *Watson*—2.226. *Breithaupt.*

Chemical Characters.—It effervesces strongly with acids.

Constituent Parts.

		Chalk from Gallicia.

Bucholz, in Gehlen's Journ. b. iv. s. 416.		Iron, .	0.05		
			——	*Kirwan*, Min. vol. i. p. 77.	
		Hacquet.			

Geognostic Situation.—It constitutes one of the newer secondary or floetz formations; is usually found in low situations, and frequently on sea-coasts. It is stratified, and the strata in general are horizontal. It often contains flint, which is disposed either in interrupted beds in the chalk, or in globular, tuberose, or tabular masses imbedded in it. It abounds in organic remains, and these are principally of animals of the lower orders, such as echinites, belemnites, terebratulites, pinnites, &c.

Geographic Situation.—It abounds in the south-eastern parts of England,—extends through several provinces in France,—occupies great tracts of country in Poland and Russia,—is met with on the shores of the Baltic,—and in the islands of Zeeland and Rugen.

Uses.—The uses of this mineral are various. The more compact kinds are employed as building-stones, when they are used either in a rough state, or are sawn into blocks of the requisite size and shape: it is burnt into quicklime, and used for mortar in different countries; thus, nearly all the houses in London are cemented with chalk-mortar†: it is also employed in great quantities in the polishing of glass and metals, and whitening the roofs of rooms, in the state of *whiting*‡; in constructing moulds to cast metal in; by carpenters and others as a material to mark with. When perfectly purified, and mixed with vegetable colours, it forms a kind of pastil colour: thus, with litmus, turmeric, saffron, and sap-green, it forms durable colours, but vegetable colours that contain an acid, become blue when mixed with it. The *Vienna white* known to artists, is perfectly purified chalk. It is used by starch-makers and chemists to dry precipitates on, for which it is peculiarly qualified, on account of the remarkable facility

* *Roestone*, so named on account of its resemblance in form to the roe of fishes.

† According to Smeaton, it makes as good lime as the best limestone or marble.

‡ In the preparation of whiting, chalk is pounded, and diffused through water, and the finer part of the sediment is then dried; by this means, the siliceous particles are separated, which, by their hardness, would scratch the surface of metallic and other surfaces, in the polishing of which whiting is used.—Aikin's *Chem. Dictionary*.

with which it absorbs water. With isinglas, or white of eggs, it forms a valuable lute or cement. In the gilding of wood, it is necessary, before laying on the gold, to cover it with a succession of coats of a mixture of whiting and size. The mineral is also used as a filtering-stone; and in a purified state, it is employed as a remedy to correct acidity in the stomach, and the morbid states which arise from this.

Fourth Subspecies.

Agaric Mineral, or Rock Milk, *Jameson.*—Berg-Milch *Werner.*

External Characters.—Colours snow-white, greyish-white, and yellowish white. Occurs frequently in crusts, also in loosely cohering tuberose pieces. Dull. Composed of fine dusty particles. Soils strongly. Feels meagre. Adheres slightly to the tongue. Very light, almost supernatant.

Chemical Characters.—It effervesces with acids, and is completely dissolved in them.

Constituent Parts.—It is a pure carbonate of lime.

Geognostic and Geographic Situations.—It is found on the north side of Oxford, between the Isis and the Cherwell, and near Chipping-Norton, also in Oxfordshire.

Fifth Subspecies.

Fibrous Limestone, *Jameson.*—Fasriger Kalkstein, *Werner.*

This subspecies is divided into two kinds, viz. Common Fibrous Limestone, or Satin-Spar, and Fibrous Calc-Sinter.

First Kind.

Common Fibrous Limestone, or Satin-Spar, *Jameson.*—Gemeiner fasriger Kalkstein, *Werner.*

External Characters.—Colours greyish, reddish, and yellowish-white. Occurs massive, also in distinct concretions, which are coarse and fine fibrous, and either straight or curved. Lustre glistening or shining, and pearly. Fragments splintery. Feebly translucent. As hard as calcareous-spar. Easily frangible. Specific gravity 2.70, *Pepys.*

Constituent Parts.

Carbonate of Lime,	95.75	Lime, .	50.8
Carbonate of Manganese,	4.25	Carbonic Acid,	47.6
			98.4
	Holme.		*Pepys*, in Kid's Min. vol. i. p. 49.

Stromeyer says that fibrous limestone contains some *per cents.* of gypsum.

Geognostic and Geographic Situations.—It occurs in thin layers in clay-slate at Aldstone Moore in Cumberland; in layers and veins in the middle district of Scotland, as in Fifeshire. On the Continent, at Potschappel, near Dresden, and at Schneeberg, also in Saxony.

Uses.—It is sometimes cut into necklaces, crosses, and other ornamental articles.

Second Kind.

Fibrous Calc-Sinter*, *Jameson.*—Fasriger Kalksinter, *Werner.*

External Characters.—Principal colours white, yellow, brown, grey, red, green, and blue. Sometimes concentrically and reniformly striped, or it is spotted or clouded. Occurs massive, stalactitic, globular, tubular, claviform, fruticose, curtain shaped, cock's-comb-shaped, coralloidal, reniform, and tuberose; also in distinct concretions, which are fibrous, and these are straight, seldom curved, and sometimes scopiform or stellular; also in reniform curved lamellar concretions, and seldom in large and coarse angulo-granular concretions; very rarely the longish external shapes, as the stalactitic, are terminated by a three-sided pyramidal crystallization. Surface generally rough, and seldom fine drusy. Internally glimmering, which passes on the one side into dull, on the other into glistening; and the lustre is pearly. Fracture fine splintery. Fragments splintery, or wedge-shaped. Translucent, or only translucent on the edges.

Constituent Parts.—	Lime . .	56.0	
	Carbonic Acid	43.0	
	Water . .	1.0	—100.0

Bucholz, in Gehlen's Journal, b. iv. s. 425.

Geognostic and Geographic Situations.—It is found encrusting the roofs, walls, and floors of caves, particularly those situated in limestone rocks. It is formed from water holding carbonate of lime in solution. Caves lined with this mineral occur in almost every country. Maccallister's Cave, in the island of Skye, and those in the limestone hills of Derbyshire, are the most striking appearances of this kind hitherto observed in Scotland and England. But the most celebrated stalactitic cave is that of Antiparos in the Archipelago, which has been particularly described by Tournefort. Similar caves occur in Germany, France, Switzerland, Spain, in the United States of America, and other countries. Italy, which is so rich in fine marble, is not less so in beautiful calc-sinter or calcareous alabaster; the territory of Volterra in Tuscany alone furnishes no fewer than twenty different varieties. Sicily is also abundant in calc-sinter; and of these, the rose-coloured variety of Trapani is much admired. Spain is, next to Italy, the most productive country of calcareous alabaster. The environs of Granada and Malaga are particularly remarkable for the beautiful varieties of this mineral which they afford. Persia also abounds in highly prized varieties of calcareous alabaster.

Uses.—Calc-sinter, or calcareous alabaster, is used for the same purposes as marble, and is cut into tables, columns, vases, drapery for marble figures, and sometimes also into statues. It was also used by the ancients in the manufacture of their unguentary vases.

Sixth Subspecies.

Tufaceous Limestone Calc-tuff†, *Jameson.*—Kalk-Tuff. *Werner.*

External Characters.—Colour yellowish-grey, which sometimes approaches to ochre yellow and yellowish-brown. Occurs massive, perforated, ramose, spongy, tubular, claviform, botryoidal, globular, cellular, and in crusts; enclosing vegetable stems and leaves; also bones of animals, as of elephants and rhinoceroses, and land shells; and also with frequent impressions of leaves, mosses, and roots. The globular variety is sometimes composed of curved lamellar concretions.

* This is the Alabaster of the ancients, and is by the moderns named *Calcareous Alabaster*, to distinguish it from another mineral, gypsum, which they name *Gypseous Alabaster*.

† The term *tufa* appears to be derived from the verb τύφω, which, in its original signification, is appropriate to volcanic productions, especially to such as are of a spongy or porous texture. *Kid.*

Internally dull, or very faintly glimmering. Fracture fine-grained uneven, inclining to earthy; and sometimes splintery. Fragments indeterminate angular. Opaque, or translucent on the edges. Sometimes semi-hard, sometimes soft, and is frequently soft, inclining to friable. Rough. Brittle, and easily frangible.

Constituent Parts.—It is nearly pure Carbonate of Lime.

Geognostic Situation.—It occurs in beds, generally in the neighbourhood of lakes and rivers: also encrusting rocks, and enveloping animal and vegetable remains in the vicinity of calcareous springs.

Geographic Situation.—It is a frequent mineral in the neighbourhood of all the calcareous springs in this country, as in those at Starly Burn in Fifeshire, and other places; and on the Continent of Europe it is also a frequent mineral.

Uses.—The hardest kinds are used for building-stones, and are also burnt into quicklime. It is sometimes also used as a filtering stone.

Seventh Subspecies.

Pisiform Limestone, or Pea-stone, *Jameson.*—Erbsenstein, *Werner.*

External Characters.—Its most common colour is yellowish-white, which sometimes approaches to snow-white; from yellowish-white it passes into pea-yellow, and pale-yellowish brown. Occurs massive; also in distinct concretions, which are coarse, small, and very seldom fine spherical round granular, composed of others which are very thin and concentric lamellar. In the centre there is either a bubble of air, or a grain of sand, or of some mineral matter. Internally dull, or very feebly glimmering. Fracture even. Fragments indeterminate angular, and blunt edged. Opaque, or feebly translucent on the edges. Soft, approaching to semi-hard Brittle, and very easily frangible. Specific gravity 2.552.

Constituent Parts.—It is carbonate of lime, slightly coloured with iron.

Geognostic and Geographic Situations.—It is found in great masses in the vicinity of the Hot Springs at Carlsbad in Bohemia.

Uses.—It is sometimes cut into plates for ornamental purposes.

Eighth Subspecies.

Slate-Spar, *Jameson.*—Schieferspath, *Werner.*

External Characters.—Colours greenish-white, reddish-white, yellowish-white, greyish-white, and snow-white. Occurs massive, also in distinct concretions, which are generally curved lamellar, and sometimes coarse and large granular. Lustre intermediate between shining and glistening, and is pearly. Fragments either indeterminate angular and blunt-edged, or are tabular. Feebly translucent, or only translucent on the edges. Soft. Intermediate between sectile and brittle. Easily frangible. Feels rather greasy. Specific gravity, 2.647, *Kirwan.*—2.474, *Blumenbach.*—2.6300, *La Methrie.*—2.611. *Breithaupt.*

Chemical Characters.—It effervesces very violently with acids: but is infusible before the blowpipe.

Constituent Parts.

From Bremsgrün.		From Kongsberg.	
Lime,	55.00	Lime,	56.00
Carbonic Acid	41.66	Carbonic Acid,	39.33
Oxide of Manganese,	3.00	Silica,	1.66
	———	Oxide of Iron,	1.00
Bucholz.		Water,	2.00
			———
		Suersee.	

Geognostic Situation.—It occurs in primitive limestone, along with calcareous spar, brown-spar, fluor-spar, and galena; in metalliferous beds, associated with magnetic ironstone, galena, and blende; and in veins, along with tinstone.

Geographic Situation.—It occurs imbedded in marble in Glen Tilt, Perthshire; and in Assynt in Sutherland: in Cornwall; and near Granard in Ireland. On the Continent, it is found along with tinstone, in the Saxon Erzgebirge; along with octahedrite, in a vein at St. Chirstophe in Dauphiny; also in Norway, in metalliferous beds, and in limestone.

Ninth Subspecies.

Aphrite, *Jameson.*—Schaumerde, *Werner.*

This subspecies is divided into three kinds, viz. Scaly Aphrite, Slaty Aphrite, and Sparry Aphrite.

First Kind.

Scaly Aphrite, *Jameson.*—Schaumerde, *Werner.* Zerreiblicher Aphrit, *Karsten.*

External Characters.—Colours snow, yellowish, and reddish white, sometimes passing into silver-white. Occurs either friable or compact. Friable varieties composed of glistening or glimmering particles, in which the lustre is pearly. Particles are fine scaly, feel fine, but not greasy. Either loose, or loosely cohering. Compact varieties massive, disseminated, or in granular concretions, with a shining or nearly splendent lustre, which is pearly, sometimes inclining to semi-metallic. Fragments indeterminate angular, and blunt edged in the great, but tabular in the small. Opaque. Soils slightly. Very soft, passing into friable. Sectile, and uncommonly easily frangible. Feels very fine, but not greasy.

Chemical Characters.—It effervesces most violently with acids.

Constituent Parts.—

Lime,	51 5
Carbonic Acid,	39.0
Silica,	5 715
Oxide of Iron,	3.285
Water,	1.0—100.5
	Bucholz.

Geognostic Situation.—It occurs in nests, disseminated, or in small veins, in flœtz or secondary lime-stone, and gypsum.

Geographic Situation.—It is found in Thuringia and Hessia.

Second Kind.

Slaty Aphrite, *Jameson.*—Schaumscheifer, *Friesleben.*

External Characters.—Colours snow-white, passing into yellowish, reddish, and silver-white. Occurs massive, seldom coarsely disseminated. Strongly glimmering, sometimes approaching to glistening, even to shining; lustre pearly; which sometimes passes into semi-metallic. Slaty in the great, but undulating curved foliated in the small. Splits very easily into extremely thin tabular fragments. Opaque, or very feebly translucent in the thinnest folia. Soils pretty strongly. Feels soft, and rather silky. Flexible in thin plates.

Chemical Characters.—It falls into pieces with a crackling noise, when put into water. When touched with an acid, it effervesces with great violence, and is entirely dissolved in it.

Geognostic and Geographic Situations.—It occurs massive, imbedded, and in veins, in the first flœtz limestone, in Thuringia and Hessia.

Third Kind.

Sparry Aphrite, *Jameson.*—Schaumspath, *Friesleben.*

External Characters.—Colours snow, yellowish, and greyish-white. Seldom occurs massive, generally disseminated; sometimes in flaky crusts, in veins, or imbedded in large crystals of selenite. Shining, sometimes inclining to splendent, sometimes to glistening; lustre pearly, which inclines to vitreous in the splendent varieties. Fracture foliated, sometimes straight, sometimes curved, and the folia have a single distinct cleavage. Opaque; feebly translucent in thin pieces. Occurs in large and small granular distinct concretions. Soils slightly, with glimmering dusty particles. Soft. Sectile.

Chemical Characters.—The same as in the other kinds.

Geognostic Situation.—It occurs in flœtz or secondary limestone and gypsum. According to Friesleben, it appears to be geognostically allied to selenite; and although it differs from that mineral in colour, transparency, lustre, sectility, feel, and effervescence with acids, yet it passes into it, and also into slaty aphrite, sometimes by simple gradations, sometimes by intermixture of the two minerals; and large lenticular crystals of selenite occur, which are pure at the edges, become gradually more opaque towards the centre, and in the centre are pure sparry aphrite.

Geographic Situation.—It occurs in Thuringia.

Tenth Subspecies.

Lucullite, *Jameson.*

This subspecies is divided into three kinds, viz. Compact Lucullite, Prismatic Lucullite, and Foliated Lucullite.

First Kind.

Compact Lucullite, *Jameson.*—Dichter Lucullan, *John.*

This kind is divided into Common Compact Lucullite, or Black Marble, and Stinkstone.

a. Common Compact Lucullite, or Black Marble, *Jameson.*

External Characters.—Colour greyish-black. Occurs massive. Internally strongly glimmering, inclining to glistening. Fracture fine-grained uneven, and large conchoidal. Fragments indeterminate angular, and rather sharp-edged. Opaque. Semi-hard. Yields a dark ash-grey coloured streak. Brittle, and easily frangible.

When two pieces are rubbed against each other, a fetid urinous odour is exhaled, the intensity of which is increased when we at the same time breathe on them.

Chemical Characters.—It is infusible without addition. When exposed to a high temperature in an open crucible, it burns white. With sulphuric acid, it forms a black-coloured mass: it dissolves in nitrous and muriatic acids, but leaves an insoluble black-coloured substance. During the solution and escape of the carbonic acid, a smell resembling that of sulphuretted hydrogen is evolved.

Constituent Parts.

Lime,	53.38
Carbonic Acid,	41.50
Black Oxide of Carbon,	0.75
Magnesia, and Oxide of Manganese,	0.12
Oxide of Iron,	0.25
Silica	1.13
Sulphur	0.25
Potash, combinations of Muriatic and Sulphuric Acids, and Water,	2.62—100.00

John, Chem. Laborat. b. ii. s. 240.

Geognostic Situation.—The geognostic relations of this mineral are still but little known: it is said to occur in beds in primitive and older secondary rocks.

Geographic Situation.—Hills of this mineral occur in the district of Assynt in Sutherland. Varieties of it are met with at Ashford, Matlock, and Monsaldale, in Derbyshire: at Kilkenney; at Crayleath, in the County of Down; at Kilcrump, in the county of Waterford; at Churchtown, in the county of Cork; and in the county of Galway, in Ireland.

Uses.—The finer varieties of this mineral have been highly prized, and used as marble from a very remote period. It was so much admired and esteemed by the Consul Lucullus, that he gave it his own name. Pliny observes: "Post hunc Lepidum ferme quadriennio L. Lucullus Consul fuit, qui nomen (ut apparet ex re) *Lucullео Marmori* dedit, admodum delectatus illo, primusque Romam invexit, atrum alioqui, cum cætera maculis aut coloribus commendentur. Nascitur autem in Nili insula, solumque horum marmorum ab amatore nomen accepit."

The finest varieties of lucullite met with in trade in this island, are the black marbles of Sutherlandshire, Kilkenney, and Galway.

b. Stinkstone, or Swinestone, *Jameson.* Stinkstein, *Werner.*

External Characters.—Its colours are white, grey, pitch-black, yellow, and brown. Sometimes dendritic on the surface, or clouded with greyish-black. Occurs massive, disseminated, also in distinct concretions, which are small granular, and concentric lamellar. Internally dull or glimmering. The fracture is sometimes small splintery, sometimes imperfect conchoidal, and fine grained uneven, which passes into earthy, or straight slaty. Fragments are indeterminate angular, or slaty. Opaque, but the cream-yellow varieties are translucent on the edges. Affords a greyish-white coloured streak, and when rubbed emits a fetid urinous odour. Brittle, and easy frangible.

Chemical Characters.—Nearly the same as in the preceding kind.

Constituent Parts.

	From Bottendorf.
Carbonate of lime	148—149.00
Silica	7.00
Alumina	5.25
Oxide of iron	2.50
Oxide of manganese	1.00
Oxide of carbon, and a little bitumen,	0.50
Lime,*	1.00
Sulphur, alkali, salt, water,	3.75—170.00

John, Chem. Laborat. t. ii. s. 242.

* We have copied the above analysis from Dr. John's work; yet we do not see how it is possible that 1 part of lime could be discovered along with 149 of carbonate of lime.

Geognostic Situation.—This mineral occurs in beds, in secondary limestone, and occasionally alternates with secondary gypsum, and beds of clay. In some places, the strata are quite straight, in others have a zig-zag direction, or are more or less deeply waved, and they are occasionally disposed in a concentric manner, like the concentric lamellar concretions of greenstone. Some strata contain angular pieces of stinkstone, which at first sight might be taken for fragments; and even whole beds occur, which are composed throughout of angular portions, either connected together by means of clay, or immediately joined without any basis. These various appearances do not seem to have been occasioned by any mechanical force acting upon the strata after their formation, but are rather to be viewed as original varieties of structure, which have taken place during the formation of the strata. It has been also met with in beds in shell limestone, and in the coal formation.

Geographic Situation.—Occurs in the vicinity of North Berwick in East Lothian, resting on red sandstone; and in the parish of Kirbean in Galloway. On the Continent, it is a frequent rock in Thuringia and Mansfeld.

Uses.—In ancient times, it was used as a medicine in veterinary practice: at present, it is principally employed as a limestone, and when burnt affords an excellent lime both for mortar and manure. In some districts, as in Thuringia, it is used as a paving-stone, and also cut into troughs, steps for stairs, door-posts, and other similar purposes.

Second Kind.

Prismatic Lucullite, *Jameson.*—Stänglicher Lucullan, *John.*

External Characters.—Colours greyish-black, pitch-black, smoke-grey, and hair-brown. Occurs massive, in balls, also in distinct concretions, which are stellular and scopiform prismatic. External surface sometimes delicately longitudinally streaked. Externally it is sometimes dull, sometimes glistening; internally shining and splendent, and the lustre is intermediate between vitreous and resinous. It has threefold cleavage, and the folia are sometimes curved. The fragments are indeterminate angular, sometimes inclining to rhomboidal. It is translucent on the edges, or opaque. Affords a grey-coloured streak. Brittle, and easily frangible. When rubbed, it emits a strongly fetid urinous smell. Specific gravity 2.653, 2.688, 2.703, *John.*

Chemical Characters.—When pounded and boiled in water, it gives out a hepatic odour, which continues but for a short time. The filtrated water possesses weak alkaline properties, and contains a small quantity of a muriatic and sulphuric salt. It does not appear to be affected by pure alkalies. It dissolves with effervescence in nitrous and muriatic acids, and leaves behind a coal-black or brownish-coloured residuum.

		From Stavern in Norway.
Constit. Parts.—	Carbonic acid	41.50
	Lime . .	53.37
	Oxide of manganese	0.75
	Oxide of Iron	1.25
	Oxide of carbon	1.25
	Sulphur . .	0.25
	Alumina .	1.25
	Silica . .	1.25
	Alkali, alkaline muriate, water, magnesia, zirconia .	2.13——100.00

John, Chem. Laborat. b. ii. s. 246.

Geognostic and Geographic Situations.—It occurs in balls, varying from the size of a pea to two feet in diameter, in brown dolomite, at Building Hill near Sunderland. At Stavern in Norway, it appears to occur in transition-rocks; in alum-slate at Garphytta in Nericke; in Greenland; and in the Russbachthal in Salzburg.

Third Kind.

Foliated or Sparry Lucullite, *Jameson.*—Späthiger Lucullan, *John.*

External Characters.—Colours yellowish, greyish, and greenish-white; also bluish-grey, and greyish and velvet black. Occurs massive, disseminated, in small granular concretions, and crystallized in acute six-sided pyramids. Internally alternates from glimmering to shining. Fragments generally rhomboidal. Translucent, or translucent on the edges. Semi-hard, approaching to soft. Brittle, and easily frangible. When rubbed, it emits an urinous smell. Specific gravity 2.650, *John.*

Chemical Characters.—They agree with those of the preceding subspecies: in its solution in acids there remains a minute black-coloured residuum.

Constituent Parts.

		From Moscau.
Carbonate of Lime,	- -	96.50
Carbonate of Manganese, Magnesia, and Iron,	- - -	1.50
Oxide of Iron,	- - -	1.00
Lime, Alumina, Carbon, Silica, & Water,		1.00—100.00

John, Chem. Laborat. b. iii. s. 90.

Geognostic and Geographic Situations.—It occurs in veins, and also in small cotemporaneous masses, in a bed of limestone in clay-slate, at Andreasberg in the Hartz; in veins of silver-ore in hornblende-slate at Kongsberg in Norway; also in transition alum-slate in larger and smaller elliptical masses, the centre of which is of iron-pyrites, and the periphery sparry lucullite, at Andrarum in Schonen, Garphytta in Nericke, and Christiania in Norway.

Eleventh Subspecies.

Marl, *Jameson.*—Mergel, *Werner.*

This subspecies is divided into two kinds, viz. Earthy Marl and Compact Marl.

First Kind.

Earthy Marl, *Jameson.*—Mergel Erde, *Werner.*

External Characters.—Colours yellowish-grey, and seldom pale smoke-grey. These are the colours it exhibits when dry: when moist, and in its original repository, its colours are pale blackish-brown or brownish-black.* Consists of fine dusty particles, either loose or

* Some of the varieties have generally a brown colour, and emit an urinous smell; these are by some authors considered as Earthy Stinkstone.

feebly cohering. Is dull. Particles feel fine, or rather rough and meagre. Soils slightly. Is light.

Chemical Characters.—It effervesces strongly with acids. It emits a strong urinous smell when first dug up; but after exposure to the air it loses this quality.

Constituent Parts.—It is said to be composed of lime, alumina, silica, and bitumen.—*Freiesleben.*

Geognostic and Geographic Situations.—It occurs in beds in flœtz or secondary limestone and gypsum formations, along with stinkstone, in Thuringia and Mansfeld.

Second Kind.

Compact or Indurated Marl, *Jameson.*—Verharteter Mergel, *Werner.*

External Characters.—Colours yellowish-grey, smoke-grey, and muddy bluish-grey. Sometimes spotted reddish and brownish in the rents, and marked with dendritic delineations. Occurs massive, in blunt angular pieces, vesicular, in flattened balls; and frequently contains petrifactions of fishes and crabs, also of gryphites, belemnites, chamites, pectinites, ammonites, terebratulites, ostracites, musculites, and mytulites. Dull both externally and internally, and only glimmering when intermixed with foreign parts. Fracture generally earthy, which approaches sometimes to splintery, sometimes to conchoidal; in the great inclines to thick and straight slaty. Fragments angular and blunt-edged, and sometimes tabular. Yields to the nail. Is opaque. Affords a greyish-white streak. Rather brittle, and easily frangible. Feels meagre. Specific gravity 2.365, 2.550, *Breithaupt.*

Chemical Characters.—Before the blow-pipe it intumesces, and melts into a greenish-black slag. It effervesces briskly with acids.

Const. Parts.—Carbonate of Lime,		50
	Silica,	12
	Alumina,	32
	Iron and Oxide of Manganese,	2—*Kirwan.*

Geognostic Situation.—It occurs in beds in the secondary flœtz limestone and coal formations; also in the new secondary formations that rest upon chalk.

Geographic Situation.—It frequently occurs in the coal formation in Scotland and England, and in the secondary formations which rest upon chalk in the south of England.

Uses.—Several different kinds of compact marl occur in nature: these are calcareous marl, in which the calcareous earth predominates; clay marl, in which the aluminous earth is in considerable quantity; and ferruginous marl, in which the mass contains a considerable intermixture of oxide of iron. The latter kind occurs in spheroidal concretions, called *septaria*, or *ludi Helmontii*, that vary from a few inches to a foot and a half in diameter. When broken in a longitudinal direction, we observe the interior of the mass intersected by a number of fissures, by which it is divided into more or less regular prisms, of from three to six or more sides, the fissures being sometimes empty, but oftener filled up with another substance, which is generally calcareous spar. From these septaria are manufactured that excellent material for building under water, known by the name of *Parker's Cement.** The calcareous and aluminous marl are used for improving particular kinds of land; also for mortar; in some kinds of pottery; and in the smelting of particular ores of iron.

Twelfth Subspecies.

Bituminous Marl-Slate, *Jameson.*—Bituminöser Mergelschiefer, *Werner.*

External Characters.—Colour intermediate between greyish-black and brownish-black. Occurs massive, and frequently contains impressions of fishes and plants. Lustre glimmering glistening, or shining, and resinous. Fracture straight, or curved slaty. Fragments slaty in the large, but indeterminate and rather sharp angular in the small. Is opaque. Shining and resinous in the streak. Soft, and feels meagre. Rather sectile, and easily frangible. Specific gravity, 2.631, 2.690, *Breithaupt.*

Constituent Parts.—It is said to be a carbonate of lime united with alumina, iron, and bitumen.

Geognostic Situation.—It occurs in secondary or flœtz limestone. It frequently contains cupreous minerals, particularly copper-pyrites, copper-glance, variegated copper-ore, and more rarely, native copper, copper green, and blue copper. It contains abundance of petrified fishes, and these are said to be most numerous in those situations where the strata are basin-shaped.

Geographic Situation.—*Europe.*—It abounds in the Hartzgebirge; also in Magdeburg and Thuringia. It is a frequent mineral in Upper and Lower Saxony: it occurs also in Franconia, Bohemia, Bavaria, Silesia, Suabia, Hesse-Cassel, and Switzerland.

America.—It is said to occur in the Cordilleras of South America.

III. Short-Axed Limestone, or Dolomite.—Kurzaxiges Kalk-Haloide, *Mohs.*

Rhomboid=107° 22′. Cleavage rhomboidal. Hardness=4.0,—4.5, sp. gr.=3.0,—3.2.

This species contains three subspecies, viz. 1. Dolomite; 2. Miemite; 3. Brown Spar.

First Subspecies

Dolomite, *Jameson.*

This subspecies is divided into three kinds, viz. Granular Dolomite, Columnar Dolomite, Compact Dolomite.

First Kind.

Granular Dolomite, *Jameson.*

This is again divided into White and Brown Granular Dolomite.

External Characters.—Colours snow-white, greyish-white, and rarely pale ash-grey. Occurs massive; also in small and fine granular distinct concretions, frequently so loosely aggregated, that they can be separated by mere pressure of the finger. Internally glimmering, approaching to glistening, and lustre pearly. Fracture in the large imperfect and slaty, in compact varieties small splintery, which passes into uneven. Fragments indeterminate angular, and blunt-edged. Faintly trans-

* These marly septaria abound in the Isle of Shepey, in the Medway, and often contain in their interior globular portions of heavy-spar, having diverging fibrous concretions. Similar septaria occur in Derbyshire, and in the county of Durham, in which latter district the internal fissures are filled with quartz.

lucent, or only translucent on the edges. Brittle, and easily frangible.

Chemical and Physical Characters.—It effervesces very feebly with acids,—a character which distinguishes it from granular limestone.

		St. Gothard.
Const. Parts.—	Carbonate of Magnesia,	46.50
	Carbonate of Lime, .	52 08
	Oxide of Manganese, .	0.25
	Oxide of Iron, . .	0.50
	Loss, ...	0.75—100

Klaproth, Beit. b. iv. s. 209.

	Iona.
Carbonic Acid, . .	48.00
Lime, ...	31.12
Magnesia, . . .	17.06
Insoluble Matter, . .	4.00

Tennant, Phil. Trans. for 1799.

Geognostic Situation.—It occurs principally in primitive mountains.

Geographic Situation.—*Europe.*—Beds of Dolomite, containing tremolite, occur in the island of Iona; and it is found in many countries on the Continent of Europe.

America.—Province of New-York, with tremolite.

Asia.—Bengal, with imbedded tremolite; also in Siberia.

Uses.—It appears to have been used by ancient sculptors in their finest works.

Observations.—It is named Dolomite, in honour of the celebrated French geologist, Dolomieu.

* Brown Dolomite, or Magnesian Limestone of Tennant.

Tennant, *Transactions of Royal Society of London for* 1799.—Thomson, *Annals of Philosophy for December*, 1814.

External Characters.—Colours yellowish-grey, yellowish-brown, and a colour intermediate between chesnut-brown and yellowish-brown; seldom bluish-grey. Occurs massive, and in minute granular concretions. Internally glistening or glimmering, and the lustre between pearly and vitreous. Fracture splintery, and sometimes flat conchoidal. Fragments indeterminate angular, and rather blunt-edged. Translucent, or translucent on the edges. Semihard; is harder than calcareous-spar. Is brittle. Specific gravity of the crystals, 2.823, *Tennant.*—2.777, 2.820, *Berger.*—2.791, *Thomson.*

Chemical Characters.—It dissolves slowly, and with but feeble effervescence, in nitrous acid.

		Building Hill, near Sunderland.
Const. Parts.—	Carbonate of Lime,	56.80
	Carbonate of Magnesia,	40.84
	Carbonate of Iron,	0.36
	Insoluble Matter, .	2.00—100.00

Thomson, *Annals of Phil.* vol. iv. p. 416.

Geognostic Situation.—In the north of England it occurs in beds of considerable thickness, and great extent, and appears to rest on the Newcastle coal-formation; but in the Isle of Man, it occurs in a limestone which rests on grey-wacke, and contains imbedded portions of quartz, rhomb-spar, and sparry-iron. It occurs in trap-rocks in Fifeshire.

Geographic Situation.—It occurs in Nottinghamshire, Derbyshire, Northamptonshire, Leicestershire, Northumberland, and Durham: also in Ireland, at Portumna in Galway, Ballyshannon in Donnegal, Castle Island, near Killarney.

Use.—Like common limestone, it is burnt and made into mortar, but it remains much longer caustic than quicklime from common limestone; and this is the cause of a very important difference between magnesian and common limestone, with regard to their employment in agriculture: Lime, from magnesian limestone, is termed *hot*, and when spread upon land in the same proportion as is generally practised with common quicklime, greatly impairs the fertility of the soil; and when used in a greater quantity, is said by Mr. Tennant to prevent all vegetation.

Observations.—A flexible variety of Dolomite occurs in England. The following account contains all the information we possess in regard to it:

Flexible Dolomite, *Jameson.*

External Characters.—Colour yellowish-grey, passing into cream-yellow. Occurs massive. Is dull. Fracture earthy in the small, and slaty in the large. Is opaque. Yields readily to the knife, but with difficulty to the nail. In thin plates it is uncommonly flexible. Specific gravity, 2.544, *Thomson.* This is probably below the truth, as the stone is porous.

Geographic Situation.—It occurs about three miles from Tinmouth Castle.

Observations.—This curious mineral was discovered by our intelligent friend Mr. Nicol, Lecturer on Natural Philosophy. To that gentleman we are indebted for the following particulars in regard to it. He finds, that its flexibility is considerably influenced by the quantity of water contained in it. When saturated with water, it is remarkably flexible; as the evaporation goes on, it becomes more and more rigid, until the water be reduced to a certain limit, when the flexibility becomes scarcely distinguishable. From this point, however, the flexibility gradually increases, as the moisture diminishes; and as soon as the water is completely exhaled, it becomes nearly as flexible as it was when saturated with that fluid.

Second Kind.

Columnar Dolomite.—Stänglicher Dolomit, *Klaproth.*

External Characters.—Colour pale greyish-white. Occurs massive, in thin, long, and straight prismatic concretions. Has an imperfect cleavage. Fracture uneven. Lustre vitreous, inclining to pearly. Breaks into acicular-shaped fragments. Feebly translucent. Is brittle.

		From the Mine Tschistagowskoy.
Const. Parts.—	Carbonate of Lime, .	51
	Carbonate of Magnesia, .	47
	Carbonated Hydrate of Iron,	1—99

Klaproth, Chem. Abhandl. s. 328.

Geognostic and Geographic Situations.—It occurs in serpentine in the mine Tschistagowskoy, on the river Mjafs, in the government of Orenberg in Russia.

Third Kind.

Compact Dolomite, or Gurhofite, *Jameson.*—Gurhofian, *Karsten.*

External Characters.—Colour snow-white. Occurs massive. Dull. Fracture flat conchoidal, passing to even. Fragments indeterminate angular, and sharp-edged. Slightly translucent on the edges. Hard, bordering on semihard. Brittle, and rather difficultly frangible.

Chemical Characters.—When pounded, and thrown into diluted and heated nitrous acid, it is completely dissolved, with effervescence.

Const. Parts.—	Carbonate of Lime,	70 50
	Carbonate of Magnesia,	29 50—100.00

Klaproth. Gesellsch. N. Fr. b. i. s. 258.

Geognostic and Geographic Situations.—It occurs in veins in serpentine rocks, between Gurrhof and Aggsbach, in Lower Austria.

Second Subspecies.

Miemite, *Jameson* and *Klaproth.*

This subspecies is divided into two kinds, viz. Granular Miemite, and Prismatic Miemite.

First Kind.

Granular Miemite.

External Characters.—Colour pale asparagus-green, which passes into greenish-white. Occurs massive, in large and coarse angulo-granular distinct concretions; crystallized in flat double three-sided pyramids, in which the lateral planes of the one are set on the lateral edges of the other. Crystals middle-sized, or small; either attached by their lateral edges, or intersecting each other; surface drusy. Internally splendent and pearly. Fragments rather blunt-edged. Translucent. Semihard. Brittle. Specific gravity 2.885.

Const. Parts.—	Carbonate of Lime, . .	53.00
	Carbonate of Magnesia, .	42.50
	Carbonate of Iron, with a little Manganese, . .	3.00
		98 50

Klaproth, Beit. b. iii. 296.

Geognostic and Geographic Situations.—It is found at Miemo in Tuscany, imbedded in gypsum.

Observations.—This mineral was first observed by the late Dr. Thomson of Naples, who sent specimens of it to Klaproth for analysis. It is named *Miemite*, after the place where it was discovered.

Second Kind.

Prismatic Miemite, *Jameson.*—Stänglicher Bitterspath, *Klaproth.*

External Characters.—Colour asparagus-green, olive-green, and oil-green. Occurs in prismatic distinct concretions, and crystallized in flat rhomboids, which are deeply truncated on all the edges. Crystals small, and very small, and sometimes they form only drusy crusts. Internally shining and vitreous. Fracture passes from concealed foliated to splintery. Fragments rather blunt-edged. Strongly translucent. As hard as the granular miemite. Specific gravity, 2.885, *Karsten.*

Chemical Characters.—It dissolves slowly, and with but feeble effervescence, in nitrous acid.

Constituent Parts.—	Lime, ...	33.00
	Magnesia, . . .	14.50
	Oxide of Iron, . .	2.50
	Carbonic Acid, . .	47.25
	Water and Loss, .	2.75—100

Klaproth, Beit. b. iii. s. 303.

Geognostic and Geographic Situations.—It occurs in cobalt veins that traverse sandstone at Glücksbrunn in Gotha, and at Beska in Servia, on the frontier of Turkey.

Third Subspecies.

Brown-Spar, or Pearl-Spar, *Jameson.* Braunspath, *Werner.*

This species is divided into two kinds, viz. Foliated Brown-Spar, and Columnar Brown-Spar.

First Kind.

Foliated Brown-Spar, *Jameson.*—Blättriger Braunspath, *Werner.*

External Characters.—Colours flesh-red and brownish-red. Often occurs massive, also disseminated, seldom globular, stalactitic, reniform, with tabular and pyramidal impressions; also in distinct concretions, which are granular, and rarely thin and straight lamellar; and frequently crystallized. Surface of the crystals usually drusy, and seldom shining, generally glistening or glimmering, and sometimes even dull. Internally alternates from shining to glistening, very rarely splendent, and lustre pearly. Fragments indeterminate angular, and rather blunt-edged in the great, but in the small are rhomboidal. Generally translucent on the edges, rarely translucent. Brittle, and easily frangible. Specific gravity 3.0, 3.2, *Mohs.*

Chemical Characters.—It hardens, and becomes dark brownish-black before the blowpipe; and effervesces feebly with acids.

Constituent Parts.—	Lime, ...	43.0
	Magnesia, ...	10.0
	Oxide of Iron, ...	8.0
	Manganese, ...	3.0
	Water, and Carbonic Acid,	26.5

Berthier, Journ. des Mines, No. 103. p. 73.

Geographic Situation.—It occurs along with galena, and other ores of lead, in the lead mines of Lead Hills and Wanlockhead in Lanarkshire; in the mines of Cumberland, Northumberland, and Derbyshire.

Second Kind.

Columnar Brown-Spar, *Jameson.* Stänglicher Braunspath, *Klaproth.*

External Characters.—Colours reddish-white, rose-red, and pearl-grey. Occurs in distinct concretions, which are wedge-shaped columnar or prismatic, and have glimmering and longitudinally streaked surfaces. Splendent, and appears pearly on the fracture surface. Has an imperfect cleavage. Fragments wedge-shaped. Translucent. Brittle. Easily frangible.

Constit. Parts.—	Carbonate of Lime, . .	51.50
	Carbonate of Magnesia,	32.00
	Carbonate of Iron, . .	7 50
	Carbonate of Manganese,	2 00
	Water, ...	5.00
		98.00

Klaproth, Beit. b. iv. s. 203.

Geographic Situation.—It is found at the mine named Segen Gottes at Gersdorf in Saxony; and in that of Valenciana at Guanauxuato in Mexico.

IV. Rhomb-spar, *Jameson.* Langaxiges Kalk-Haloid, *Mohs.*

Rhomboid=106° 16′. Cleavage rhomboidal. Hardness=3.5—4.0. Sp. gravity=2.8, 3.2.

External Characters.—Colours white, grey, and yellow. Occurs massive and disseminated; and crystallized in rhomboids, in which the obtuse angle is 106° 15′. These rhomboids are sometimes rounded or truncated on the edges. Crystals middle-sized and small; the surface is sometimes smooth, sometimes rough, and either shining or glimmering. Internally the lustre is splendent, between vitreous and pearly. Fracture imperfect conchoidal. Fragments rhomboidal. Easily frangible and brittle.

Chemical Characters.—Before the blowpipe it is infusible, without addition; even when pounded it effervesces but feebly; and dissolves slowly in muriatic acid.

Constit. Parts.—Carbonate of Lime, . 56.60
Carbonate of Magnesia, 42.00—98.60

Or by another result; Carbonate of Lime, 56.2
Carbonate of Magnesia, 43.5—98.9
With a trace of Manganese and Iron, *Murray.**

Geognostic Situation.—It occurs imbedded in chlorite-slate, talc-slate, limestone, and serpentine; in the salt formation, where it is imbedded in anhydrite and gypsum; in drusy cavities in compact dolomite, and in metalliferous veins.

Geographic Situation.—It occurs imbedded in chlorite-slate on the banks of Loch Lomond; in a vein in transition rocks, along with galena, blende, copper-pyrites, and calcareous-spar, near Newton-Stewart in Galloway; in compact dolomite in the Isle of Man and the north of England.

Order II. BARYTE.

No metallic lustre. Colour rarely changed in the streak; if orange-yellow, the specific gravity is 6, and more. Hardness ranges from 2.5. to 5. Sp. gravity ranges from 3.3 to 7.2. If the specific gravity be less than 3.6, and the hardness 5, the cleavage is di-prismatic.

Genus I.—RED MANGANESE.

One axis. Cleavage rhomboidal. Hardness=3.5, 4.5. Sp. gr.=3.3, 3.9.

This genus contains one species, viz. Rhomboidal Red Manganese.

1. Rhomboidal Red Manganese, *Jameson.*—Langaxiger Flintz-Baryt, *Mohs.*

Rhomboid= . Cleavage rhomboidal. Hardness =3.5. Sp. gravity=3.3, 3.6.

This species is divided into three subspecies, viz. 1. Foliated rhomboidal red manganese, 2. Fibrous rhomboidal red manganese, and 3. Compact rhomboidal red manganese.

First Subspecies.

Foliated Rhomboidal Red Manganese, *Jameson.*

External Characters.—Colour bright rose-red, slightly inclining to flesh-red. Occurs massive, disseminated, small reniform, globular, with tabular and rhomboidal impressions, and in granular distinct concretions. Internally shining, inclining sometimes to glistening, sometimes to splendent, and the lustre pearly. Fragments indeterminate angular, and rather sharp-edged, or rhomboidal. Generally translucent on the edges; in some rare varieties translucent. Brittle, and rather easily frangible.

Chemical Character.—Before the blowpipe, without addition, it first becomes dark brown, and then melts into a dark reddish-brown bead.

Const. Parts.—Oxide of Manganese,	.	52 60
Silica,	. . . .	39.60
Oxide of Iron,	. . .	4.60
Lime,	. . . .	1.50
Volatile ingredients,	.	2.75—101.5

Berzelius, in Afh. i. Fys. och. Min. i. 110.

Geognostic and Geographic Situations.—It occurs in beds of specular iron-ore and magnetic iron-ore, along with compact garnet and calcareous-spar, in the gneiss hills at Langbanshytta, in Wermeland in Sweden; also at Catharinenburg in Siberia, and in Saxony.

Uses.—The Siberian varieties are cut and polished, and worn as ornamental stones.

Second Subspecies.

Fibrous Rhomboidal Red Manganese, *Jameson.*

External Characters.—Colours rose-red andflesh-red, inclining to grey and brown. Occurs massive, and in prismatic fibrous concretions, which are straight, scopiform and stellular. Internally glistening and pearly. Fragments splintery and wedge-shaped. Feebly translucent.

Geognostic and Geographic Situations.—It occurs in veins in primitive and transition rocks. It is a rare mineral, and is principally found at Kapnik in Transylvania, and at Schemnitz in Hungary.

Third Subspecies.

Compact Rhomboidal Red Manganese, *Jameson.*

External Characters.—Its principal colour is pale rose-red, which sometimes passes into dark reddish-white. Occurs massive, disseminated, and sometimes imperfectly reniform. Internally dull or glimmering. Fracture even sometimes inclining to splintery. Fragments indeterminate angular, and rather sharp-edged. Brittle, and easily frangible.

Chemical Characters.—It is infusible before the blowpipe, but becomes black by ignition.

		Siberia.
Constituent Parts.—Oxide of Manganese,	.	61
Silica,	. . . .	30
Oxide of Iron,	. . .	5
Alumina,	. . . . .	2—98

Lampadius, in Pract. Chem. Abh. b. ii. s. 209.

Geognostic and Geographic Situations.—It occurs at Kapnik in Transylvania; at Langbanshytta, in Wermeland in Sweden; and Catharinenburg in Siberia.

* The above analysis was communicated to us by the late Dr. Murray.

Genus II.—SPARRY IRON.

Kurzaxiger Flinz Baryt, *Mohs.*—Spathisenstein, *Werner.* Fer oxydé carbonatée, *Haüy.*

One axis. Cleavage rhomboidal. Hardness = 3.5, 4.6. Sp. gr. = 3.6, 3.9.

This genus contains one species, viz. Common Sparry iron.

1. Common Sparry Iron, *Jameson* —Spatheisenstein, *Werner.* Fer oxydé carbonatée, *Haüy.*

Rhomboid=107°. The most perfect cleavage is in the direction of the planes of the primitive rhomboid ; the least perfect in the direction of the planes of a flat rhomboid. Hardness=3.5, 4.5. Spec. gravity = 3.6, 3.9.

External Characters.—Colours yellow, white, brown, and black. Occurs massive, disseminated, with pyramidal impressions ; also in granular distinct concretions ; and crystallized. The following are some of its principal crystallizations :

1. Primitive rhomboid.
   a. Perfect, with straight or spherical convex lateral faces.
   b. Truncated on the apices.
   c. Truncated on the terminal edges.
   d. Rounded off on the apices and edges.
   When the truncating planes in the variety 1. *c.* become so large that the original planes disappear, there is formed
2. A still flatter rhomboid.
   From the variety 1. *d.* there arises
3. The spherical lenticular form.
   From the rhomboid with curved faces there is formed
4. The saddle-shaped lens.
   We sometimes observe the primitive form arranged in rows, so as to form an
5. Equiangular six-sided prism, flatly acuminated with three planes, which are set on the alternate lateral planes.

Crystals middle-sized, small, and very small. Seldom singly superimposed, as is the case with the lens, most generally aggregated in druses. Planes of the lens delicate drusy, but all of the other forms generally smooth ; and the lustre varies from splendent, through shining, to glistening. Internally generally glistening, sometimes inclining to shining, and even to splendent; but the black variety is only glimmering, and the lustre is pearly. The imperfect foliated fracture is sometimes conjoined with the splintery ; and this occurs principally in the greenish-grey varieties. Fragments rhomboidal in the foliated varieties, but rather sharp-edged in the compact. Generally translucent on the edges, also translucent ; but the black varieties are opaque. The pale varieties afford a white, the darker varieties a yellowish-brown streak. It is not particularly brittle, and is easily frangible.

Chemical Characters.—It blackens, and becomes magnetic before the blowpipe, but does not melt : it effervesces with muriatic acid. It dissolves with ebullition in glass of borax, and communicates to it an olive-green colour.

Constituent Parts.		Steinhem.
	Oxide of iron .	63.75
	Carbonic acid .	34.00
	Oxide of manganese	0.75
	Magnesia . .	0.25
	Loss . .	1.25—100.00

Klaproth, in Magaz. Natf. Fr. b. v. s. 335.

Geognostic Situation.—It occurs in veins in granite, gneiss, mica-slate, clay-slate, and grey-wacke, and in these it is associated with ores of lead, cobalt, silver, and seldomer with nickel and bismuth ; more frequently with galena, grey copper ore, iron-pyrites, and grey antimony ore. In other veins it is accompanied with brown, red, and black iron ore, calcareous-spar, and quartz. But the most extensive formations of this mineral are in limestone, by some referred to primitive, by others to secondary rocks, in which it is arranged in thick beds. It also occurs filling up amygdaloidal cavities in trap rocks.

Geographic Situation.—Europe.—It occurs in small quantities in different places in England, Scotland, and Ireland ; but very abundant in Hessia, Carinthia, and other countries on the continent of Europe.

Uses —It affords an iron which is excellently suited for steel making. The black variety is said to afford the best kind of iron.

Genus III. CALAMINE.*

Zink-Baryt, *Mohs.*

One and three axes. Cleavage di-prismatic ; rhomboidal. If rhomboidal, = 4.2 and more. Hardness = 5.0 sp. gr. = 3 3,—4.5.

This genus contains two species, viz. 1. Prismatic Calamine; and. 2. Rhomboidal Calamine.

1. Prismatic Calamine, or Electric Calamine, *Jameson* —Prismatischer Zink-Baryt, *Mohs.* Zinc Oxydé, *Haüy.*

Vertical prism = 99° 56′. Horizontal prism, in the direction of the longest diagonal, = 120°. Cleavage the same. Hardness = 5.0. Sp. gr. = 3.3, 3.6.

External Characters.—Most common colours white and yellow ; it also occurs green, grey, yellow, and brown. Has sometimes a curved striped colour delineation. Occurs massive, disseminated, in crusts, stalactitic, reniform, botryoidal, cellular, corroded ; also in distinct concretions, which are scopiform, radiated, or fibrous, granular, and curved lamellar. Sometimes crystallized. The following are some of its secondary forms : 1. Six-sided prism. 2. Flat six-sided prism, bevelled on the terminal planes ; the bevelling planes set on the broader lateral planes. This prism is sometimes so flat, that it appears like a longish rectangular four-sided table bevelled on the terminal planes. 3. Acute double four-sided pyramid, sometimes perfect, sometimes truncated on the summits. 4. Acute double four-sided pyramid, acuminated on both extremities, with four planes, which are set on the lateral planes, and sometimes the summits are truncated.

Crystals small ; either solitary or scopiformly aggregated. Internally, the lustre alternates from glistening to dull, and lustre pearly, inclining to adamantine. Fracture small and fine grained uneven. Alternates from transparent to translucent on the edges, and opaque.

* Agricola says, that because the cadmia (calamine) in the furnace attaches itself to the iron bars in forms like a reed, (calamus) it was named *Calamine.*

Crystallized varieties as hard as apatite; the massive and opaque softer. Dark-coloured varieties afford a yellowish grey streak.

Physical Characters.—When gently heated, it is strongly electric.

Chemical Characters.—It loses, according to Pelletier, about 12 *per cent.* by ignition; it is soluble in muriatic acid without effervescence; and the solution gelatinises on cooling.

		Rezbanya.
Constituent Parts.—	Oxide of Zinc,	68.30
	Silica, - -	25.00
	Water, - -	4 40—97.70

Smithson, in Phil. Trans. Part i. for 1803.

Geognostic Situation.—It occurs in small quantities in metalliferous veins, principally along with ores of lead, in grey-wacke, grey-wacke-slate, and clay-slate; but most frequently in secondary or floetz limestone, in imbedded masses, and irregular beds.

Geographic Situation.—It occurs in the lead-mines at Wanlockhead; also in Leicestershire and Flintshire, and in several countries on the Continents of Europe and Asia.

2. Rhomboidal Calamine, *Jameson.*—Galmei, *Werner.* Rhomboedrischer Zink-Baryt, *Mohs.*

Rhomboid about 110°. Cleavage in the direction of the planes of the rhomboid. Hardness = 5.0. Sp. gr. = 4.2, 4.4.

This species is divided into three subspecies, viz. Sparry Rhomboidal Calamine, Compact Rhomboidal Calamine, and Earthy Rhomboidal Calamine.

First Subspecies.

Sparry Rhomboidal Calamine, *Jameson.*—Spathiger Galmei, *Karsten.*

External Characters.—Colours white, grey, green, and brown. Occurs massive, botryoidal, reniform, stalactitic, tabular, cellular; also in distinct concretions, which are prismatic, granular, and curved lamellar; and sometimes crystallized. Internally shining and pearly. Fragments rhomboidal. Alternates from semitransparent to opaque.

Chemical Characters.—It dissolves with effervescence in muriatic acid; it is infusible; loses about 34 *per cent.* by ignition.

Constituent Parts.

	Derbyshire.	Somersetshire.
Oxide of Zinc, -	65.2	64.8
Carbonic Acid, -	34.8—100	35.2—100

Smithson, in Phil. Trans. Part i. for 1803.

Second Subspecies.

Compact Rhomboidal Calamine, *Jameson.*—Gemeiner Galmei, *Karsten.*

External Characters.—Colours grey, yellow, and yellowish-brown. Occurs massive, disseminated, corroded, reniform, stalactitic, and cellular; also in concentric curved lamellar concretions. Rarely in supposititious crystals, or incrusting other crystals. Internally dull, or very feebly glimmering and resinous. Fracture coarse-grained uneven, fine splintery, even, and flat conchoidal. Opaque, or feebly translucent on the edges.

Chemical Characters.—The same as in the preceding subspecies.

Third Subspecies.

Earthy Rhomboidal Calamine, *Jameson.*—Zinkbluthe, *Karsten.*

External Characters.—Colour white, sometimes with a yellowish-brownish exterior. Occurs massive, disseminated, botryoidal, flat, reniform, and with impressions. Internally dull. Fracture fine earthy. Opaque. Yields to the nail. Adheres to the tongue.

Chemical Characters.—The same as in the first subspecies.

		Bleiberg in Carinthia.
Constituent Parts.—	Oxide of Zinc,	71.4
	Carbonic Acid,	13.5
	Water, ..	15.1—100.0

Smithson, in Phil. Trans. Part I. for 1803.

Geognostic Situation of the Species.—It occurs in beds, nests, filling up or lining hollows, in transition limestone, and in secondary or floetz limestone, and conglomerate rock; also in veins.

Geographic Situation of the Species.—*Europe.*—It occurs in the Mendip Hills, at Shipham, near Cross, Somersetshire; at Alionhead in Durham; at Holywell, and elsewhere in Flintshire; and in Derbyshire.

Uses.—Both prismatic and rhomboidal calamine, when purified and roasted, are used for the fabrication of brass, which is a compound of zinc and copper; and the pure metal is also employed for a variety of other purposes.

Genus IV. TUNGSTEN,* or SCHEELIUM.†

Scheel Baryt, *Mohs.*

One axis. Cleavage pyramidal. Hardness = 4.0—4.5. Sp. gr. = 6.0—6.1.

This genus contains one species, viz. Pyramidal Tungsten.

1. Pyramidal Tungsten, *Jameson.*—Pyramidaler Scheel-Baryt, *Mohs.* Schwerstein, *Werner.*

Pyramid = 107° 26′—113° 36′. The most distinct cleavage is that parallel with the planes of the primitive pyramid; another, less distinct, in which the planes are parallel with the sides of an acute pyramid, (100° 8′; 130° 20′;) and a third, the least distinct, parallel with the common base of the pyramid.

External Characters.—White is the principal colour of this mineral. The following varieties of colour also sometimes occur, viz. brown, which sometimes inclines to orange-yellow and hyacinth-red. Occurs massive, disseminated, also in distinct concretions, which are granular, seldomer wedge-shaped prismatic, and these latter traversed by others which are curved lamellar. Sometimes crystallized. The following are the secondary forms:

1. The primitive figure, in which the angles of the common base are flatly bevelled, and the bevelling planes set on the lateral edges. 2. Very acute double four-sided pyramid, in which the lateral planes of the one are set on the lateral planes of the other. 3. Flat double four-sided pyramid.

Crystals middle-sized, small and very small; they are always superimposed, sometimes in single crystals, sometimes in druses. Lateral planes of the crystals

* The name *Tungsten* was given to this mineral by the Swedes, on account of its great weight.

† Werner gave the name *Scheele* to this genus, in honour of the illustrious chemist Scheele, who discovered the peculiar metal which characterises it.

generally smooth; planes of the first pyramids slightly streaked; shining and splendent; lustre inclines to adamantine. Internally shining, lustre resinous, sometimes inclining to adamantine. Fracture coarse, or small-grained uneven, passing into imperfect conchoidal. Fragments indeterminate angular, rather blunt-edged. More or less translucent, seldom semitransparent. Rather brittle, easily frangible.

Chemical Characters.—It crackles before the blowpipe and becomes opaque, but does not melt; with borax it forms a transparent or opaque white glass, according to the proportions of each.

		Cornwall.
Constit. Parts.—	Oxide of Tungsten	75.25
	Lime, . .	18.70
	Silica, . .	1.56
	Oxide of Iron, .	1.25
	Oxide of Manganese,	0.75—97.45

Geognostic Situation.—It occurs along with tinstone, magnetic iron-ore, and brown iron-ore, in primitive rocks.

Geographic Situation.—It occurs along with wolfram and tin-ore at Pengilly in Breage in Cornwall; at Bispberg in Sweden, in a bed of magnetic iron-ore.

Genus V. BARYTE.

One and three axes. Cleavage rhomboidal and prismatic. If cleavage rhomboidal, specific gravity =4.2 and more. Hardness =3.0, —3.5. Sp. gravity =3.6 —4.6.

1. Di-Prismatic Baryte, or Strontianite, *Jameson.*—Diprismatischer Hal-Baryt, *Mohs.* Strontian, *Werner.*

Vertical prism =117° 19′. Horizontal prism in the direction of the smaller diagonal. Cleavage in the direction of the planes of both prisms. Hardness =3.5. Sp. gravity =3.6—3.8.

External Characters.—Colour pale asparagus-green, which sometimes inclines to apple-green, sometimes to yellowish-white and greenish-grey. The greenish-grey variety sometimes passes into milk and yellowish-white, and pale straw-yellow. Occurs massive, in distinct concretions, which are scopiform, radiated and fibrous, and crystallized. The primitive form is an oblique four-sided prism, bevelled on the extremities. Its secondary figures are the following: 1. Acicular six-sided prism, acutely acuminated with six planes, which are set on the lateral planes. 2. Acicular acute double six-sided pyramid. Crystals are sometimes scopiformly and manipularly aggregated. Lustre of the distinct concretions shining or glistening; the fracture glistening, and pearly. Fracture fine-grained uneven. Fragments wedge-shaped or splintery. More or less translucent, and sometimes semi-transparent. Brittle, and easily frangible.

Chemical Characters.—Is fusible before the blowpipe, but becomes white and opaque, and tinges the flame of a dark purple colour. Is soluble, with effervescence, in muriatic or nitric acid; and paper dipped in the solutions thus produced burns with a purple flame.

Constituent Parts.—	Strontian, .	61.21
	Carbonic Acid,	30 20
	Water, .	8.50—100.00

Hope, Edin. Trans. for 1790.

Geognostic and Geographic Situations.—It occurs at Strontian in Argyleshire, in veins that traverse gneiss, along with galena or lead-glance, heavy-spar, and calcareous-spar.

2. Rhomboidal Baryte, or Witherite, *Jameson.* Rhomboedrischer Hal-Baryt, *Mohs.* Witherit, *Werner.*

Rhomboid =91° 54′. The most distinct cleavage is that parallel with the planes of the rhomboid, and another, less distinct, parallel with the alternate planes of the six-sided pyramid. Hardness =3.0, 3.3. Sp. gr. =4.2, 4.4.

External Characters.—Colours white, grey, and yellow. Occurs massive, disseminated, in crusts, cellular, corroded, large globular, reniform, botryoidal, stalactitic; also in distinct concretions, which are wedge-shaped, sometimes scopiform radiated, and occasionally pass into coarse granular. More rarely crystallized. The following are the secondary forms:

1. Equiangular six-sided prism.
   a. Truncated on the terminal edges.
   b. Acutely acuminated on the extremities with six planes, which are set on the lateral planes.
2. Acute double six-sided pyramid, in which the lateral planes of the one are set on the lateral planes of the other.

The crystals are small, and very small, seldom middle-sized. The prisms are sometimes scopiformly grouped, or they are in druses. Externally glistening; internally shining on the cleavage, and glistening on the fracture, and the lustre is resinous. Principal fracture uneven, inclining to splintery. Fragments wedge-shaped, or indeterminate angular. Translucent, rarely semi-transparent. Brittle, and easily frangible.

Chemical Characters.—Before the blowpipe it decrepitates slightly, and melts readily into a white enamel; it is soluble, with effervescence, in diluted muriatic or nitric acid.

Constit. Parts.—	Carbonate of Barytes	96.3
	Carbonate of Strontian	1.1
	Sulphate of Barytes	0.9
	Silex . . .	0.5
	Alumina, and Oxide of Iron . .	6.25—99.05

Aikin, Gol. Tr. v. iv. part ii. p. 442.

Geognostic and Geographic Situations.—It occurs in Cumberland and Durham, in lead veins that traverse a secondary limestone, which rests on red sandstone, and in these it is associated with coralloidal arragonite, brown spar, earthy fluor spar, heavy spar, and galena or lead-glance, white lead spar, green lead spar, copper-pyrites, blue copper, malachite, iron-pyrites, sparry iron, calamine, and blende.

Uses.—It is a very active poison, and in some districts, as in Cumberland, it is employed for the purpose of destroying rats. When dissolved by muriatic acid, the solution thus obtained is said to prove serviceable in scrofula.

3. Prismatic Baryte, or heavy spar, *Jameson.* Prismatischer Hal-Baryt, *Mohs.* Schwerspath, *Werner.*

Prism =101° 55′. The most distinct cleavage is that parallel with the terminal planes of the oblique four-sided prism; less perfect are those parallel with the lateral planes of the prism. Hardness =3.0, 3.5. Sp. gravity =4.1, 4.6.

This species is divided into nine subspecies, viz. 1. Earthy Heavy spar, 2. Compact Heavy spar, 3. Granular Heavy spar, 4. Curved Lamellar Heavy spar, 5. Straight Lamellar Heavy spar, 6. Fibrous Heavy spar,

7. Radiated Heavy spar, 8. Columnar Heavy spar, and 9. Prismatic Heavy spar.

First Subspecies.

Earthy heavy spar, *Jameson*. Schwerspath Erde, *Werner*.

External Characters.—Colours yellowish and reddish white. Of friable consistence, and consists of feebly glimmering, nearly dull, particles, which are intermediate between scaly and dusty, soils feebly, and are generally loose, or but feebly cohering. Feels meagre, and rather rough. Specific gravity, 4.0.

Constituent Parts.—It is sulphate of Barytes.

Geognostic and Geographic Situations.—It occurs in drusy cavities in veins of heavy spar, in Staffordshire and Derbyshire; at Freyberg in Saxony; Rieglesdorf in Hessia; and Mies in Bohemia.

Second Subspecies.

Compact heavy spar, *Jameson*. Dichter Schwerspath, *Werner*.

External Characters.—Colours white and grey. Occurs massive, disseminated, reniform, semi-globular, tuberose, with cubic impressions; and in curved lamellar concretions. Internally glimmering. Fracture intermediate between coarse earthy and fine grained uneven, which sometimes passes into imperfect foliated, and more rarely into splintery. Fragments indeterminate angular, and blunt-edged. Opaque or translucent on the edges. Rather sectile, and easily frangible. Sp. gravity, 4.84.

Geognostic and Geographic Situations.—It is found in the mines of Staffordshire and Derbyshire, where it is named *Cawk*.

Third Subspecies.

Granular Heavy Spar, *Jameson*.——Körniger Schwerspath, *Werner*.

External Characters.—Colours white, and sometimes ash-grey. Occasionally spotted brown and yellow on the surface. Occurs massive, and in fine granular concretions, which are sometimes so minute as scarcely to be discernable. Internally glistening, approaching to shining, and pearly. Fragments indeterminate angular, and blunt-edged. Feebly translucent. Soft. Rather brittle, and easibly frangible. Specific gravity, 4.300, *Klaproth*.

Constituent Parts.—Sulphate of Barytes,		90
Silica,	. .	10—100

Geognostic Situation.—Occurs principally in beds, along with galena, blende, copper-pyrites, and iron-pyrites.

Geographic Situation.—It occurs in beds, along with galena, blende, copper-pyrites, and iron-pyrites, at Peggau in Stiria; also in the Hartz, in beds, along with copper and iron pyrites, galena, and blende.

Fourth Subspecies.

Curved Lamellar Heavy-Spar, *Jameson*.——Krummschaaliger Schwerspath, *Werner*.

External Characters.—Principal colours white, grey, and red. Sometimes several colours occur together, and arranged in broad stripes. Generally occurs massive, more frequently reniform, and long globular, with a drusy surface; the drusy surface is formed of very small, thin, and longish four-sided tables; also in reniform curved lamellar concretions, which are frequently floriform, and these are again composed of prismatic concretions. It is rarely marked with cubical impressions. Internally intermediate between shining and glistening, and the lustre pearly, inclining to resinous. Fracture curved foliated, which sometimes inclines to splintery, and thus approaches to the compact subspecies. Fragments indeterminate angular, and rather blunt-edged. Translucent on the edges. Brittle, and easily frangible. Specific gravity, 4.307, *Breithaupt*.

Geognostic and Geographic Situations.—It is one of the most common subspecies of heavy-spar. In Scotland, it occurs in trap and sandstone rocks: in Derbyshire, it occurs in secondary limestone: it characterises a particular venigenous formation at Freyberg in Saxony, where it is associated with radiated pyrites, argentiferous galena, brown blende, calcareous-spar, and fluor-spar. It occurs in Sweden, Carinthia, and other countries.

Fifth Subspecies.

Straight Lamellar Heavy-Spar.

It is divided into three kinds, viz. Fresh Straight Lamellar Heavy-Spar, Disintegrated Straight Lamellar Heavy-Spar, and Fetid Straight Lamellar Heavy-Spar.

First Kind.

Fresh Straight Lamellar Heavy-Spar, *Jameson*.—Geradschaaliger Schwerspath, *Werner*.

External Characters.—Colours white, grey, black, blue, green, yellow, red, and brown. Occurs generally massive; also in distinct concretions, which are straight and thin lamellar; and again collected into others which are coarse granular; and also crystallized. The following are the secondary figures it exhibits:

1. Rectangular four-sided table. 2. Oblique four-sided table. 3. Longish six-sided table. 4. Eight-sided table.

Crystals vary in size, from large to small; and rest on one another, or intersect one another. Externally they are smooth and splendent; internally shining and splendent, and the lustre intermediate between resinous and pearly. Fragments tabular and rhomboidal. Translucent, or transparent, and refracts double. Brittle, and easily frangible.

Chemical Characters.—It decrepitates briskly before the blowpipe, and, by continuance of the heat, melts into a hard white enamel.

Constituent Parts.—Sulphate of Barytes,		97.60
	Sulphate of Strontian,	0.85
	Water, . . .	0.10
	Oxide of Iron, . .	0.80
	Alumina, . .	0.05

Klaproth, Beit, b. ii. s. 78.

Geognostic Situation.—It is found almost always in veins, which occur in granite, gneiss, mica-slate, clay-slate, greywacke, limestone, and sandstone. It is often accompanied with ores, particularly the flesh-red variety, and these are, native silver, silver-glance or sulphuretted silver, copper-pyrites, lead glance, white cobalt-ore, light red-silver, native arsenic, earthy cobalt, cobalt-bloom or red cobalt, antimony, and manganese. It occurs sometimes in beds, and encrusting the walls of drusy cavities.

Geographic Situation.—In this island, it occurs in veins in different primitive and transition rocks, and also in secondary limestone, sandstone, and trap. Beautiful crystallized varieties are found in the lead mines of Cumberland, Durham, and Westmoreland.

Second Kind.

DISINTEGRATED STRAIGHT LAMELLAR HEAVY-SPAR, *Jameson.*—Mulmicher oder murber geradschaaliger.—Schwerspath, *Werner.*

External Characters.—Colour white. Occurs massive. Glistening and pearly. Opaque, or faintly translucent on the edges. Very easily frangible. Other characters same as the preceding.

Geognostic and Geographic Situations.—It was formerly met with in considerable quantity at Freyberg in Saxony, in a mixture of galena, blende, and iron-pyrites.

Third Kind.

FETID STRAIGHT LAMELLAR HEAVY-SPAR, or HEPATITE, *Jameson.*

External Characters.—Colours white, grey, and black. Occurs massive, disseminated, and in globular or elliptical pieces, from an inch to a foot and upwards in diameter; also in lamellar concretions, which are generally straight, sometimes curved and floriform; sometimes there is a tendency to wedge-shaped and radiated concretions. Externally feebly glimmering; internally shining, and intermediate between pearly and resinous. Fragments indeterminate angular, and blunt-edged. Opaque, or translucent on the edges. Nearly as hard as straight lamellar heavy-spar. Affords a greyish-white coloured streak.

Chemical Characters.—It burns white before the blowpipe; and when rubbed or heated, gives out a fetid sulphureous odour.

Constituent Parts.—	Sulphate of Barytes,	85.25
	Carbon . .	0.50
	Sulphate of Lime,	6.00
	Oxide of Iron, .	5.00
	Alumina, . .	1.00
	Loss, including Moisture and Sulphur, .	2.25
		100.00

Klaproth, Beit. b. v. s. 121.

Geognostic and Geographic Situations.—It occurs at Buxton in Derbyshire; at Kongsberg, and Andrarum in Norway.

SIXTH SUBSPECIES.

FIBROUS HEAVY-SPAR, *Jameson.*—Fasriger Schwerspath, *Werner.*

External Characters.—Colour pale-yellowish, and wood-brown, which sometimes passes into yellowish-grey. Occurs massive and reniform; also in distinct concretions, which are scopiform prismatic or fibrous, sometimes collected into others, which are curved lamellar, and sometimes into coarse angulo-granular concretions. Internally shining, and lustre resinous. Fragments splintery, and wedge-shaped. Translucent on the edges.

Specific gravity, 4.080, *Klaproth.*—4.239, *Noeggerath.*

Constit. Parts.—	Sulphate of Barytes,	99.0
	Trace of Iron,	—99.0

Klaproth. Beit. b. iii. s. 288.

Geognostic and Geographic Situations.—Found at Neu-Leiningen in the Palatinate; also in an ironstone mine in clay-slate, at Chaud-Fontaine, near Luttich, in the Ourthe department; and at Mies in Bohemia.

SEVENTH SUBSPECIES.

RADIATED HEAVY-SPAR, or BOLOGNESE SPAR, *Jameson.*—Bologneser Spath, *Werner.*

External Characters.—Principal colour smoke-grey, which passes into ash-grey and yellowish-grey. Occurs in roundish pieces, which have a lenticular aspect and uneven surface; also in distinct concretions, which are parallel and scopiform prismatic, and also granular. Internally shining or glistening, and the lustre pearly, inclining to resinous. Fragments splintery, or wedge-shaped. Translucent. In other characters it agrees with the preceding.

Geognostic and Geographic Situations.—It occurs imbedded in marl in Monte Paterno, near Bologna: also at Rimini; and in Jutland.

EIGHTH SUBSPECIES.

COLUMNAR HEAVY-SPAR, *Jameson.*—Stangenspath, *Werner.*

External Characters.—Colours yellowish, greyish, and greenish-white. Occurs crystallized, in acicular oblique four-sided prisms, which are always columnarly aggregated, and intersect each other. Externally frequently invested with iron-ochre, but when unsoiled, shining and pearly. Cleavage the same as that of lamellar heavy-spar. Fragments indeterminate angular, and rather sharp-edged. Translucent. Specific gravity, 4.500.

Constituent Parts.—	Barytes, .	63.00
	Sulphuric Acid,	33.00
	Strontian Earth,	3.10
	Oxide of Iron,	1.50
	Water, -	1.20

Lampadius.

Geognostic and Geographic Situations.—It was formerly found in the vein of Lorenzgegentrum, near Freyburg in Saxony, along with ores of different kinds, and also fluor-spar, quartz, and straight and curved lamellar heavy-spar.

NINTH SUBSPECIES.

PRISMATIC HEAVY-SPAR, *Jameson.* Saulenspath, *Werner.*

External Characters.—Principal colours grey, white, greenish olive-green, flesh-red, and indigo-blue. Seldom occurs massive, or in angulo-granular and promiscuous prismatic concretions, generally crystallized, and in the following figures:

1. Slightly oblique four-sided prism, rather acutely bevelled on the extremities, and the bevelling planes set on the acuter lateral edges. 2. Oblique four-sided prism, rather acutely acuminated on the extremities with four planes, which are set on the lateral edges. 3. Unequiangular six-sided prism, with two opposite acuter lateral edges, and with the same terminal bevelment and acuminations as in figures 1 and 2. 4. Flat double four-sided pyramid, in which the lateral planes of the one are set on the lateral planes of the other.

Crystals middle-sized and small, and generally promiscuously aggregated. Surface of crystals splendent, and lateral planes transversely streaked. Internally shining or splendent, and lustre pearly, inclining to resinous. Alternates from translucent to semi-transparent. Specific gravity, 4.471, *Breithaupt*.

Geognostic Situation.—Occurs in veins, along with fluor-spar, and ores of silver and cobalt; in gneiss, mica-slate, and other primitive rocks. It is rare in clay-slate, and very rare in secondary rocks.

Geographic Situation.—Occurs at Kongsberg in Norway; Mies in Bohemia; and Freyberg, Marienberg, and Ehrenfriedersdorf, in Saxony; Roya in Auvergne.

4. Axifrangible Baryte, or Celestine, *Jameson*.—Axentheilender Hal-Baryt, *Mohs*. Zolestein, *Werner*.

Prism =104° 48′. The most distinct cleavage is that at right angles to the axis of the prism; another less distinct cleavage is parallel with the lateral planes of the prism. Hardness =3.0—3.3. Sp. gravity =3.6—4.0.

This species is divided into five subspecies, viz. Foliated Celestine, Prismatic Celestine, Fibrous Celestine, Radiated Celestine, and Fine Granular Celestine.

First Subspecies.

Foliated Celestine, *Jameson*.—Blattricher Celestin, *Karsten*. Schaaliger Zolestin, *Werner*.

External Characters.—Its colours are milk-white, blue, and red. Occurs massive; also in lamellar distinct concretions, which are generally straight, or slightly curved, and in which the surfaces are smooth and shining; and crystallized in the following figures: 1. Rectangular four-sided table, in which the terminal planes are bevelled, and the lateral planes are truncated. 2. Rectangular four-sided table, bevelled on the terminal edges. Crystals are middle-sized and small, and frequently rest on each other, or intersect each other. Externally shining and splendent; internally shining and pearly, inclining to vitreous. Fracture uneven. Fragments rhomboidal, or indeterminate angular, and rather sharp-edged. Is translucent, semi-transparent, or tranparent. Is rather sectile, and very easily frangible.

Chemical Characters.—It melts before the blowpipe into a white friable enamel, without very sensibly tinging the flame: after a short exposure to heat it becomes opaque, and has then acquired a somewhat caustic acrid flavour, very different from that of sulphuretted hydrogen, which heavy-spar acquires in similar circumstances. These characters apply also to the other subspecies.

Constituent Parts.

Strontian and Sulphuric Acid	97.601
Sulphate of Barytes	00.975
Silica	00.107
Oxide of Iron, and intermixed Hydrate of Iron	00.646
Water,	00.248—99.577

Stromeyer, in Got. Gel. Anz. 1812, 22, 114.

Geognostic and Geographic Situations.—Occurs in trap-tuff in the Calton Hill at Edinburgh,* and in red sandstone at Inverness. Is frequent along with some of the other subspecies at Aust Passage, and elsewhere in the neighbourhood of Bristol, and in the islands in the Bristol Channel, particularly in Barry Island, on the coast of Glamorganshire; also in amygdaloid at Bechely, in Glocestershire;† and it has been found on the banks of the Nidd, near Knaresborough, Yorkshire.

Second Subspecies.

Prismatic Celestine, *Jameson*.—Saulenförmiger Zölestin, *Werner*.

External Characters.—Colours white and blue. Occurs massive, also in distinct concretions, which are thick, straight, and wedge-shaped prismatic; but most frequently crystallized. The following are the most frequent crystallizations: 1. Long oblique four-sided prism, flatly bevelled on the extremities, the bevelling planes set on the obtuse lateral edges. Sometimes the angles between the bevelling and lateral planes are more or less deeply truncated, and thus form a four-planed acumination, in which the acuminating planes are set on the lateral edge. 3. Sometimes the acute edges of the preceding figure are truncated, and thus a six-sided prism is formed. Crystals middle-sized, and scopiformly aggregated, under an acute angle, and forming druses. Externally smooth, splendent, and resinous. Internally glistening and pearly, inclining to resinous. Cleavage the same as in the foliated subspecies. Fracture uneven. Fragments wedge-shaped and indeterminate angular. Is translucent, or transparent. In other characters it agrees with the preceding subspecies.

		Sicily.
Constituent Parts.—Strontian		54
	Sulphuric Acid	46—100

Vauquelin.

Geognostic and Geographic Situations—It occurs in drusy cavities in a bed of sulphur, which is associated with gypsum and marl, in the valleys of Noto and Mazzara, in Sicily.

Third Subspecies.

Fibrous Celestine, *Jameson*.—Fasriger Zölestin, *Werner*.

External Characters.—Colours blue, grey, and white. Occurs massive, also in distinct concretions, which are straight, parallel, and sometimes curved, fibrous. Internally glistening and pearly. Cleavage indistinct. Fragments splintery. Translucent. In other characters it agrees with the preceding species.

Constit. Parts.—Strontian		56.0
	Sulphuric Acid	42.0—98.0

Klaproth, Beit. b. ii. s. 97.

Geognostic and Geographic Situations.—Occurs in the red sandstone formation near Bristol; imbedded in marl, which is probably connected with gypsum, at Frankstown in Pennsylvania; and at Bouveron, near Toul, in the department of Meurthe in France.

Fourth Subspecies.

Radiated Celestine, *Jameson*.—Strahliger Zölestin, *Werner*.

External Characters.—Colour milk-white, which rarely approaches to yellowish and snow white. Occurs massive; also in prismatic concretions, which are scopiform radiated, collected into others which are wedge-shaped, and these again into very large and angulo-granular concretions. Internally shining and splendent, and lustre pearly, slightly inclining to vitreous. Frag-

* It was discovered in the Calton Hill by Mr. Sivright of Meggetland.
† It was discovered in the Becheley amygdaloid by Dr. Daubeny.

ments wedge-shaped and splintery. Translucent or semitransparent. In other characters agrees with the other subspecies.

FIFTH SUBSPECIES.

FINE GRANULAR CELESTINE, *Jameson.*—Fein Körniger Zolestin, *Werner.*

External Characters.—Colours greyish and yellowish-grey, and the first inclines sometimes to olive-green. Occurs massive, in fine granular concretions, in spheroidal or reniform masses, which are often traversed by fissures that divide its surface into quadrangular pieces, which are sometimes lined with minute crystals of celestine. Towards the surface it has a marly aspect. Internally dull and glimmering, and pearly. Fracture fine splintery, passing into uneven. Fragments blunt-edged. Opaque, or translucent on the edges. In other characters it agrees with the preceding subspecies.

Chemical Characters.—	Sulphate of Strontian	91.42
	Carbonate of Lime	8.33
	Oxide of Iron .	0.25
		100.00

Vauquelin, in Brongniart's Mineralogie, t. i. p. 258.

Geognostic and Geographic Situations.—Occurs imbedded in marly clay, with gypsum, at Montmartre, near Paris; and is said to form a whole bed in Champagne.

GENUS VI. LEAD-SPAR.

One and three axes. Cleavage rhomboidal, pyramidal, prismatic. Hardness ranges from 2.5 to 4.0. If above 3.5 the specific gravity is equal to 6.5 and more. Specific gravity ranges from 6.0 to 7.2.

This genus contains five species, viz. 1. Di-prismatic, or white lead-spar. 2. Rhomboidal, or green and brown lead-spar. 3. Prismatic or red lead-spar. 4. Pyramidal, or yellow lead-spar. 5. Tri-prismatic, or lead-vitriol.* Corneous lead, Arseniate of lead, Native minium.

1. DI-PRISMATIC LEAD-SPAR, *Jameson.* Di-prismatischer Blei-Baryt, *Mohs.*

Vertical prism = 117° 4′. Horizontal prism in the direction of the smaller diagonal = 109° 30′. Cleavage the same. Hardness = 3.0—3.5. Sp. gr. = 6.2—6.6.

This species is divided into three subspecies, viz. White lead-spar, Black lead-spar, and Earthy lead-spar.

FIRST SUBSPECIES.

WHITE LEAD-SPAR, *Jameson.* Weiss-Bleierz, *Werner.* Plomb carbonaté, *Hauy.*

External Characters.—Its colours are white, yellow, brown, and grey. It has sometimes a tempered steel tarnish. It is sometimes coloured externally yellow or brown, by yellow or brown iron-ochre; occasionally green, by earthy malachite; and blue, by earthy blue copper. It occurs massive, disseminated, in membranes, seldom reticulated; and crystallized in the following forms:—1. Unequiangular six-sided prism, in which the terminal edges are truncated. 2. Unequiangular six-sided prism, acutely acuminated with six planes, which are set on the lateral planes. 3. Acute double six-sided pyramid, which is perfect. 4. Unequiangular six-sided prism, acuminated with four planes, two of which are set on the lateral planes, bounded by the obtuse lateral edges, but the other two are set on the acuter lateral edges. 5. Acute oblique double four-sided pyramid, in the lateral planes of the one are set on the lateral planes of the other. It is the preceding figure without the prism. 6. Long acicular and capillary crystals, columnarly aggregated. 7. Occurs also in twin and triple crystals. The crystals are usually small, and very small; seldom middle-sized; are often long and acicular, also broad and tabular. Crystals occur superimposed, and either single or in druses; more frequently columnarly and scopiformly, or promiscuously aggregated. Externally, it alternates from specular splendent to glistening. Internally, it alternates from shining to glistening, and the lustre is adamantine, sometimes inclining to semimetallic, sometimes to resinous. Fracture is small conchoidal, which sometimes passes into uneven and splintery. Fragments are indeterminate angular, and rather sharp-edged. Alternates from translucent to transparent; and it refracts double in a high degree. Brittle, and very easily frangible.

		Leadhills.
Constituent Parts.—	Oxide of lead	82
	Carbonic acid	16
	Water	2—100

Klaproth, Beit. b. iii. s. 168.

Chemical Characters.—It is insoluble in water. It dissolves with effervescence in muriatic and nitric acids. Before the blowpipe it decrepitates, becomes yellow, then red, and is soon reduced to a metallic globule.

Geognostic Situation.—It occurs in veins, and sometimes also in beds, in gneiss, mica-slate, clay-slate, foliated granular limestone, grey-wacke, grey-wackeslate, and secondary limestone.

Geographic Situation.—It occurs at Leadhills in Lanarkshire, in veins that traverse transition rocks, in which it is associated with galena or lead-glance, earthy white lead-spar, green lead-spar, lead-vitriol or sulphat of lead, sparry iron, iron-pyrites, brown hematite, calamine, and blue copper; and the vein-stones are quartz, lamellar heavy-spar, calcareous-spar, brown-spar, and mountain-cork. It is found also with galena or lead-glance at Allonhead and Teesdale in Durham; with the same ore at Alston in Cumberland, and Snailback in Shropshire.

SECOND SUBSPECIES.

BLACK LEAD SPAR, *Jameson.* Schwarz Bleierz, *Werner.*

External Characters.—Its colour is greyish-black, of different degrees of intensity, which sometimes passes into ash-grey. Occurs massive, disseminated, corroded, cellular, and seldom crystallized, in small and very small six-sided prisms. The surface of the crystals is sometimes drusy, sometimes smooth, and sometimes longitudinally streaked. Externally it is generally splendent, and sometimes shining. Internally it is only shining, sometimes passing into glistening, and the lustre is metallo-adamantine. The fracture is small-grained uneven, which sometimes passes into imperfect conchoidal. Alternates from translucent to opaque. Its streak is whitish-grey. In other characters agrees with the preceding.

Constituent Parts.—	Oxide of lead	79
	Carbonic acid	18
	Carbon	2—99

Lampadius, Handb. Zu. Chem. Anal.

Geognostic Situation.—It generally occurs in the upper part of veins, associated with white lead-spar, and galena or lead-glance.

Geographic Situation.—It occurs at Leadhills; at Fair Hill and Flow Edge, Durham.

THIRD SUBSPECIES.

EARTHY LEAD-SPAR, *Jameson.* Bleierde, *Werner.*

This subspecies is divided into two kinds, viz. Indurated earthy lead-spar, and Friable earthy lead-spar.

First Kind.

INDURATED EARTHY LEAD-SPAR. *Jameson.* Verhärtete Bleierde, *Werner.*

External Characters.—Its most frequent colours are grey, from which it passes on the one side into yellow, on the other into brown. It occurs also smoke-grey, bluish-grey, and light-brownish red. It occurs massive. Internally it is glimmering, inclining to glistening; and the lustre is resinous*. The fracture is small and fine grained uneven, which passes on the one side into fine splintery, on the other into earthy. The fragments are indeterminate angular, and blunt-edged. Is usually opaque, or extremely faintly translucent on the edges. It yields a brown-coloured streak

Chemical Characters.—It is very easily reduced before the blowpipe; effervesces with acids, and becomes black with sulphuret of ammonia.

		Tarnowitz.
Constit. Parts.—	Oxide of lead	66.00
	Carbonic acid	12.00
	Water	2.25
	Silica	10.50
	Alumina	4.75
	Iron and oxide of manganese	2.25
		97.75

John, Chem. Unt. b. ii. s. 229.

Geognostic Situation.—The yellow-coloured varieties occur in a bed in primitive limestone in the Bannat; the grey-coloured varieties occur sometimes in veins, sometimes in beds, and either in transition or secondary rocks.

Geographic Situation.—It is found in the lead veins of Wanlockhead and Leadhills; also at Grassfield Mine near Nenthead in Durham, and in Derbyshire.

Second Kind.

FRIABLE EARTHY LEAD-SPAR, *Jameson.* Zerreibliche Bleierde, *Werner.*

External Characters.—Its colours are yellowish-grey and straw-yellow, which sometimes approaches to sulphur-yellow and lemon-yellow. It occurs massive, disseminated, and in crusts. It is composed of dull dusty particles, which are feebly cohering. Soils feebly. It is meagre, and rough to the feel. It is heavy.

Geognostic Situation.—It occurs on the surface, or in the hollows of other minerals, and is usually accompanied with galena or lead-glance and lead-spars.

Geographic Situation.—It is found at Wanlockhead and Leadhills; Zellerfeld in the Hartz.

2. RHOMBOIDAL LEAD-SPAR, *Jameson.*—Rhomboedrisches Blei Baryt, *Mohs.*

Di-rhomboid = 141° 47′, 81° 46′. Cleavage in the direction of the faces of the rhomboid, and in the direction of the lateral faces of the six-sided prism. Hardness = 3.5, 4.0. Specific Gravity = 6.9—7.2.

This species contains two subspecies, viz. Green lead-spar and Brown lead-spar.

FIRST SUBSPECIES.

GREEN LEAD-SPAR, *Jameson.*—Grün Bleierz, *Werner.* Plomb phosphate, *Hauy*

External Characters.—Its colours are green, yellow, and white. It seldom occurs massive, sometimes stalactitic, reniform, and botryoidal, sometimes in distinct concretions, which are granular or prismatic; but most commonly crystallized. The following are the secondary forms: 1. Equiangular six-sided prism. 2. Six-sided prism, truncated on all the lateral edges, thus forming a twelve-sided prism. 3. Six-sided prism, flatly acuminated on the extremities with six planes, which are set on the lateral planes. The crystals are small, and very small, seldom middle-sized; they are superimposed, in druses, or scalarwise, or rose-like aggregated. Sometimes they form velvety or moss-like drusy crusts. Externally it is smooth and shining, or splendent; internally glistening, and the lustre is resinous. The fracture is small grained uneven, passing on the one hand into splintery, on the other into conchoidal. The fragments are indeterminate angular, and blunt-edged. It is more or less translucent, seldom nearly transparent, and is sometimes only translucent on the edges. It is brittle, and easily frangible.

Chemical Characters.—It dissolves in acids without effervescence.

		Wanlockhead.
Constit. Parts.—	Oxide of lead	80.00
	Phosphoric acid	18.00
	Muriatic acid	1.62
	Oxide of iron	a trace—99.96.

Geognostic Situation.—It occurs in veins and beds in primitive, transition, and secondary rocks.

Geographic Situation.—It occurs along with galena or lead glance, and other ores of lead, at Leadhills and Wanlockhead. In England, it is met with at Alston in Cumberland, Allonhead, Grasshill, and Teesdale, in Durham, and Nithisdale in Yorkshire.

SECOND SUBSPECIES.

BROWN LEAD SPAR, *Jameson.* Braun Bleierz, *Werner.* Plomb phosph. é *Hauy.*

External Characters.—Colour clove-brown, of different degrees of intensity, rarely approaching to liver-brown, sometimes so pale that it inclines to white. Occurs massive, also in distinct concretions, which are thin prismatic, and curved lamellar; and crystallized in the following figures: 1. Equiangular six-sided prism, which is sometimes bulging. 2. Six-sided prism, converging towards both ends, and thus inclining to the pyramidal form. 3. Acute double three-sided pyramid, in which the lateral planes of the one are set on the lateral planes of the other, and in which the common basis is sometimes more or less deeply truncated. The crystals are middle sized and small, sometimes short and acicular, singly imbedded, or scopiformly or globularly aggregated. Surface of the crystals is sometimes blackish or yellowish brown, and rough. Internally it is

* This lustre is accidental, and appears to be owing to intermixed white lead-ore or lead-vitriol.

glistening, and the lustre resinous. Fracture small and fine-grained uneven, and sometimes passes into small splintery. Fragments indeterminate angular. Feebly translucent, or translucent on the edges. The streak is greyish-white. Rather brittle, and easily frangible.

		From Huelgoet in Brittany.
Constituent Parts.—Oxide of lead		78.58
	Phosphoric acid	19.73
	Muriatic acid	1.65—99.96

Klaproth, Beit. b. iii. s. 157.

Geognostic Situation.—It occurs in veins that traverse gneiss, clay-slate, and porphyry. The veins generally contain lead and silver ores, also native silver, iron and copper pyrites, malachite, blende, ochry ironstone, heavy-spar, and quartz.

Geographic Situation.—*Europe.* It is found at Mies in Bohemia; near Schemnitz in Hungary; Saska in the Bannat; Zschoppau in Saxony; Huelgoët and Poullaouen in Lower Brittany.

America.—Zimapan in Mexico.

3. Prismatic Lead-Spar, or Red Lead-Spar,—*Jameson.*—Prismatischer Blei-Baryt, *Mohs.* Roth-Bleierz, *Werner.* Plomb chromaté, *Hauy.*

Prism unknown. Cleavage in the direction of a rectangular prism. Hardness = 2.5. Sp. gr. = 6.0,—6.1.

External Characters.—Colour hyacinth-red, more or less deep or pale. Seldom occurs massive, generally in flakes; and crystallized in the following figures:

1. Long slightly oblique four-sided prism. 2. Prism acutely and obliquely bevelled on the extremities, the bevelling planes set on the lateral edges. 3. Prism acuminated with four planes, which are set on the lateral planes.

Crystals generally small, thin, and always superimposed. Lateral planes formed by bevelment longitudinally streaked, the other planes smooth, shining or splendent. Internally shining or splendent, and the lustre adamantine. Fracture small-grained uneven, sometimes passing into imperfect and small conchoidal. Fragments indeterminate angular, and rather sharp-edged. More or less translucent. Gives a streak, of a yellow intermediate between lemon-yellow and orange-yellow. Almost sectile, and easily frangible.

Chemical Characters.—Before the blowpipe it crackles and melts into a grey slag. With borax it is partly reduced. It does not effervesce with acid.

Constituent Parts.—Oxide of Lead,		63.96
	Chromic Acid,	36.40—100.36

Vauquelin, Journ. des Mines, n. 34. 737.

Geognostic and Geographic Situations.—It occurs in veins in gneiss, in the gold mines of Beresofsk, in the Uralian mountains. In these mines, it is associated with brown iron-ore, cubes of iron-pyrites, native gold, green lead-spar, galena, and quartz.

Use.—In Russia, a very beautiful and costly orange-yellow colour is prepared from it, and which is used by painters.

4. Pyramidal Lead Spar, or Yellow Lead-Spar, *Jameson.*—Pyramidal Blei-Baryt, *Mohs.* Gelb Bleierz, *Werner.* Plomb molybdate, *Haüy.*

Pyramid = 99° 40′; 131° 45′. Cleavage in the direction of the faces of the pyramid, or in the direction of the terminal faces of a rectangular four-sided prism. Hardness = 3. Sp. gr. = 6.5. 6.8.

External Characters.—Most frequent colour wax-yellow. Occurs massive, in crusts, cellular; and crystallized in the following figures:

1. The pyramid truncated on the angles and summits. 2. The pyramid so deeply truncated in all the angles, and on the common base, that the original faces disappear, when there is formed a regular eight-sided table, which is sometimes so thick as to appear as an eight-sided prism. Sometimes four of the terminal edges are truncated, when a twelve-sided table is formed. 3. Pyramid deeply truncated on the summits, and on the common base, and the angles of the common base bevelled, which gives rise to the rectangular four-sided table, bevelled on the terminal edges. 4. Pyramid truncated on the lateral edges, which gives rise to the double eight-sided pyramid. When this figure is deeply truncated on the summits, there is formed, 5. A regular eight-sided table, bevelled on the terminal planes.

Tables usually broad and thin, alternate from small to very small, but are seldom middle-sized. Frequently intersect each other, and are often closely aggregated. Externally generally splendent or shining; internally shining or glistening, and the lustre resinous, inclining to adamantine. Fracture small and fine-grained uneven, or small conchoidal. Fragments indeterminate angular, and rather sharp-edged. Generally translucent, or only translucent on the edges; some rare crystals are semi-transparent. Rather brittle, and easily frangible.

Chemical Characters.—It decrepitates before the blowpipe, and then melts into a dark greyish-coloured mass, in which the globules of reduced lead are dispersed.

Constituent Parts.—Oxide of Lead,		58.40
	Molybdic Acid,	38.00
	Oxide of Iron,	2.08
	Silica . .	0.28—96.66

Hatchett, Phil. Trans. for 1796.

Geognostic and Geographic Situations.—It occurs at Bleiberg in Carinthia, in a compact limestone; also in the Maukeriz, near Brixlegg in the Tyrol; at Annaberg in Austria, and Rezbanya in Transylvania.

5. Tri-prismatic Lead-Spar, or sulphate of lead, *Jameson.*—Tri-prismatischer Blei Baryt, *Mohs.* Vitriol Bleierz, *Werner.* Plomb Sulphaté, *Haüy.*

The vertical prism = 120°; horizontal prism in the direction of the longer diagonal = 70° 31′; and in the smaller 101° 32′. Cleavage is the same. Hardness = 3.0. sp. gr. = 6.3.

External Characters.—Colours yellowish and greyish-white, occasionally stained pale-yellowish, from brown iron-ochre. Occurs massive, disseminated, and in angulo granular distinct concretions, but most frequently crystallized. The following are the principal crystallizations:

1. Oblique four-sided prism, acutely bevelled on the extremities, and the bevelling planes set on the acuter lateral edges. 2. Broad rectangular four-sided pyramid.

Crystals small, and very small, seldom middle-sized; and occur in druses, or superimposed. Externally splendent and shining; internally shining, and the lustre adamantine. Fracture small conchoidal. Fragments indeterminate angular, and rather blunt-edged. Alternates from transparent to translucent. Streak white. Rather brittle, and easily frangible.

Chemical Characters.—It decrepitates before the blowpipe, then melts, and is soon reduced to the metallic state.

		Wanlockhead.
Constituent Parts.—Oxide of Lead,		70.50
Sulphuric Acid,		25 75
Water of Crystallization,	. .	2.25—98.0

Klaproth, Beit. b. iii. s. 164. and 166.

Geognostic and Geographic Situations.—It occurs in veins along with galena and lead-glance, and different spars of lead, at Wanlockhead in Dumfriesshire, and Lead Hills in Lanarkshire; at Pary's Mine in Anglesey, and Penzance in Cornwall. On the Continent, it is met with at Zellerfeld in the Hartz, and in the Westerwald mountains.

* Corneous Lead (a.) *Jameson.*—Hornblei, *Werner.*

External Characters.—Colours greyish-white, and yellowish-grey, passing into pale wine-yellow. Occurs crystallized in oblique four-sided prisms. Internally splendent, and lustre adamantine. Has a threefold cleavage, the cleavages parallel to the planes of the four-sided prism. Fracture conchoidal. More or less transparent. Is soft; rather softer than white lead-spar. Is sectile, and easily frangible. Specific gravity, 6.065, *Chenevix.*

Chemical Characters.—On exposure to the blow-pipe or charcoal, it melts into an orange-coloured globule, and appears reticular externally, and of a white colour when solid; when again melted it becomes white; and on increase of the heat the acid flies off, and minute globules of lead remain behind.

Constituent Parts.—Oxide of Lead,	85.5
Muriatic Acid,	8.5
Carbonic Acid,	6.0—100.0

Klaproth, Beit. b. iii. s. 144.

Geographic Situation.—*Europe.*—In Cromford Level near Matlock in Derbyshire; and at Hausbaden, near Badweiler in Germany.

America.—In the neighbourhood of Southampton in the United States.

*Arseniate of lead, *Jameson.*—Bleiblüthe, *Hausmann.*

This species is divided into three subspecies, viz. Reniform arseniate of Lead. Filamentous arseniate of Lead, and Earthy arseniate of Lead.

First subspecies.

Reniform arseniate of lead, *Jameson.*—Bleiniere, *Hausmann.*

External Characters.—Colours on the fresh fracture reddish-brown and brownish-red; externally ochre-yellow, and straw-yellow. Occurs reniform and tuberose; also in curved lamellar concretions. Internally shining and resinous. Fracture conchoidal, sometimes inclining to even and uneven. Opaque. Soft and brittle. Specific gravity 3.933, *Karsten.*

Chemical Characters.—It is insoluble in water. Before the blowpipe on charcoal it gives out arsenical vapours; and is more or less perfectly reduced. It colours glass of borax lemon-yellow

Constituent Parts —Oxide of Lead,	35 00
Arsenic Acid,	25.00
Water, .	10.00
Oxide of Iron,	14.00
Silver, .	1.15
Silica, .	7.00
Alumina, .	2.00—95.15

Bindheim, in Beob. u. Endeck. de Berl. Ges. Natf. Fr. iv. s. 374.

Geographic Situation.—It has been hitherto found only in one mine, near Nertschinsky in Siberia.

Second Subspecies.

Filamentous arseniate of lead, *Jameson.*—Flockenerz, *Karsten.*

External Characters.—Colours green and yellow. Occurs massive, in granular concretions, and either in small acicular six-sided prisms, which are collected into flakes, or in very delicate capillary silky fibres, which are transparent, slightly flexible, and easily frangible. Specific gravity 5.0, 6.4.

Constituent Parts.—Oxide of Lead,	69.76
Arsenic Acid,	26.04
Muriatic Acid,	1.58 *Gregor.*

Geographic Situation.—It occurs in the mine of Huel-Unity in Gwennap in Cornwall; at St. Prix, in the Department of the Soane and Loire in France.

Third Subspecies.

Earthy arseniate of lead, *Jameson.*—Erdige Bleiblüthe, *Hausmann.*

External Characters.—Colour yellow. Occurs in crusts. Fracture earthy. Friable.

Geognostic and Geographic Situations.—It occurs along with filamentous arseniate of lead at St. Prix; and also near St. Oisans.

* Native minium, or native red oxide of lead, *Jameson.*—Naturliche Menninge, Roth Bleioxyd, *Hausmann.*

External Characters.—Colour scarlet-red. Occurs massive, amorphous, and pulverulent; but when examined by the lens, exhibits a crystalline structure, like that of galena, on which it generally rests.

Chemical Characters.—Before the blowpipe, on charcoal, it is first converted into litharge, and then into metallic lead.

Geognostic and Geographic Situations.—It is found in Grassington Moor, Craven; Grasshill Chapel, Wierdale, Yorkshire. On the Continent it is found in the mine of Hausbaden, near Badenweiler, on galena, and associated with quartz.

Order III.—KERATE.†

No metallic lustre. Streak colourless. Sectile. Cleavage is neither distinctly axifrangible nor prismatoidal. Hardness ranges from 1 to 2. Specific gravity from 4 to 6.

Genus I.—CORNEOUS SILVER.

Three axes. Cleavage invisible. Hardness=1.0,—2.0. Spec. grav.=4.6.

(*a*) The minerals marked * are not yet included in the Genus Lead-spar, as their characters have not been completely ascertained.
† *Kerate*, from the Greek word κερας, *horn*, given to it on account of the species resembling horn in general aspect and tenacity.

This genus contains one species, viz. Hexahedral Corneous Silver. * Earthy Corneous Silver.

1. Hexahedral Corneous Silver, *Jameson.*—Hexedrisches Perl Kerat, *Mohs.* Hornerz, *Werner.* Argent muriaté, *Haüy.*

Tessular. Cleavage not visible. Malleable.

External Characters.—Most frequent colour pearl-grey, from which it passes on the one side into blue, on the other white, and further into leek-green. On exposure to light, it becomes brownish. Occurs massive in prismatic and granular concretions, in thick flakes, disseminated, in egg-shaped pieces, hollow in the centre, and the hollows lined with crystals. The crystals are the following:

1. Cube. 2. Octahedron. 3. Rhomboidal dodecahedron.

Crystals small and very small, occasionally aggregated in rows, or in a scalar-like form. External surface smooth, sometimes marked with little hollows. Externally shining, but becomes gradually duller on exposure: internally intermediate between shining and glistening, and the lustre resinous. Fracture conchoidal, sometimes inclines to earthy. Fragments indeterminate angular and blunt-edged. Translucent, or only feebly translucent on the edges. Retains its colour, and becomes more shining in the streak. Is malleable. Flexible, but not elastic.

Chemical Characters.—It is fusible in the flame of a candle.

Constituent Parts.—	Silver, .	67.75
	Muriatic Acid,	14.75
	Oxygen, .	6.75
	Oxide of Iron,	6.00
	Alumina, .	1.75
	Sulphuric Acid,	0.25—97.25

Klaproth, Beit. b. iv. s. 13.

Geognostic Situation.—It occurs in silver veins, and generally in their upper part. These veins traverse gneiss, mica-slate, clay slate, grey-wacke, porphyry, and limestone, and contain, besides the corneous silver, various ores.

Geographic Situation.—*Europe.*—At Huel-Mexico in Cornwall.

Asia.—In Siberia, it occurs along with native gold.

America.—This mineral, which is so seldom found in Europe, is very abundant in the mines of Catorce, Fresnillo, and the Cerro San Pedro, near the town of San Luis Potosi.

Earthy Corneous Silver-Ore (†), *Jameson.*—Erdiges Hornerz, *Karsten.*

External Characters.—Internally the colour is pale mountain-green, inclining to greyish-white; externally it has a bluish-grey tarnish. Occurs in thick crusts. Internally dull. Fracture coarse and fine earthy. Fragments blunt angular. Very soft, almost friable. Streak shining and resinous. Sectile. Heavy.

Constituent Parts.—	Silver, . . .	24.64
	Muriatic Acid, .	8.28
	Alumina, with a trace of copper,	67.08—100.00

Klaproth, Beit. b. i. s. 137.

Geognostic and Geographic Situations.—It is found in veins that traverse transition rocks at Andreasberg in the Hartz.

Genus II.—CORNEOUS MERCURY.

Pearl Kerate, *Mohs.*

One axis. Cleaving very indistinct. Hardnes, = 1.0, 2.0. Sp. gr. =

This genus contains one species, viz. Pyramidal Corneous Mercury.

1. Pyramidal Corneous Mercury, *Jameson.*—Pyramidales Pearl Kerate, *Mohs.* Quecksilber Hornerz, *Werner.* Mercure muriaté, *Haüy.*

Pyramid unknown. Cleavage indistinct axifrangible, sectile.

External Characters.—Colour grey. Occurs very rarely massive, almost always in small vesicles crystallized in the interior. The crystals are the following:

1. Rectangular four-sided prism, acuminated on the extremities with four planes, which are set on the lateral planes. 2. Rectangular four-sided prism, acuminated with four planes, which are set on the lateral edges. 3. Double four-sided pyramid.

Crystals always so minute that it is with difficulty their forms can be determined. External surface sometimes smooth, sometimes drusy, and in general shining and adamantine. Internally shining, with an adamantine lustre. Has a single cleavage, which appears to be parallel with the terminal planes of the prism. Faintly translucent, or only translucent on the edges. Sectile, and easily frangible.

Chemical Characters.—It is totally volatilized before the blowpipe, and emits a garlic smell. It is soluble in water, and the solution mixed with lime-water gives an orange-coloured precipitate.

Constituent Parts.—	Oxide of Mercury,	76.00
	Muriatic Acid,	16.40
	Sulphuric Acid,	7.60—100.00

Klaproth.

Geognostic Situation.—In the quicksilver mines of the Palatinate, and Dutchy of Deux Ponts.

Geographic Situation.—It occurs in Bohemia, Deux Ponts, Palatinate, Upper Hessia; and at Almaden in Spain.

Order IV.—MALACHITE.

No metallic lustre. Streak blue, green, brown. If white, the specific gravity is 2.2 and less. Colour not inclining to yellow. Cleavage is neither distinctly axifrangible nor prismatoidal. Hardness ranges from 2 to 5. If the streak is brown, the hardness is less than 3.5. Specific gravity ranges from 2 to 4.6.; if it is less than 3.2, the hardness is below 3.

This Order contains four Genera, viz. 1. Copper-Green, 2. Malachite, 3. Olivenite, and, 4. Emerald-Copper.

Genus I.—COPPER-GREEN.

Trauben Malachit, *Mohs.*

Reniform; botryoidal. Streak white. Hardness = 2.0.—3.0. Sp. gravity = 2.0.—2.2.

(†) This mineral appears to be a mechanical mixture of corneous silver and clay, and hence it is placed beside it, but not as a variety of the species.

This genus contains one Species, viz. Common Copper-Green.

1. Common Copper-Green, or Chrysocolla.—*Jameson.*—Untheilbarer Trauben Malachit, *Mohs.*—Kupfergrün, *Werner.*

No cleavage.

This species is divided into three subspecies, viz. 1. Conchoidal Copper-Green, 2. Earthy Iron-shot Copper-Green, 3. Slaggy Iron-shot Copper-green.

First Subspecies.

Conchoidal Copper-Green, *Jameson.*—Kupfergrün, *Werner.*

External Characters.—Principal colour green. Occurs massive, disseminated, and coating or incrusting malachite, sometimes small reniform, and small botryoidal. Internally shining, passing into glistening; lustre resinous. Fracture small conchoidal. Fragments indeterminate angular, and more or less sharp-edged. It alternates from translucent to translucent on the edges. Colour not changed in the streak. Easily frangible, and rather brittle.

Chemical Characters.—Before the blowpipe, it becomes first black, then brown, but is infusible.

Constituent Parts.—	Copper, . . .	40.00
	Oxygen, . . .	10.00
	Carbonic Acid, .	7.00
	Water, . . .	17.00
	Silica, ...	26.00—00.100

Klaproth, Beit. b. i. s. 36.

Geognostic Situation.—It is met with in the same geognostic situations as malachite.

Geographic Situation.—It occurs in Cornwall, along with olivenite, and also in the vale of Newlands, near Keswick.

Siliceous Copper, *Jameson.* Kieselkupfer, *John.*

Its colours are asparagus-green, and celandine-green, inclining to sky-blue. Occurs in crusts. Dull, faintly glistening, and resinous. Fracture even or earthy. Opaque, or rarely translucent on the edges. Soft.

Constituent Parts.—Copper, 37.8. Oxygen, 8. Water, 21.8. Silica 2.9; and Sulphate of Lime, 3.

Second Subspecies.

Earthy Ironshot Copper-Green, *Jameson.*—Erdiches eisenschüssiges Kupfergrün, *Werner.*

External Characters.—Colour olive-green, which sometimes passes into pistachio-green, and inclines to leek-green. Occurs massive, and in crusts. Generally of friable consistence, and composed of dull, dusty particles, which are more or less cohering, and that do not soil. Compact varieties have an earthy fracture. Opaque. Very soft, passing into friable. Sectile, and easily frangible.

Third Subspecies.

Slaggy Ironshot Copper-Green, *Jameson.*—Schlackiges-eisenschüssiges Kupfergrün, *Werner.*

External Characters.—It is blackish-green, and dark pistachio-green. Occurs massive, and disseminated. Internally shining, glistening, lustre resinous. Fracture small conchoidal. Fragments indeterminate angular, and more or less sharp-edged. Opaque. Colour becomes paler in the streak. Soft, verging into very soft. Easily frangible.

Constituent Parts.—It is probably a compound of Conchoidal Copper-Green and Oxide of Iron.

Geognostic Situation.—Both subspecies usually occur together, and they frequently pass into each other.

Geographic Situation.—It occurs in Cornwall, along with olivenite.

Genus II.—MALACHITE.

Kalo Malachit, *Mohs.*

Three axes. Cleavage prismatic. Streak blue; green; very pure. Hardness = 3.5,—4.0. Sp. gravity = 3.5,—3.7.

This Genus contains two species, viz. 1. Blue Copper or Prismatic Malachite, and 2. Common or Acicular Malachite. * Brown Copper.

1. Blue Copper or Prismatic Malachite, *Jameson.*—Prismatischer Kalo-Malachit, *Mohs.* Kupferlazur, *Werner.*

Prism = . Cleavage uncertain. Streak blue.

This species is divided into two subspecies, viz. Radiated Blue copper, and Earthy Blue Copper. *Velvet Blue Copper.

First Subspecies.

Radiated Blue Copper, *Jameson.*—Feste Kupferlazur, *Werner.*

External Characters.—Principal colour azure-blue, which often passes into blackish-blue, seldomer into Berlin-blue and smalt-blue. Occurs massive, disseminated, in plates, in crusts; also globular, botryoidal, reniform, stalactitic, and cellular; in prismatic distinct concretions, which are straight, narrow, scopiform, and stellular, and these are again traversed by others which are curved lamellar. Sometimes there is a tendency to granular concretions. Very frequently crystallized. Generally occurs in oblique four-sided prisms, rather acutely bevelled on the terminal planes, and the bevelling planes set on the acuter lateral edges. Crystals small, and very small, seldom middle-sized. Sometimes aggregated in globular and botryoidal forms; other crystals occur in druses, or singly superimposed. External surface of the particular external shapes drusy and glimmering; that of the crystals sometimes smooth and splendent. Externally the crystallized varieties are shining, but the massive and particular external shapes dull. Internally shining and glistening, and lustre intermediate between vitreous and resinous. Fracture small and imperfect conchoidal. Fragments of the prismatic or radiated varieties wedge-shaped; those of the foliated and conchoidal splintery. Crystals translucent, passing into semi-transparent, sometimes only translucent on the edges. Colour becomes lighter in the streak. Brittle, and rather easily frangible.

Chemical Characters.—It is soluble with effervescence in nitric acid.

		Chessy.
Constituent Parts.—	Copper, . . .	56.00
	Carbonic Acid, .	25.00
	Oxygen, . . .	12.50
	Water, . . .	6.50—100.00

Vauquelin, An. du Mus. xx. p. 3.

Geognostic Situation.—This mineral occurs in veins that traverse primitive, transition, and secondary or flœtz rocks; in smaller quantity, and less frequently in beds.

Geographic Situation.—Occurs at Leadhills in Lanarkshire, and Wanlockhead in Dumfriesshire; Huel-Virgin and Carharrack in Cornwall.

SECOND SUBSPECIES.

EARTHY BLUE COPPER, *Jameson.*—Erdiger Kupferlazur, *Werner.*

External Characters.—Colour smalt-blue, which sometimes inclines slightly to sky-blue. Massive, often disseminated, thinly coating, and rarely small botryoidal. Of friable consistence, and composed of dull and fine dusty particles that soil very faintly, and which are more or less cohering.

Geognostic and Geographic Situations.—Occurs in small quantity, and usually accompanied with malachite and copper-green. In Silesia, found incrusting bituminous marl-slate; in Thuringia, coating varieties of the old red-sandstone; and in Siberia, disseminated in sandstone.

* VELVET-BLUE COPPER, *Jameson.*—Kupfersammterz, *Werner.* Kupfersammterz, *Karsten*, Tabel. s. 62. *Id. Hoff.* b. iv. s. 143.

External Characters.—Colour intermediate between smalt-blue and sky-blue, and sometimes passes into sky-blue. Occurs in very small and delicate capillary crystals, which generally form a velvety crust, and are seldom aggregated in balls. Externally and internally lustre glistening and pearly, or silky. Very soft.

Geognostic and Geographic Situations.—A very rare mineral, and has hitherto been found only at Oravicza in the Bannat, along with malachite and brown ironstone.

2. COMMON OR ACICULAR MALACHITE,† *Jameson.* Malachit, *Werner.*

Prism = . Cleavage uncertain. Streak green.

This species is divided into two subspecies, viz. Fibrous Malachite, and Compact Malachite. * Brown Copper.

FIRST SUBSPECIES.

FIBROUS MALACHITE, *Jameson.*—Fasricher Malachit, *Werner.*

External Characters.—Most common colour perfect emerald-green, sometimes inclining to grass-green, and sometimes to dark leek-green. Seldom massive, sometimes disseminated, tuberose, stalactitic, reniform, botryoidal, fruticose, most frequently as a coating, also in fibrous distinct concretions, which are delicate and scopiform or stellular, and collected into others which are large, coarse, and sometimes longish granular, or wedge-shaped. Frequently crystallized; and the following are the figures which have been observed:

1. Rather oblique four-sided prism, bevelled on the extremities, the bevelling planes set on the obtuse lateral edges. 2. The preceding figure truncated on the obtuse lateral edges, which thus forms a six-sided prism, in which the bevelling planes are set on two opposite lateral planes.

Crystals generally short, capillary, and acicular. When very short, they form velvety drusy pellicles; and when longer, they are scopiformly aggregated. Internally intermediate between glistening and glimmering, and the lustre pearly or silky. Fragments wedge-shaped and splintery. Crystals translucent, but the massive varieties only translucent on the edges, or opaque. Colour of the streak pale-green. Brittle, inclining to sectile, and easily frangible.

Chemical Characters.—Before the blowpipe it decrepitates and becomes black, and is partly infusible, partly reduced to a black slag.

		Chessy.
Constituent Parts.—Copper,	.	56 10
Carbonic Acid,		21 25
Oxygen,	.	14.00
Water,	.	8.75—100.00

An. Mus. t. xx. p. 8.

Geognostic Situation.—Occurs principally in veins that traverse primitive, transition, and secondary rocks.

Geographic Situation.—Occurs at Sandlodge, in Mainland, one of the Shetland Islands, in veins that traverse red sandstone, in which it is associated with grey copper, copper-pyrites, and brown iron-ore; at Landidno in Caernarvonshire; and in various mines in other parts of the world.

SECOND SUBSPECIES.

COMPACT MALACHITE, *Jameson.*—Dichter Malachit, *Werner.*

External Characters.—Colour intermediate between emerald-green and verdegris-green; but in general inclining more to the first. Colours often disposed in concentric delineations, and varied with dark-coloured dendritic markings. Occurs massive, disseminated, and in membranes; most frequently reniform and botryoidal, frequently tuberose, stalactitic, fruticose, cellular, and amorphous; also in distinct concretions, which are sometimes extremely delicate and scopiform fibrous; more frequently thin lamellar, or large, coarse, and small angulo-granular; and sometimes crystallized in oblique four-sided prisms. External surface of the particular shapes generally rough and drusy, seldomer smooth, and then it is shining and glistening. Surface of the distinct concretions apparently covered with a greenish-white film. Internally it passes from glistening through glimmering to dull, but most commonly glimmering, and the lustre silky. Fracture small and fine-grained uneven, which sometimes passes into small and flat conchoidal, and even. Fragments indeterminate angular, and rather sharp-edged. Opaque. Rather brittle, and easily frangible. Streak pale-green.

Chemical Characters and Constituent Parts nearly the same with the preceding subspecies.

Geognostic Situation.—It occurs in veins, which traverse primitive transition, and secondary rocks.

Geographic Situation.—*Europe.*—In the copper-mines of Huel-Carpenter and Huel-Husband, in Cornwall; in the copper-mines of Aardal in Norway; and in many other mines on the Continent of Europe.

Asia.—In the mines of Kolwyan, Gamasherk, Turja, &c. in Siberia, where the most beautiful and largest specimens of this mineral are met with, along with tile-ore, red copper-ore, brown iron-ore, copper-glance or vitreous copper, blue copper, copper-green, white lead-spar, brown spar, ironshot quartz, hornstone, &c. It is also met with in different parts of China.

Uses.—It was formerly esteemed as a precious stone, and was cut into ornamental forms of various descriptions. Even at present it is highly prized, and is cut into consoles, candlesticks, snuff-boxes, and other similar articles. Where it occurs in quantity, it is smelted

† The name of the species is derived from the word μαλαχη, *malva*, from the resemblance of its green colour to that of the *marsh-mallow.* The Greek word is sometimes corruptly written μολοχη, whence Pliny has derived the term *molochites:* "Non translucet molochites, spissius virens et crassius quam smaragdus, a colore malvæ nomine accepto."

as an ore of copper, and is sometimes used as a green pigment.

*Brown Copper.—Analysis of a new species of Copper-ore, by *Dr. Thomson*, Phil. Trans. for 1814.

External Characters.—Colour, when pure, dark blackish-brown; but very generally intermixed with malachite and red copper-ore, so that the colour appears a mixture of green, red, and brown, sometimes one and sometimes another prevailing. Small green veins of malachite likewise traverse it in different directions. Occurs massive, with numerous imbedded small rock-crystals. Lustre glimmering and resinous. Fracture small conchoidal, and sometimes inclining to foliated. Soft, being easily scratched by the knife. Sectile. Streak reddish-brown. Specific gravity, 2 620, *Thomson.*

Chemical Characters.—It effervesces in acids, and dissolves, letting fall a red powder. The solution is green or blue, according to the acid, indicating that it consists chiefly of copper.

Constituent Parts.—Carbonic Acid,	16 70	
Per-oxide of Copper,	60 75	
Per-oxide of Iron,	19.50	
Silica, .	2.10	
Loss, . .	0.95	100.00

Thompson, in Phil. Trans. for 1814.

Geognostic Situation.—It appears to occur in nests in primitive rocks, which are of greenstone, or some similar rock of the primitive trap series subordinate to mica-slate. It is associated with malachite.

Geographic Situation.—In the peninsula of Hindostan, near the eastern border of the Mysore country.

Genus III. OLIVENITE.

Oliven-Malachit, *Mohs.*

Many axes. Cleavage prismatic, tessular; streak blue, green, brown. If streak green or blue, the specific gravity is 4 and more, or 3 and less. Hardness from 2 5 to 5. Sp. gr. from 2.8 to 4.6.

This genus contains four species, viz. 1. Prismatic Olivenite, or Phosphat of Copper; 2 Di-prismatic Olivenite, or Lenticular Copper; 3. Acicular Olivenite; 4. Hexahedral Olivenite, or Cube-Ore, *Atacamite.

1. Prismatic Olivenite, or Phosphat of Copper, *Jameson.*—Prismatischer Oliven-Malachit, *Mohs.*

Prism =116°. Cleavage the same. Streak emerald green. Hardness =5. Sp. gr. =4.0—4.3.

External Characters.—Principal colour emerald-green, which passes into blackish-green; externally, sometimes greenish-black. Occurs massive, in imperfect reniform masses, with a very drusy surface, and in coarse fibrous distinct concretions, which are straight and scopiform. Crystals small and very small, superimposed and in druses. Externally shining; internally passes from shining, through glistening, to glimmering, and the lustre resinous, inclining to pearly. Fracture splintery. Fragments wedge-shaped splintery, or indeterminate angular, and rather blunt-edged. Opaque. Streak verdigris-green. Brittle, and easily frangible.

Chemical Characters.—On the first impression of the heat it fuses into a brownish globule, which, by the further action of the blowpipe, extends on the surface of the charcoal, and acquires a reddish-grey metallic colour.

Constituent Parts.—Oxide of Copper,	68.13	
Phosphoric Acid,	30.95	99.08

Klaproth, Beit. b. iii. s. 201.

Geognostic and Geographic Situations.—The principal locality of this rare mineral is Virneberg, near Rheinbreitenbach, on the Rhine, where it occurs along with quartz, calcedony, red copper-ore, and malachite, in greywacke.

II. Di-prismatic Olivenite, or Lenticular Copper, *Jameson.*——Di-prismatischer Oliven-Malachit, *Mohs*—Linsenerz, *Werner.*

Prism unknown. Cleavage in the direction of the terminal and bevelling faces of an oblique four-sided prism. Streak pale verdigris-green, and sky-blue. Hardness =2.5. Sp. gr. =2.8—2.9.

External Characters.—Colour sky-blue, which sometimes passes into verdigris-green. Scarcely occurs massive, generally crystallized:

1. Very oblique four-sided prism, acutely bevelled on the extremity, and the bevelling planes set on the obtuse lateral edges. 2. Very flat, longish, rectangular double four-sided pyramid, in which the lateral planes of the one are set on the lateral planes of the other.*

Crystals middle-sized and small, and sometimes crystallized in druses. Externally smooth and shining; internally glistening and shining, and pearly, inclining to vitreous. Fracture small-grained uneven, which sometimes passes into imperfect conchoidal. Fragments indeterminate angular, and rather sharp-edged. Translucent. Yields a pale verdigris-green, or sky-blue coloured streak. Brittle, and uncommonly easily frangible.

Chemical Characters.—Before the blowpipe it is converted into a black friable scoria.

Constituent Parts.—Oxide of Copper,	49	
Arsenic Acid, .	14	
Water, . .	35	98

Chenevix in Phil. Trans. for 1801.

Geognostic and Geographic Situations.—It has been hitherto found only in Cornwall, where it is associated with copper-mica, and other cupreous minerals.

III. Acicular Olivenite, *Jameson.*—Nadelförmiger Oliven-Malachit, *Mohs.*

Prism unknown. Cleavage unknown. Streak olive-green; brown. Hardness =3.0. Sp. gr. =4.2—4.6.

This species is subdivided into four subspecies, viz. Radiated Acicular Olivenite, Foliated Acicular Olivenite, Fibrous Acicular Olivenite, and Earthy Acicular Olivenite.

First Subspecies.

Radiated Acicular Olivenite, *Jameson.*—Strahlerz. *Werner.*

External Characters.—Externally colour dark verdigris-green, sometimes bordering on blackish-green; internally pale verdigris-green, either pure, or intermixed with sky-blue. Occurs massive, and flat reniform; also in radiated prismatic concretions, which are straight and scopiform; and crystallized in flat oblique four-sided prisms, acuminated with four planes. Crystals generally small, and superimposed. External surface of the reniform shape very drusy. Internally lustre intermediate between shining and glistening, and pearly. Fragments wedge-shaped. Translucent on the edges. Brittle, and easily frangible.

* The double four-sided pyramid is so flat that it has a lenticular aspect; hence the name *Lenticular Copper* given to this species.

Second Subspecies.

Foliated Acicular Olivenite, *Jameson.*—Blättriches Olivenerz. *Werner.*

External Characters.—Colour green. Seldom occurs massive, and in angulo-granular concretions, generally in drusy crusts, and in small crystals, which present the following varieties of form:

1. Oblique four-sided prism, acutely bevelled on the extremities, the bevelling planes set on the acute lateral edges. 2. Preceding figure, in which the obtuse lateral edges are more or less deeply truncated. 3. Acute double four-sided pyramid; sometimes the angles on the common base are flatly bevelled; and the bevelling planes are set on the lateral edges.

Crystals small, and very small, and always superimposed. Planes of the crystals smooth, shining, and splendent. Internally glistening, and lustre resinous, inclining to pearly. Fracture small and imperfect conchoidal, which passes into uneven. Fragments indeterminate angular, and rather sharp-edged. Ranges from translucent to translucent on the edges. Yields an olive-green coloured streak. Rather brittle, and easily frangible.

Chemical Characters.—Before the blowpipe, it first boils, and then gives a hard reddish brown scoria.

Constituent Parts.—Oxide of Copper,	60.0
Arsenic Acid,	89.7—99.7.

Chenevix, Phil. Trans. 1801.

Geognostic and Geographic Situations.—It has been hitherto found only in the copper-mines of Cornwall.

Third Subspecies.

Fibrous Acicular Olivenite, *Jameson.*—Fasriges Olivenerz. *Werner.*

External Characters.—Colours green, yellow, brown, and white. Colours sometimes arranged in curved and striped delineations. Occurs massive, and reniform; in fibrous concretions, which are delicate, straight, and scopiform, and these are collected into coarse or small granular concretions, and sometimes traversed by others, which are curved lamellar; also crystallized in capillary and acicular oblique four-sided prisms, in which the obtuse lateral edges are truncated, and bevelled on the extremities, the bevelling planes being set on the acute edges. Crystals small, and very small, and sometimes scopiformly aggregated. Internally the massive varieties are glistening or glimmering, with a pearly or silky lustre. Fragments indeterminate angular, and wedge-shaped. Opaque, seldom translucent on the edges, and only translucent in the crystals. Rather brittle. Fibres sometimes flexible.* Streak brown or yellow.

Constituent Parts.—Oxide of Copper,	50
Arsenic Acid, .	29
Water, . .	21—100

Chenevix, in Phil. Trans. for 1801.

Geognostic and Geographic Situations.—It is associated generally with the other arseniates of copper and various ores of copper. It occurs principally in Cornwall.

Fourth Subspecies.

Earthy Acicular Olivenite, *Jameson.*

External Characters.—Colour olive-green. Occurs massive, disseminated, and in crusts. Dull. Fracture fine earthy. Sometimes occurs in concentric lamellar distinct concretions. Opaque. Soft, and very soft.

Geognostic and Geographic Situations.—It occurs along with the other subspecies of olivenite in the copper-mines of Cornwall.

IV. Hexahedral Olivenite, or Cube-Ore, *Jameson.* Wurfelerez, *Werner.*

Tessular. Cleavage hexahedral. Streak olive-green; brown. Hardness = 2.5. Sp. gr. = 2.9 — 3.0.

External Characters.—Colour green. Occurs massive; and crystallized in the following figures:

1. Perfect cube. 2. Cube, in which four diagonally opposite angles are truncated. 3. Cube truncated on all the edges. 4. Cube truncated on all the edges and angles.

Crystals small and very small, and always superimposed and in druses. Planes of the crystals smooth and splendent. Internally glistening, and lustre intermediate between vitreous and resinous. Fragments indeterminate angular, and rather sharp-edged. Translucent, or translucent on the edges. Streak straw-yellow. Rather brittle, and easily frangible.

Chemical Characters.—Before the blowpipe it melts, and gives out arsenical vapours.

Constituent Parts.—Arsenic Acid, .	31.0
Oxide of Iron, .	45.5
Oxide of Copper, .	9.0
Silica, . .	4.0
Water, . . .	10.5—100

Chenevix, in Phil. Trans. for 1801.

Geognostic Situation.—It is found in veins, accompanied with ironshot quartz, copper-glance or vitreous copper, copper-pyrites, and brown iron-ore.

Geographic Situation.—It occurs in Tincroft, Carrarach, Muttrel, Huel-Gorland, and Gwenap mines in Cornwall.

* Atacamite, or Muriate of Copper, *Jameson.* Salzkupfererz, *Werner.*

This species is divided into two subspecies, viz. Compact and Arenaceous.

First Subspecies.

Compact Atacamite, or Muriate of Copper,† *Jameson.* Festes Salzkupfererz, *Werner.*

External Characters.—Colour green. Occurs massive, disseminated, imperfect reniform, in prismatic distinct concretions, which are short, small, and scopiform, also in granular concretions; in crusts or investing; and in short needle-shaped crystals, of the following forms:

1. Oblique four-sided prism, bevelled on the extre-

* The fibres are sometimes so delicate, so short, and so confusedly grouped together, that the whole appears like a dusty cottony mass, the true nature of which is discoverable only by the lens. At other times, this variety appears in thin laminæ, rather flexible, sometimes scarcely perceptible to the naked eye, sometimes tolerably large, and perfectly like Amianthus papyraceus.—*Bournon*, Phil. Trans. for 1801, part i. p. 180.

† We place this mineral immediately after the Genus Olivenite, on account of its resemblance to it; but want of accurate information prevents us from including it as a species of that genus.

mities; the bevelling planes set on the acute lateral edges. 2. The preceding figure, in which the acuter lateral edges are deeply truncated, thus forming a six-sided prism.

Internally shining and glistening, and pearly. Has an imperfect cleavage. Fragments indeterminate angular. Translucent on the edges. Soft. Brittle, and easily frangible. Specific gravity, 4.4?

Chemical Characters.—It tinges the flame of the blowpipe of a bright green and blue, muriatic acid rises in vapours, and a bead of copper remains on the charcoal. It is soluble in nitric acid without effervescence.

Constituent Parts.—	Oxide of Copper,	73.0
	Water,	16.9
	Muriatic Acid,	10.1—100.0

Klaproth, Beit. b. iii. s. 200.

Geognostic and Geographic Situations.—It occurs in veins in Chili; also at Virneberg near Rheinbretenbach on the Rhine, and at Schwartzenberg in Saxony. In the fissures of the lavas of Vesuvius, particularly those of the years 1804 and 1805.

Second Subspecies.

Arenaceous Atacamite, or Copper-Sand, *Jameson.*—Kupfersand, *Werner.*

External Characters.—Colour grass-green, inclining to emerald-green. Occurs in scaly particles, which are shining, glistening, and pearly. Does not soil. Translucent.

Constit. Parts.—	Oxide of Copper,	70.5
	Water,	18 1
	Muriatic Acid,	11.4
		100.0

Proust, Journ. de Phys. t. 50. p. 63.

Geognostic and Geographic Situations.—It is found in the sand of the river Lipes, 200 leagues beyond Copiapu, in the desert of Atacama, which separates Chili from Peru.

Genus IV. EMERALD COPPER.

Smaragd-Malachite, *Mohs.*

One axis. Cleavage rhomboidal. Streak. Hardness = 5.0. Sp. gr. = 3.3. — 34.

This genus contains but one species, viz. Rhomboidal Emerald Copper, or Dioptase.

1. Rhomboidal Emerald Copper, or Dioptase. *Jameson.*—Rhomboedrischer Smaragd-Malachite, *Mohs.* Kupfer-Schmaragd, *Werner.*

Rhomboid = 123° 58′. Cleavage rhomboidal.

External Characters.—Colour emerald green, which sometimes inclines to pistachio and blackish green. Occurs only crystallized. The only secondary form at present known, is the equi-angular six-sided prism, which is rather acutely acuminated on both extremities by three planes, which are set on the alternate lateral edges. Lateral planes smooth. Internally shining, and lustre pearly. Fracture small conchoidal. Translucent, passing to semi-transparent. Brittle, and easily frangible.

Chemical Characters.—It becomes of a chestnut-brown colour before the blow-pipe, and tinges the flame green, but is infusible; with borax it gives a bead or globule of copper.

Constituent Parts.—	Oxide of Copper,	28.57
	Carbonate of Lime,	42.85
	Silica,	28.57—99.99

Vauquelin, in Haüy, t. iii. p. 137.

Geognostic and Geographic Situations.—Found, according to Hermann, in the land of the Kirguise, 125 leagues from the Russian frontier, where it is associated with the fibrous and compact malachite, calcareous-spar, and limestone.

Order V. MICA.

If no metallic lustre, the specific gravity is above 2.2. Streak neither yellow nor dark-red. If the specific gravity is under 2.2. the lustre is perfectly metallic and shining. The cleavage is distinctly axifrangible and prismatoidal. The hardness varies from 1. to 2.5. Specific gravity ranges from 1.9 to 5.6.

This order contains seven genera, viz. 1. Copper-mica; 2. Uran-mica; 3. Cobalt-mica; 4. Antimony-mica; 5. Blue iron; 6. Graphite; 7. Mica; 8. Pearl-mica.

Genus I. COPPER-MICA.

Three axes. Cleavage prismatic. Streak green. Hardness = 2.0. Sp. gr. = 2.5 —2.6.

This genus contains one species, viz. prismatic copper-mica.

1. Prismatic Copper-Mica, *Jameson.*—Prismatischer Kupferglimmer, *Mohs.* Kupferglimmer, *Werner.*

Prism unknown. Cleavage prismatic.

External Characters.—Colour green. Occurs massive, disseminated, and in granular distinct concretions; seldom crystallized in very thin equi-angular six-sided tables, in which the alternate terminal planes are set on obliquely. Externally smooth and splendent; internally splendent, lustre pearly. Fracture small-grained, uneven, inclining to conchoidal. Fragments indeterminate angular and tabular. Massive varieties translucent; crystallized transparent. Streak green. Sectile. Rather brittle.

Chemical Characters.—It decrepitates before the blowpipe; and passes, first, to the state of a black spongy scoria, after which it melts into a black globule, of a slightly vitreous appearance.

Constit. Parts.	Oxide of Copper,	58
	Arsenic Acid,	21
	Water,	21——100

Chenevix, Phil. Tr. for 1801, p. 201.

Geognostic and Geographic Situations.—It has been hitherto found only in veins in the copper-mines in Cornwall.

Genus II. URAN-MICA, or URANITE.

One axis. Cleavage pyramidal. Streak green. Hardness = 2 0.—2.5. Sp. gr. =3.1 —3.3.

This genus contains one species, viz. Pyramidal Uranite.

1. Pyramidal Uranite, *Jameson.*—Pyramidaler Uran-Glimmer, *Mohs.* Uran-Glimmer, *Werner.*

Pyramid = 95°, 13′; 144° 56′. The only distinct cleavage is that parallel with the base of the prism.

External Characters.—Chief colours green and yellow. Seldom massive, sometimes in flakes; the massive varieties are disposed in angulo-granular concretions. Frequently crystallized. The secondary forms are the following:

1. Rectangular four-sided table, or short prism. Sometimes elongated. 2. The four-sided table bevelled on the terminal planes, and the bevelling planes set on the lateral planes. 3. The terminal edges of the table truncated, thus forming an eight-sided table. 4. The terminal planes of the four-sided table bevelled; and sometimes the edges of the bevelment truncated. 5. When the bevelling planes of No. 4, increase very much in size, there is formed a very acute double four-sided pyramid, in which the apices are more or less deeply truncated. 6. Sometimes the figure, No. 4. is acuminated on both extremities with four planes, which are set on the lateral planes, and the apices of the acuminations deeply truncated.

Crystals are small and very small, superimposed, and form druses. Terminal planes of the table streaked, but the lateral planes smooth. Externally, it is usually shining and sometimes splendent. Internally shining, approaching to glistening; lustre pearly. Transparent and translucent. Streak green. Sectile. Not flexible. Easily frangible.

Chemical Characters.—It decrepitates violently before the blowpipe on charcoal; loses about 33 *per cent.* by ignition, and acquires a brass-yellow colour.

		Cornwall.
Constit. Parts.—	Oxide of Uranium, with a trace of Oxide of Lead,	74.4
	Oxide of Copper, .	8.2
	Water, . . .	15.4
	Loss, . . .	2. —100

Gregor, in Annals of Phil. vol. v. p. 284.

Geognostic and Geographic Situations.—Occurs in veins in primitive rocks. In Cornwall in tinstone and copper veins that traverse granite and clay-slate.

Werner describes a soft mineral, found along with Uranite, under the name Uran-Ochre. It does not appear to form a distinct species, nor can it be considered as a subspecies of Uranite. It is here placed immediately after Uranite.

* Uran-Ochre, *Jameson.*—Uran-Ocker, *Werner.*

There are two kinds of this mineral, viz. Friable and Indurated.

1. Friable Uran-Ochre, *Jameson.*—Zerreibliche Uranocker, *Werner.*

External Characters.—Colour lemon-yellow, which passes into straw-yellow and sulphur-yellow, and also into orange-yellow. Occurs usually as a coating or efflorescence on pitch-ore, and sometimes small reniform. Is friable, and composed of dull, dusty, and weakly cohering particles. Feels meagre.

Geognostic Situation.—Occurs always on pitch-ore.

2. Indurated Uran-Ochre, *Jameson.*—Feste Uranocker, *Werner.*

External Characters.—Colours are straw-yellow, lemon-yellow, and orange-yellow; and this latter passes into aurora-red and hyacinth-red, and reddish and yellowish brown. Occurs massive, disseminated, and superimposed; and sometimes a tendency to fibrous concretions. Internally glimmering, glistening, and resinous. Fracture imperfect conchoidal. Opaque. Soft and very soft. Rather Sectile. Specific gravity, 3.1500, *La Metherie.*—3.2438, *Haüy.*

Chemical Characters.—According to Klaproth, the yellow varieties are pure oxide of uranium, but the brownish and reddish contain also a little iron.

Geognostic and Geographical Situations.—It is found at Joachimsthal, and Gottesgab in Bohemia, and at Johanngeorgenstadt in Saxony.

Genus III.—COBALT MICA, or RED COBALT.

Kobalt Glimmer, *Mohs.*

Three axes. Cleavage prismatic. Streak red, green. Hardness = 2.5. Sp. gr. = 4.43.

This genus contains one species, viz. Prismatic Red Cobalt.

1. Prismatic Red Cobalt, *Jameson*.—Prismatischer Kobalt Glimmer, *Mohs.*

Prism unknown. Cleavage prismatoidal.

This species is divided into three subspecies, viz. Radiated Red Cobalt, Earthy Red Cobalt, and Slaggy Red Cobalt.

First Subspecies.

Radiated red cobalt, or cobalt-bloom, *Jameson.*—Kobalt-bluthe, *Werner.*

External Characters.—Principal colour red; rarely greenish-grey, and olive-green. Occurs massive, disseminated, often in membranes, small reniform, small botryoidal; also in stellular and scopiform radiated or fibrous concretions, which are sometimes collected into granular concretions; it also occurs crystallized. Crystals generally acicular or capillary, and scopiformly or stellularly aggregated. Externally shining, passing into splendent. Internally shining and glistening, and lustre pearly. Fragments splintery and wedge-shaped. More or less translucent; sometimes translucent on the edges. Colour not changed in the streak. Rather sectile. Easily frangible.

Chemical Characters.—Before the blowpipe it becomes grey, and emits an arsenical odour, and tinges borax glass blue.

Constituent Parts.—	Cobalt, . .	39
	Arsenic Acid, .	38
	Water . .	23— 100

Buckholtz. in J. d. Min. t. 25 p. 158.

Geognostic Situation.—Occurs in veins, in primitive, transition, and secondary rocks, along with various metalliferous compounds.

Geographic Situation.—Occurs in veins in secondary rocks at Alva, in Stirlingshire; in limestone of the coal formation in Linlithgowshire; formerly in small veins in sandstone of the coal formation, along with galena and blende, at Broughton, in Edinburgh; in the Clifton lead-mines near Tyndrum; and at Dolcoath in Cornwall.

Second Subspecies.

Earthy Red Cobalt, or Cobalt-crust. *Jameson.*—Kobold-beschlag, *Werner.*

External Characters.—Colour red. Seldom occurs massive or disseminated, generally in velvety crusts, and also small reniform and botryoidal. Generally friable, and composed of scaly and dusty particles, which are feebly glimmering or dull. The massive varieties have a fine earthy fracture. Fragments indeterminate angular, and blunt edged. Very easily frangible. Very soft or friable. Sectile. Streak shining. Does not soil.

Third Subspecies.

Slaggy Red Cobalt, *Jameson.*—Schlackige Kobaltbluthe, *Hausmann.*

External Characters.—Colours muddy crimson-red, and dark hyacinth-red, which passes into chesnut-brown. Occurs in thin crusts, and sometimes reniform. Externally smooth. Lustre shining and resinous. Fracture conchoidal. Translucent. Soft and brittle.

Geognostic and Geographic Situations.—Occurs in veins along with other cobaltic minerals, in the mine of Sophia, at Wittichen in Furstemberg.

Cobalt Ochre.

The Black, Brown, and Yellow Cobalt Ochres, and other similar minerals, ought to be arranged together, and form a particular order by themselves. In the mean time, we place them beside the Red Cobalt, on account of their being often associated in nature with that mineral.

*I. Black Cobalt Ochre, *Jameson.*—Schwarz Erdkobold, *Werner.*

It is distinguished into Earthy Black Cobalt-ochre, and indurated Black Cobalt-ochre.

a. Earthy Black Cobalt-Ochre, *Jameson.*——Schwarzer Kobold Mulm, *Werner.* Cobalt oxide noire terreux, *Haüy.*

External Characters—Colour intermediate between brownish and blackish-brown. Friable, and composed of dull coarse particles, which soil very little. Streak shining. Meagre to the feel. Light.

Chemical Characters.—Before the blowpipe, it yields a white arsenical vapour; and it colours borax blue.

b. Indurated Black Cobalt-Ochre, *Jameson.* Fester Schwarz Erdkobold, *Werner.*

External Characters—Colour distinct bluish-black. Occurs massive, disseminated, in crusts, small botryoidal, small reniform, fruticose, moss-like, stalactitic, corroded, specular, and with pyradimal impressions. Sometimes it occurs in thin and curved lamellar concretions. Surface feebly glimmering. Fracture fine earthy, sometimes passing into conchoidal. Fragments indeterminate angular, and blunt-edged. Opaque. Streak shining and resinous. Very soft, approaching to soft. Soils feebly. Sectile. Very easily frangible. Specific gravity, 2.019 to 2.425, *Gellert.*—2.200, *Breithaupt.*

Chemical Characters.—Before the blowpipe it yields an arsenical odour, and colours glass of borax smalt-blue.

Constituent Parts.—It is considered as black oxide of cobalt, with arsenic and oxide of iron.

Geognostic Situation.—Both sorts usually occur together, and in the same kind of repository; but the first is the rarest. They are found sometimes in primitive mountains, but most frequently in secondary mountains.

Geographic Situation.—It is found at Alderly Edge, Cheshire, in red sandstone; in slate-clay in the peninsula of Howth near Dublin; at Riegelsdorf in Hessia, and in many other countries on the continent.

Uses.—It is used in the making of smalt, and affords a good blue colour, but not so fine as that obtained from grey cobalt. Of the two kinds of black cobalt, the compact is that which affords the most esteemed blue colour.

II. Brown Cobalt Ochre, *Jameson.*—Brauner Erdkobold, *Werner*

External Characters.—Principal colour brown, grey, and brownish black. Occurs massive, disseminated, and sometimes very much cracked. Internally dull. Fracture fine earthy, approaching to conchoidal in the large. Fragments indeterminate angular, and blunt-edged. Opaque. Streak shining and resinous. Very soft. Sectile. Very easily frangible. Light.

Chemical Characters.—Before the blowpipe it emits an arsenical odour, and communicates a blue colour to borax.

Constituent Parts.—It is considered to be a compound of Brown Ochre of Cobalt, Arsenic, and Oxide of Iron.

Geognostic Situation—It appears to occur principally in secondary mountains, and is generally accompanied with red and black cobalt-ochre, ochry-brown iron stone, and lamellar heavy spar.

Geographic Situation.—It is found at Kamsdorf and Saalfeld in Saxony; Alpirsbach in Wurtemberg; and in the valley of Gistain in Spain.

Uses.—It is used for making smalt, but is not so valuable as the black cobalt.

Observations.—Distinguished from *Umber*, *Bole*, and other minerals of the same description, by its streak and softness.

3. Yellow Cobalt Ochre, *Jameson.*—Gelber Erdkobold, *Werner.* Cobalt arseniaté terreaux argentifere(?) *Haüy*

External Characters.—Colour yellow, which in some varieties is grey and white. Occurs massive, disseminated, corroded, and incrusting. Frequently appears rent in different directions. Internally it is dull. Fracture fine earthy in the small, conchoidal in the large. Fragments indeterminate angular, and blunt-edged. Streak shining. Is soft, passing into friable. Is sectile. Is very easily frangible.

Specific gravity 2.677, *Kirwan*, after having absorbed water.

Chemical Characters.—It emits an arsenical odour before the blowpipe, and colours borax blue. Appears to be the purest of the cobalt ochres. Generally contains a portion of silver.

Geognostic Situation.—Occurs in the same geognostic situation as the preceding, and is almost always associated with earthy red cobalt, and sometimes with radiated red cobalt, nickel-ochre, iron-shot, copper-green, and azure copper.

Geographic Situation.—Occurs at Saalfeld in Thuringia; Kupferberg in Silesia; Wittichen in Furstenberg; and Alpirsbach in Wurtemberg, in Swabia; and Allemont in France.

Use.—Affords a better smalt than the preceding, and, owing to the silver it contains in the countries where it occurs, is also valued as an ore of silver.

Genus IV. ANTIMONY MICA, or WHITE ANTIMONY.

Spiessglass-glimmer, *Mohs.*

Three axes. Cleavage prismatic. Hardness = 1.5—2.0. Sp. gravity = 5.0—5.6.

This genus contains one species, viz. Prismatic Antimony Mica, or White Antimony.

1. Prismatic White Antimony, *Jameson.*—Prismatischer Speissglass-glimmer, *Mohs.* Weiss-spiesglaserz, *Werner.*

Prism unknown. Cleavage prismatic.

External Characters.—Its colours are white and grey. Seldom occurs massive, more frequently disseminated, and in membranes; also in distinct concretions, which are coarse and small granular, and scopiform and stellular radiated. Is often crystallized. The following figures have been observed :—1. Rectangular four-sided prism, bevelled on the extremities; 2. Oblique four-sided prism; 3. Rectangular four-sided table; 4. Six-sided prism; 5. Acicular and capillary crystals. The tables are small and very small, usually adhering by their lateral planes, and sometimes, although seldom, manipularly aggregated, and often intersecting each other, in such a manner as to form cellular groups. The crystals are sometimes smooth, sometimes feebly longitudinally streaked, and splendent. Internally it is shining, and the lustre is intermediate between pearly and adamantine. The fragments are indeterminate angular, or wedge-shaped. Is translucent. Is rather sectile.

Chemical Characters.—Before the blowpipe it melts very easily, and is volatilized in the form of a white vapour.

		Allemont.
Constit. Parts.—Oxide of Antimony	.	86
Oxides of Antimony and Iron		3
Silica	. . . .	8—98

Vauquelin, Hauy, t. iv. p. 274.

Geognostic and Geographic Situations.—It occurs in veins in primitive rocks, and is usually accompanied with the other ores of antimony. At Prizbram, in Bohemia, it occurs along with crystallized galena or lead-glance; and at Allemont, with native antimony, and grey and red antimony. It has also been found in Malaxa in Hungary.

* Antimony Ochre, *Jameson.*—Spiesglanzocker, *Werner.*

External Characters.—Its colour is yellow, grey, and brown. Scarcely occurs massive, and disseminated, generally incrusting crystals of grey antimony. Is dull. Fracture earthy, and sometimes inclines to radiated. Is opaque. Is soft, passing into very soft. Is brittle, and easily frangible.

Chemical Characters.—Before the blowpipe, on charcoal, it becomes white, and evaporates without melting. With borax, it intumesces, and is partly reduced to the metallic state.

Geognostic and Geographic Situations.—It occurs always in veins, and accompanied with grey antimony, and sometimes with red antimony. It is found at Huel Boys, in Endellion, in Cornwall.

Genus V. BIUE IRON, or IRON MICA.

Eisen Glimmer, *Mohs.*

Three axes. Cleavage prismatic. Streak white? Hardness =2.0. Sp. gravity =2.8—3.0.

This genus contains two species, viz. Prismatic Blue Iron.

1. Prismatic Blue Iron.

Prism unknown. Cleavage prismatoidal.

This species is divided into three subspecies, viz. Foliated Blue Iron, Fibrous Blue Iron, and Earthy Blue Iron.

First Subspecies.

Foliated Blue Iron, *Jameson.*—Blättriches Eisenblau, *Hausmann.*

External Characters.—Its colours are blue and green. The secondary forms are the following.

1. Broad rectangular four sided prism, in which the lateral edges are truncated, (the truncating planes are set obliquely on the smaller lateral planes, and are the original planes of the oblique four-sided prism,) flatly bevelled on the extremities; the bevelling planes set obliquely on the broader lateral planes. 2. Eight-sided prism, acuminated with four planes. The crystals are sometimes acicular, and deeply longitudinally streaked. Are small, or middle-sized, and superimposed. Externally shining or splendent. Internally shining, passing into splendent, and pearly, inclining to adamantine. Fragments long tabular, or splintery. Is translucent on the edges, or strongly translucent. Colour paler blue in the streak. Sectile, and easily frangible. Flexible in thin pieces.

	From the Isle of France
Constituent Parts.—Oxide of Iron, .	41.25
Phosphoric Acid,	19 25
Water, . .	31.25
Ironshot Silica,	1.25
Alumina, . .	5.00—98

Fourcroy and Laugier, *in Ann. du Mus.* t. iii. p. 405.

Geographic and Geognostic Situations.—It occurs in Whealkind Mine, in St. Agnes's, in Cornwall; along with iron-pyrites, and magnetic-pyrites, in gneiss, in the Silberberg, at Bodenmais, in Bavaria; and in the department of Allier, in France.

Second Subspecies.

Fibrous Blue Iron, *Jameson.*—Fasriges Eisenblau, *Hausmann.* Fasriges Eisenblau, *Haus.* Hand. b. iii. s. 1076.

External Characters.—Its colour is indigo-blue. Occurs massive, and sometimes intimately connected with hornblende, and in roundish blunt angular pieces; also in delicate fibrous concretions, which are scopiform or promiscuous. Internally glimmering and silky. Opaque. Soft.

Geognostic and Geographic Situations.—*Europe.*—It occurs in transition syenite at Stavern in Norway.—*America.*—In West Greenland.

Third Subspecies.

Earthy Blue Iron, *Jameson.*—Blau Eisenerde, *Werner.* Erdiges Eisenblau, *Hausmann.*

External Characters.—In its original repository it is said to be white, but afterwards becomes indigo-blue, of different degrees of intensity, which sometimes passes into smalt-blue. Is usually friable, sometimes loose, and sometimes cohering. Occurs massive, disseminated, and thinly coating. Its particles are dull and dusty. It soils slightly. Feels fine and meagre. Is rather light.

Chemical Characters.—Communicates to glass of borax a brown colour, which at length becomes dark-yellow. Dissolves rapidly in acids.

	From Eckartsberg.
Constituent Parts.—Oxide of Iron,	47.50
Phosphoric Acid,	32.00
Water .	20.00—99.50

Klaproth, *Beit.* b. iv. s. 122.

Geognostic Situation.—Occurs in nests and beds in clay-beds, also disseminated in bog iron-ore, or incrusting turf and peat.

Geographic Situation.—*Europe.*—On the surface of peat-mosses in several of the Shetland Islands; and in river mud at Toxteth, near Liverpool; Iceland.—*Asia*. Borders of the Lake Baikal in Siberia.—*America*. Along with bog iron-ore in alluvial soil in New Jersey.

Uses.—Is sometimes used as a pigment. Is principally employed in water-colours, because, when mixed with oil, the colour is said to change into black.

Genus VI. GRAPHITE.*

Kohlen Glimmer, *Mohs*.

One axis. Cleavage rhomboidal. Streak black. Hardness=1.0—2 5. Sp. gravity=2.7—3.0.

This genus contains one species, viz. Rhomboidal Graphite.

1. Rhomboidal Graphite, *Jameson*.—Graphit, *Werner*.

Rhomboid unknown. Cleavage axifrangible.

This species is divided into two subspecies, viz. Scaly Graphite, and Compact Graphite.

First Subspecies.

Scaly Graphite.—Schuppiger Graphit, *Werner*.

External Characters.—Colour dark steel-grey, which approaches to light iron-black. Occurs massive, disseminated; in coarse, small, and fine granular concretions; and crystallized. Only secondary form hitherto met with, is the equiangular six-sided table. Internally shining, passing into splendent, and lustre metallic. Fracture scaly foliated. Fragments indeterminate angular, and blunt-edged. Streak shining, even splendent, and lustre metallic. Perfectly sectile. Rather difficultly frangible. Writes and soils. Streak black. Feels very greasy.

Second Subspecies.

Compact Graphite, *Jameson*.—Dichter Graphite, *Werner*.

External Characters.—Colour is nearly the same with the preceding, only rather blacker. Occurs massive and disseminated, also in columnar concretions. Internally it is glimmering, sometimes glistening, and the lustre is metallic. Fracture small and fine grained uneven, which passes into even, and also into large and flat conchoidal; the large is sometimes slaty longitudinal. Fragments indeterminate angular and blunt-edged, and sometimes also tabular. In other characters it agrees with the preceding subspecies.

Chemical Characters.—When heated in a furnace it burns without flame or smoke, and during combustion emits carbonic acid, and leaves a residuum of red oxide of iron.

Constituent Parts.

Berthollet.		Graphite of Pluffier.	
Carbon,	90.0	Carbon,	23
Iron,	9.1—100.00	Iron,	2
		Alumina,	37
		Silica,	38—100

Journal des Mines, N. 12, p. 16.

Geognostic Situation.—Occurs usually in beds, sometimes disseminated, and in imbedded masses, in granite, gneiss, mica-slate, clay-slate, foliated granular limestone, coal and trap formations.

Geographic Situation.—Occurs in imbedded masses, and disseminated in gneiss in Glen Strath Farrar in Inverness-shire; in the coal formation near Cumnock, in Ayrshire, where it is imbedded in greenstone, and in columnar glance-coal. At Borrodale, in Cumberland, it occurs in a bed or beds of very varying thickness, included in a bed of trap, which is subordinate to clay-slate. This trap varies in its nature, being sometimes greenstone, or trap-tuff, in other instances amygdaloid, which is occasionally slaty, and contains agates.

Uses.—The finer kinds are first boiled in oil, and then cut into tables or pencils: the coarser parts, and the refuse of the sawings, are melted with sulphur, and then cast into coarse pencils for carpenters; they are easily distinguished by their sulphureous smell. It is also used for brightening and preserving grates and ovens from rust; and, on account of its greasy quality, for diminishing the friction in machines. Crucibles are made with it, which resist great degrees of heat, and have more tenacity and expansibility than those manufactured with the usual clay mixtures.

Genus VII. MICA.

Talk-glimmer, *Mohs*.

One axis. Cleavage rhomboidal. Streak green, white. Hardness=1.0—1.5. Sp. gravity=2 7—3.0.

This genus contains one species, viz. Rhomboidal Mica.

1. Rhomboidal Mica, *Jameson*.—Rhomboedrischer Talk-glimmer, *Mohs*.

Rhomboid unknown. Cleavage parallel with the terminal planes of the regular six-sided prism.

This species is subdivided into ten subspecies, viz. 1. Mica; 2. Pinite; 3. Lepidolite; 4. Chlorite; 5. Green Earth; 6. Talc; 7. Nacrite; 8. Potstone; 9. Steatite; 10. Figure-stone. *Clay-slate, Whet-slate, Black Chalk, Alum-slate.

First Subspecies.

Mica,† *Jameson*.—Glimmer, *Werner*.

External Characters.—Its most common colours are grey, brown, black, and white, and very rarely peach-blossom red. It occurs massive, and disseminated; also in distinct concretions, which are large, coarse, and small granular, and wedge-shaped prismatic. The following are the secondary forms:

1. Equiangular six-sided prism. 2. Equiangular six-sided table. 3. Equiangular six-sided table, truncated on four of the terminal edges. 4. Equiangular six-sided table, bevelled on the terminal planes, and the edges of the bevelment truncated. 5. Rectangular four-sided table. 6. Rectangular four-sided prism.

Crystals middle-sized and small, seldom large. Tables generally adhere by their terminal planes, seldom by their lateral planes, and form druses. Sometimes arranged in rows, rarely in the rose-form, and seldom intersecting each other. Lateral planes of the tables, and the terminal planes of the prism, smooth and resplendent; terminal planes of the table longitudinally streak-

* *Graphite*, from γραφω, *I write*, on account of its writing quality.

† *Mica*, from the Latin word *mico*, to shine, given to it on account of its lustre.

ed, lateral planes of the prism transversely streaked. Internally generally resplendent, seldom shining, generally pearly, sometimes semimetallic, and in the silver-white variety passing into metallic. Fracture not discernible. Fragments tabular and splintery. Translucent or transparent in thin plates, but rarely in crystals of considerable thickness or length. Sectile. Affords a grey-coloured dull streak. Feels fine and meagre, smooth. Elastic-flexible.

Chemical Characters.—Before the blowpipe, it melts into a greyish-white enamel.

		Black Mica from Siberia.
Constituent Parts.—	Silica,	42 50
	Alumina,	11.50
	Oxide of Iron,	22.00
	Oxide of Manganese,	2.00
	Potash,	10.00
	Magnesia,	9.00
	Loss by heating,	1.00—98.00

Klaproth, B. v. s. 78.

Geognostic Situation.—This mineral occurs as an essential constituent part of granite, gneiss, and mica-slate, and is accidentally intermixed with other rocks, both of the primitive, transition, secondary or flœtz, and alluvial classes.

Geographic Situation.—The rocks in which mica occurs, are so universally distributed, that it is not necessary to enter into any detail of localities.

Uses.—In Siberia, where window-glass is scarce, it is used for windows; also for a similar purpose in Peru, and, I believe, also in New Spain, as it appears that the mineral named *Teculi* by Ulloa, and which is used for that purpose, is a variety of mica. It is also used in lanterns, in place of glass, as it resists the alternations of heat and cold better than that substance. In Russia, it is employed in different kinds of inlaid work. It is sometimes intermixed with the glaze in particular kinds of earthen-ware; the heat which melts the glaze has no effect on the mica; hence it appears dispersed throughout the glaze, like plates or scales of silver or gold, and thus gives to the surface of the ware a very agreeable appearance. Some artists use it in the making of artificial aventurines.

Second Subspecies.

Pinite, *Jameson.*—Pinit, *Werner.* Micarelle, *Kirwan.*

External Characters.—Colour blackish-green, altered on the surface by brown or red iron-ochre into brownish-red. Sometimes iron-shot. Occurs massive, also in distinct concretions, which are thick and thin lamellar, collected into large and coarse granular, and crystallized in the following figures:

1. Equiangular six-sided prism. 2. The preceding figure truncated or bevelled on all the lateral edges. Owing to the number of planes, figures of this description have a cylindrical form. The terminal angles are sometimes truncated.

Crystals seldom middle-sized, generally small. They are imbedded, and frequently intersect each other. Cleavage shining; fracture glistening and glimmering; lustre resinous. Fracture small grained uneven. Fragments blunt-angular, seldom tabular. Opaque; faintly translucent on the edges. Sectile. Easily frangible. Not flexible. Feels somewhat greasy.

Chemical Character.—It is infusible before the blowpipe.

Constituent Parts.—	Silica,	29.50
	Alumina,	63.75
	Oxide of Iron,	6.75—100.00

Klaproth, Jour. des Mines, N. 100. p. 311.

Geognostic and Geographic Situations.—It is found imbedded in the granite of St. Michael's Mount in Cornwall; in porphyry in Ben Gloe and Blair-Gowrie.

Third Subspecies.

Lepidolite, *Jameson.*—Lepidolith, *Werner.*

External Characters.—Colour peach-blossom-red, inclining sometimes to rose-red, sometimes to lilac-blue; passes into pearl-grey, yellowish-grey, and greenish-grey. Occurs massive, and in small granular distinct concretions. Internally its lustre is glistening, passing into shining, and pearly. Fracture coarse splintery. Fragments indeterminate angular and blunt-edged. Feebly translucent. Soft. Rather sectile. Rather easily frangible. Specific gravity, 2.816, *Klaproth.*—2.58, *Karsten.*

Chemical Characters.—Before the blowpipe it intumesces, and melts very easily into a milk-white nearly translucent globule.

Constituent Parts.—	Silica,	54.00
	Alumina,	20.00
	Potash,	18.00
	Fluate of Lime,	4.00
	Manganese,	3.00
	Iron,	1.00—100

Vauquelin Jour. de Min. t. ix. p. 235.

Geognostic and Geographic Situations.—It occurs disseminated, in foliated and granular limestone, at Dalmally, and in other quarters of the Highlands.

Fourth Subspecies.

Chlorite, *Jameson.*—Chlorit, *Werner.*

This subspecies is divided into four kinds, viz. Earthy Chlorite, Common Chlorite, Slaty Chlorite, and Foliated Chlorite.

First Kind.

Earthy Chlorite, *Jameson.*—Erdiger Chlorit, *Karsten.*

External Characters.—Colour green. Occurs massive, desseminated, in crusts, and moss-like, inclosed in adularia and rock-crystal. Glimmering or glistening; lustre pearly. Consists of fine scaly particles, which are more or less cohering, and feel rather greasy. Does not soil. Streak is of a mountain-green colour.

Chemical Characters.—It melts before the blowpipe into a blackish slag.

Constituent Parts.—	Silica,	26.00
	Alumina,	18 50
	Magnesia,	8.00
	Muriate of Soda, or Potash,	2.00
	Oxide of Iron,	43 00
	Loss,	2.50—99.00

Vauquelin, Journ. des Mines, N. 39. p. 167.

Geognostic and Geographic Situations.—It occurs in veins along with common chlorite at Forneth Cottage in Perthshire.

Second Kind.

Common Chlorite, *Jameson.*—Gemeiner Chlorit, *Werner.*

External Characters.—Colour is intermediate between dark blackish-green and leek-green. Occurs massive and disseminated. Lustre glimmering, or glistening; pearly, inclining to resinous. Fracture fine earthy; fine scaly foliated. Fragments blunt-edged. Opaque. Becomes light mountain-green in the streak, with a feeble lustre. Soft. Sectile. Does not adhere to the tongue. Feels somewhat greasy.

Geognostic and Geographic Situations.—Occurs not only disseminated through rocks of different kinds, as granite and mica-slate, but also in beds and veins. It is met with in Arran, Bute, &c.

Third Kind.

Slaty Chlorite or Chlorite-Slate, *Jameson.*—Chlorit-Schiefer, *Werner.* Schiefriger Chlorit, *Karsten.*

External Characters.—Colour intermediate between dark mountain and leek-green; sometimes passes into blackish-green and greenish-black. Occurs massive, and in whole beds. Lustre glistening, sometimes inclining to shining, and intermediate between pearly and resinous. Fracture more or less perfect slaty, seldom straight, generally waved slaty, and sometimes scaly foliated. Fragments tabular. Opaque. Affords a pale mountain-green streak. Sectile; rather easily frangible. Does not adhere to the tongue. Feels slightly greasy.

Geognostic Situation.—Occurs principally in beds, subordinate to clay-slate, and is occasionally associated with potstone and talc-slate.

Geographic Situation.—Occurs in beds, in the clay-slate districts of the Grampians, and other parts of Scotland.

Fourth Kind.

Foliated Chlorite, *Jameson.*—Blättriger Chlorit, *Werner.*

External Characters.—Colour dark blackish-green, which in some rare varieties is dark olive-green. Occurs massive, disseminated, in granular concretions, and crystallized in four-sided prisms, and in six-sided tables. These tables are aggregated together, in such a manner as to form the two following figures:

A. Cylinder terminated by two cones.

B. Two truncated cones, joined base to base.

Crystals generally longitudinally streaked, and are small or middle-sized. Externally glistening, approaching to shining, and resinous; internally shining, and pearly. Fragments indeterminate angular; tabular. Opaque; translucent on the edges; sectile; rather difficultly frangible. Feels rather greasy. Colour lighter in the streak.

Geognostic and Geographic Situations.—It occurs in the Island of Jura, one of the Hebrides, in quartz rock.

Fifth Subspecies.

Green Earth, *Jameson.*—Grünerde, *Werner.*

External Characters.—Colour green. Occurs massive, seldomer disseminated, more frequently in globular and amygdaloidal-shaped pieces, which are sometimes hollow, in crusts lining the vesicular cavities in amygdaloid, or on the surface of agate balls. Internally dull. Fracture earthy, sometimes small grained uneven. Opaque. Feebly glistening in the streak, but without any change of colour. Feels rather greasy. Adheres slightly to the tongue.

Chemical Characters.—Before the blowpipe it is converted into a black vesicular slag.

		From the Veronese.
Constituent Parts.—	Silica,	53.0
	Oxide of Iron	28.0
	Magnesia,	2.0
	Potash,	10.0
	Water,	6.0—99.0

Klaproth, Beit. B. iv. s. 241.

Geognostic Situation.—It occurs principally in the amygdaloidal cavities of amygdaloid, and incrusting the agates found in that rock. It also occasionally colours sandstone, and is disseminated in porphyry.

Geographic Situation.—It is a frequent mineral in the amygdaloid of Scotland; it occurs also in that of England and Ireland.

Uses.—It is used as a pigment in water-painting, and is the *mountain-green* of painters.

Sixth Subspecies.

Talc, *Jameson.*—Talk, *Werner.*

This species is divided into two kinds, viz. Common Talc and Indurated Talc.

First Kind.

Common Talc, *Jameson.*—Gemeiner Talk, *Werner.*

External Characters.—Common colours white and blue. Occurs massive, disseminated, in plates, reniform and botryoidal; in distinct concretions, which are large, coarse and small granular; also narrow or broad and stellular or promiscuous radiated, which are again collected into other concretions, having a wedge-shaped prismatic form. Sometimes crystallized in small six-sided tables, which are in druses. Generally splendent; shining; pearly; semi-metallic. Fragments wedge-shaped, seldom splintery. Translucent; in thin folia transparent. Flexible; not elastic. Sectile. Feels very greasy.

Chemical Characters.—It becomes white before the blow-pipe, and at length, with difficulty affords a small globule of enamel.

Constituent Parts.—	Silica,	61.75
	Magnesia,	30.50
	Potash,	2.75
	Oxide of Iron,	2.50
	Water,	0 25
	Loss,	2.25

Klaproth, Karst. Tab. s. 43.

Geognostic Situation.—It occurs in beds in mica-slate and clay-slate, and in a similar situation in granular limestone and dolomite; also in cotemporaneous veins, in beds of indurated talc, serpentine, and porphyry; and in the reniform external shape in tinstone veins.

Geographic Situation.—It is found in Aberdeenshire, Banffshire, and Perthshire.

Use.—It enters into the composition of the cosmetic named *rouge.*

Second Kind.

Indurated Talc, or Talc Slate, *Jameson.*—Verhärteter Talk, *Werner.*

External Characters.—Colours grey and green. Occurs massive, and rarely in fibrous distinct concretions. Lustre shining, passing to glistening; pearly. Fracture curved slaty, passing into imperfect foliated. Fragments tabular. Strongly translucent on the edges; sometimes feebly translucent. Rather sectile. Rather easily frangible. Not flexible. Feels greasy.

Geognostic Situation.—It occurs in primitive mountains, where it forms beds in clay-slate and serpentine, and is associated with amianthus, chlorite, rhomb-spar, garnet, actynolite, quartz, kyanite and grenatite.

Geographic Situation.—It occurs in Perthshire, Banffshire, and the Shetland islands.

Uses.—It is employed for drawing lines by carpenters, tailors, hat-makers, and glaziers. The lines are not so easily effaced as those made by chalk, and besides remain unaltered under water.

Seventh Subspecies.

Nacrite, *Jameson.*—Nacrite, *Brongniart.* Erdiger Talk, *Werner.*

External Characters.—Colours greenish-white, and greenish-grey. Consists of scaly parts, which are more or less compacted; the most compact varieties have a thick or curved slaty fracture. Strongly glimmering; pearly; inclining to resinous. Friable. Feels very greasy; soils.

Chemical Characters.—It melts easily before the blowpipe.

Constituent Parts.—		
	Alumina,	81.75
	Magnesia,	0.75
	Lime,	4.00
	Potash,	0.50
	Water,	13.50—100.50.

John.

Geognostic and Geographic Situations.—This is a very rare mineral; it occurs in veins with sparry ironstone, galena, iron-pyrites and quartz, in the mining district of Freyberg in Saxony; Gieren in Silesia; and Sylva in Piedmont.

Eighth Subspecies.

Potstone, or Lapis Ollaris, *Jameson.*—Topfstein, *Werner.*

External Characters.—Colour greenish-grey, of different degrees of intensity; darker varieties incline to leek-green, and blackish-green. Occurs massive, and in granular concretions, which are indistinct. Internally glistening, inclining to shining; pearly, inclining to resinous. Fracture curved, and imperfect foliated, which passes into slaty. Fragments indeterminate angular, or slaty. Translucent on the edges. Affords a white-coloured streak. Perfectly sectile. Feels greasy. Rather difficultly frangible.

Chemical Character.—It is infusible before the blowpipe.

Geognostic Situation.—It occurs in thick beds, in primitive clay slate.

Geographic Situation.—It occurs abundantly on the shores of the lake Como in Lombardy, and at Chiavenna in the Valteline; also in different parts in Norway, Sweden, and Finland.

Uses.—When newly extracted from the quarry it is very soft and tenacious, so that it is frequently fashioned into various kinds of culinary vessels, which harden in drying, and are very refractory in the fire.

Ninth Subspecies.

Steatite, or Soapstone, *Jameson.*—Speckstein, *Werner.*

External Characters.—Colours white, reddish-white, and yellow. Sometimes marked with spotted and dendritic greyish-black delineations. Occurs massive, disseminated, in crusts, reniform; and also in the following figures:

1. Equiangular six-sided prism, acutely acuminated on both extremities with six planes. 2. Acute double six-sided pyramid. 3. Rhomboid.

The six-sided prism, and six-sided pyramid, are from rock-crystal, and the rhomboid from calcareous-spar. Both appear to be supposititious, and are small or middle sized, generally imbedded in massive steatite. Lateral planes transversely streaked, and the acuminating planes smooth and shining. Internally dull, and, when glimmering, owing to its being intermixed with foreign parts. Fracture coarse splintery, passing into coarse and fine-grained uneven. Internally dull, seldom feebly glimmering. Fragments indeterminate angular, and blunt-edged. Translucent on the edges. Becomes shining in the streak. Writes but feebly. Very sectile. Rather difficultly frangible. Does not adhere to the tongue. Feels very greasy.

Chemical Characters.—Before the blowpipe, it loses its colour, but is infusible without addition.

Steatite of Monte Ramuzo.

Constituent Parts.—		
	Silica,	44.00
	Magnesia,	44.00
	Alumina,	2.00
	Iron,	7.30
	Manganese,	1.50
	Chrome,	5.00
	Trace of lime and muriatic acid.	——100.80

Vauquelin.

Geognostic Situation.—It occurs frequently in small cotemporaneous veins, that traverse serpentine in all directions; and in angular and other shaped pieces in secondary or floetz-trap rocks. It also occurs in metalliferous veins that traverse primitive rocks.

Geographic Situation.—It occurs in the serpentine of Portsoy and Shetland; in the limestone of Icolmkill; and in the trap-rocks of Fifeshire, the Lothians, Arran, Skye, Canna, and other parts in Scotland. In England, in the serpentine of Cornwall, and at Amlwch in Anglesey.

Uses.—The steatite of Cornwall is used at Worcester, in the manufacture of porcelain. Like fullers earth and indurated talc, it readily absorbs oily and greasy matter, and hence it is used for extracting spots of grease from silk and woollen stuffs. It is also employed in polishing gypsum, serpentine, and marble. When pounded and slightly burnt, it forms the basis of certain cosmetics. It writes readily on glass, in which character it differs from common chalk, which leaves no trace; hence it is used by glaziers, in marking plates of glass before they are cut with diamond.

Tenth Subspecies.

Figurestone, or Agalmatolite†, *Jameson.*—Bildstein, *Werner.* Agalmatolith, *Klaproth.*

† *Agalmatolite,* from the Greek words αγαλμα and λιθος, which signifies *figure-stone,* because it is cut into figures of different kinds in the countries where it is principally found.

External Characters.—Colours grey, green, white, red, and brown. Occurs massive. Internally dull or feebly gimmering. Fracture large and flat conchoidal in the large, splintery in the small, and sometimes imperfect slaty. Fragments indeterminate angular, rather sharp-edged, or imperfect tabular. Translucent, sometimes only on the edges. Becomes feebly resinous in the streak. Immediate between sectile and brittle. Feels rather greasy.

Chemical Characters.—It is infusible before the blowpipe.

		Chinese Figurestone.
Constit. Parts	—Silica,	35 00
	Alumina,	29.00
	Lime,	2.00
	Potash,	7.00
	Iron,	1.00
	Water,	5.00—99.00—*Vauquelin.*

Geographic Situation.—It occurs in China and at Nagyag in Transylvania, but the geognostic situations are unknown.

Uses.—This mineral, owing to its softness, can easily be fashioned into various shapes with the knife: hence, in China, where it frequently occurs, it is cut into human figures, also into pagodas, cups, snuff-boxes, &c.

* Clay Slate*. *Jameson.*—Thonschiefer, *Werner.*

External Characters.—Colours yellowish, ash, smoke bluish, pearl, and greenish grey; from greenish-grey it passes into a colour intermediate between leek-green and blackish-green; from dark smoke-grey into greyish-black and bluish-black; and from pearl-grey into brownish-red† and cherry-red. Sometimes spotted, striped, or flamed. Occurs massive. Lustre pearly, glistening, or glimmering. Fracture more or less perfect slaty; some varieties approach to foliated, others to compact. The slaty is either straight, or undulating curved, and the latter has a twofold obliquely intersecting cleavage. Fragments generally tabular, seldom long splintery or trapezoidal. Is opaque. Affords a greyish-white dull streak. Sectile, and easily split. Feels rather greasy. Specific gravity, 2.661, *Kirwan.* 2.706 *Karsten.*

Chemical Characters.—It is fusible into a slag before the blowpipe.

Constituent Parts.	—Silica,	48.6
	Alumina,	23.5
	Magnesia,	1.6
	Peroxide of Iron,	11.3
	Oxide of Manganese,	0.5
	Potash,	4 7
	Carbon,	0.3
	Sulphur,	0.1
	Water, and Volatile Matter,	7.6
	Loss,	1.8—100
		Daubuisson.

Geognostic Situation.—It occurs in primitive and transition mountains.

Geographic Situation.—It is a very generally distributed rock throughout the mountainous regions in the different quarters of the globe. It abounds in many of the Highland districts in Great Britain and Ireland, and in several of the smaller islands that lie near their coasts.

Use.—It is principally used for roofing houses.

* Whet-Slate, *Jameson.*—Wetzschiefer, *Werner.*

External Characters.—Most common colour greenish-grey; it is found also mountain, asparagus, olive and oil green. Occurs massive. Internally feebly glimmering. Fracture in the large is straight slaty; in the small, splintery. Fragments tabular. Translucent on the edges. Streak greyish-white. Soft in a low degree. Feels rather greasy. Specific gravity 2.722, *Karsten.*

Geognostic Situation.—It occurs in beds in primitive and transition clay-slate.

Geographic Situation.—Very fine varieties are brought from Turkey.

Uses.—When cut and polished, it is used for sharpening iron and steel instruments. For these purposes, it is necessary that it contain no intermixed hard minerals, such as quartz. The light-green coloured varieties, from the Levant, are the most highly prized: those from Bohemia are also much esteemed in commerce. The Levant whet-slate is brought in masses to Marseilles, and is there cut into pieces of various sizes. It is ground by means of sand or sandstone, and polished with pumice and tripoli. These whet-stones, or *hones*, as they are called, ought to be kept in damp and cool places; for when much exposed to the sun, they become too hard and dry for many purposes.

The powder of whet slate is used for cutting and polishing metals, and is by artists considered as a variety of emery.

Drawing-Slate, or Black Chalk, *Jameson.*—Zeichenschiefer, *Werner.*

External Characters.—Colour intermediate between bluish and greyish black, rather more inclining to the latter. Massive. Lustre of the principal fracture glimmering. Cross fracture dull. Principal fracture slaty, generally straight, sometimes curved; cross fracture fine earthy. Fragments partly tabular, partly long splintery. Opaque. Soils slightly, and writes. Retains its colour in the streak, and becomes glistening. Very soft. Sectile. Easily frangible. Adheres slightly to the tongue. Feels fine, but meagre. Specific gravity, 2.110. *Kirwan.*—2.111, *Karsten.*

Chemical Character.—Infusible.

Geognostic Situation.—Occurs in beds in primitive and transition clay-slate; also in secondary or flœtz formations.

Geographic Situations.—Found at Marvilla in Spain, Brittany in France, and in Italy; also in Germany, as in the mountains of Bareuth; and in the coal formation in Scotland.

Uses.—Used for drawing, and also as a black colour in painting.

* Alum Slate.—Alum slate is divided into two kinds, viz. common alum slate, and glossy alum slate.

First Kind.

Common Alum Slate, *Jameson.*—Gemeiner Alaunschiefer, *Werner.*

External Characters.—Colour intermediate between bluish and iron black. Massive, and sometimes in roundish balls, which are imbedded in the massive va-

* Clay-slate, whet-slate, black chalk, and alum-slate, are placed immediately after the subspecies of Rhomboidal Mica, on account of their affinity with it.

† Houses roofed with the red variety of clay-slate appear as if covered with copper.

rieties. Lustre more or less glimmering. Fracture nearly perfect straight slaty. Fragments tabular. Opaque. Does not soil. Retains its colour in the streak, but becomes glistening. Intermediate between soft and semihard. Easily frangible, and rather brittle. Specific gravity 2.384, *Kirwan.*

Second Kind.

Glossy Alum Slate, *Jameson.*—Glänzender Alaunschiefer, *Werner*

External Characters.—Colour intermediate between bluish and iron black, and it sometimes exhibits on the surface of fissures the pavonine, columbine, or temper-steel tarnish. Occurs massive. Lustre semi-metallic and splendent, shining, or glistening, on the principal fracture, and glimmering or dull on the cross fracture. Principal fracture is generally undulating curved and short slaty; seldom inclines to straight slaty. Cross fracture earthy. Fragments tabular, and these run into wedge-shaped fragments. Specific gravity 2.588, 2.339, *Kirwan.*

In all the other characters it agrees with the preceding subspecies.

Geognostic Situation.—Both subspecies agree in geognostic situation: they occur in primitive, and also in transition clay slate, and more rarely in veins traversing these rocks. Some varieties of alum slate have been observed associated with secondary rocks.

Geographic Situation.—It occurs along with greywacke and greywacke slate in the vicinity of Moffat, in Dumfriesshire; in the transition districts of Lanarkshire, particularly in the neighbourhood of Lead Hills; and near the Ferry-town of Cree in Galloway.*

Use.—This mineral, when roasted and lixiviated, affords alum.

The following minerals are placed immediately after the genus Mica, on account of the general affinity to it. Their present situation is not to be considered as fixed, but only temporary.

* 1. Native Magnesia; 2. Magnesite; 3. Meerschaum,
** 4. Nephrite; 5 Serpentine; 6. Fuller's Earth.

1. Native Magnesia.—*Jameson* and *Bruce.*

External Characters.—Colour snow white, passing into greenish white. Occurs massive, and in granular and prismatic concretions. Lustre pearly. Semi-transparent in the mass, transparent in single folia. Soft, and somewhat elastic. Adheres slightly to the tongue. Specific gravity 2.13.

Chemical Characters.—Before the blowpipe it becomes opaque and friable, and loses weight. Soluble in sulphuric, nitric, and muriatic acids.

Constituent Parts.—	Magnesia	70
	Water of crystallization,	30—100

Bruce, American Min. Jour. vol. i. p. 30.

Geognostic and Geographic Situations.—Occurs in small veins in serpentine, at Hoboken in New-Jersey.

2. Magnesite, *Jameson.*—Reine oder Natürliche Talkerde *Werner.*

External Characters.—Colours grey and white. Marked with yellowish and ash-grey spots, and also with bluish-grey dots, and dendritic delineations. Occurs massive, tuberose, reniform, and in a shape intermediate between vesicular and perforated; walls of vesicles rough and uneven. Has a rough surface. Internally dull. Fracture large and flat conchoidal, which passes into fine earthy. Fragments rather sharp-edged. Nearly opaque. Scratched by fluor-spar, but it scratches calcareous-spar. Adheres pretty strongly to the tongue. Feels rather meagre. Dull in the streak. Rather easily frangible. Specific gravity, 2.881, *Haberle.*

Chemical Characters.—Infusible; but before the blowpipe it becomes so hard as to scratch glass.

Constituent Parts.—	Magnesia,	45.42
	Carbonic acid,	47 00
	Silica,	4.50
	Alumina,	0.50
	Ferruginous Manganese,	0.50
	Lime,	0.08
	Water,	2.00—*Bucholz.*

Geognostic and Geographic Situations.—Found at Hrubschitz in Moravia, in serpentine rocks, along with meerschaum, common and earthy talc, mountain cork, and rhomb spar.

3. Meerschaum,† *Jameson.*—Meerschaum, *Werner.*

External Characters.—Colours yellowish and greyish-white, seldom snow-white. Occurs massive. Internally dull. Fracture fine earthy, passing on the one side into flat conchoidal, on the other into even. Fragments indeterminate angular, and not particularly sharp-edged. Opaque, rarely translucent on the edges. Becomes slightly shining in the streak. Does not soil. Very soft. Sectile. Rather difficultly frangible. Adheres strongly to the tongue. Feels rather greasy. Specific gravity, 1.209, *Karsten.*—1.600, *Klaproth.*—0.988, 1.279, *Breithaupt.*

Chemical Character.—Before the blowpipe it melts on the edges into a white enamel.

Constituent Parts.—	Silica, . .	41.50
	Magnesia, .	18.25
	Lime . .	0.50
	Water and carbonic acid, .	39.00—98.25

Klaproth, Beit. b. ii. s. 172.

Geognostic and Geographic Situations.—It occurs in veins in the serpentine of Cornwall; in serpentine, at Hrubschitz in Moravia; at Vallecas, near Madrid in Spain, also in serpentine. It is dug at Sebastopol and Kaffa, in the Crimea; and near Thebes in Greece.

Asia.—It occurs in beds immediately under the soil, at Kittisch and Bursa in Natolia; and in the mountains of Eskischehir, also in Natolia, where from 600 to 700 men are employed in digging meerschaum.

Uses.—When first dug from the earth, it is soft and greasy. It lathers with water like soap; hence it is used by some nations, as by the Tartars, for washing. In Turkey, it is made into tobacco-pipes.

4. Nephrite, *Jameson.*—Nephrit, *Werner.*

Of this mineral there are two kinds, viz. Common Nephrite and Axestone

a. Common Nephrite *Jameson*.—Gemeiner Nephrit, *Werner* F[illegible] N[illegible] *Saussure*

External Characters.—Colour leek-green, of various

† *Meerschaum*, in German, signifies *sea-froth*, and is by some philologists alleged to have been applied to this mineral on account of its general aspect and lightness; while others derive it from the Natolian word *myrsen.*

degrees of intensity, sometimes passes into mountain-green, greenish-grey, and greenish-white. Occurs massive, in blunt-edged pieces, and rolled pieces. Internally dull or glimmering, owing to intermixed talc and asbestus. Fracture coarse-splintery, and the splinters are greenish-white. Fragments indeterminate angular, and rather sharp-edged. Strongly translucent. Nearly as hard as rock-crystal. Difficultly frangible. Feels rather greasy. Rather brittle. Specific gravity, 2.962, Oriental, according to *Karsten*.

Chemical Characters.—Before the blowpipe, it melts into a white enamel.

Constituent Parts.—Silica,	.	50.50
Magnesia,	.	31.00
Alumina,	.	10.00
Iron, .	.	5.50
Chrome,	.	0.05
Water,	.	2.75—*Karsten.*

Geognostic and Geographic Situations.—*Europe.*—In Switzerland, nephrite occurs in granite and gneiss; in the Hartz, in veins that traverse primitive greenstone; and in rolled masses near Leipsic in Saxony.—*Asia.*—The most beautiful varieties of this mineral are brought from Persia and Egypt, from the mines of Seminowski, near Kolyvan in Siberia; and from China.—*America.*—It is found on the banks of the river of Amazons, and near Tlascala in Mexico.

Uses.—Nephrite, when cut and polished, has always an oily and muddy aspect, yet it is prized as an ornamental stone. The Turks cut it into handles for sabres and daggers. Artists sometimes engrave figures of different kinds on it; and it is said to be highly esteemed as a talisman by the savage tribes of the countries where it is found. It was formerly believed to be useful in alleviating or preventing nephritic complaints: hence it has been called *Nephritic Stone.*

b. Axestone, *Jameson.*—Beilstein, *Werner.*—Panamustein, *Blumenbach.*

External Characters.—Colour intermediate between grass-green and leek-green, passes into mountain-green, oil-green, and greenish-grey. Occurs massive. Internally its lustre is strongly glimmering, inclining to glistening. Fracture slaty in the great, and more or less distinctly splintery in the small. Fragments tabular. Translucent, or only strongly translucent on the edges. Semihard, approaching to hard. Softer than common nephrite. Rather difficultly frangible. Specific gravity, 3.008.

Geographic Situation.—It occurs in New Zealand, and several of the Islands in the South Sea. Also in Saxony; and at Gothaab in Greenland, in primitive rocks.

Uses.—It is used by the natives of New Zealand, and other islanders in the South Sea, for hatchets and ear-drops.

5. Serpentine, *Jameson.*—Serpentin, *Werner.*

There are two kinds of this mineral, viz. Common Serpentine, and Precious Serpentine.

a. Common Serpentine, *Jameson.*—Gemeiner Serpentin, *Werner.*

External Characters.—Its colours are green, black, yellow, red. The colours are either uniform, or veined, spotted, dotted, and clouded; and frequently several of these delineations occur together. Occurs massive. Internally it is dull, or glimmering, owing to intermixed foreign parts. Fracture small and fine splintery, sometimes small and fine-grained uneven, which sometimes passes into even; and it is occasionally large, and flat conchoidal. Fragments rather sharp-edged. Translucent on the edges, or opaque. Soft. It does not yield to the nail, but is scratched by calcareous-spar. Rather sectile. Rather difficultly frangible. Feels somewhat greasy. Specific gravity, 2.560, 2.604, *Breithaupt.*

Physical Characters.—Some varieties of serpentine not only move the magnetic needle, but even possess magnetic poles.

Chemical Characters.—It is infusible before the blowpipe, but on exposure to a higher temperature, it melts with difficulty into an enamel.

Constituent Parts.—Silica,	.	.	32.00
Magnesia,	.	.	37.24
Alumina,	.	.	0.50
Lime,	.	.	10.60
Iron,	.	.	0.66
Volatile matter, and Carbonic acid,	.	.	14.16

Hisinger, Afhandlingar, i. Fysik, iii. p. 303.

Geognostic Situation.—Serpentine occurs in primitive, transition, and secondary rocks.

Geographic Situation.—In Scotland, it occurs in the islands of Unst and Fetlar, in Shetland; Isle of Glass in the Hebrides; at Portsoy in Banffshire; near Drimnadrochit, and the town of Inverness, in Inverness-shire; at the Bridge of Cortachie in Forfarshire; and between Ballantrae and Girvan, in Ayrshire. It abounds in some districts in Cornwall in England; and it occurs at Cloghan Lee, on the west coast of Ireland, in the county of Donnegal.

Uses.—As it is soft and sectile, and takes a good polish, it is cut and turned into vessels and ornaments of various kinds.

b. Precious serpentine, *Jameson.*—Edler Serpentin, *Werner.*

This mineral is divided into two sub-kinds, viz. Splintery Precious Serpentine, and Conchoidal Precious Serpentine.

α. Splintery precious serpentine, *Jameson.*—Edler Splittriger Serpentin, *Werner.*

External Characters.—Colour dark leek-green. Occurs massive. Internally it is feebly glimmering. Fracture coarse and long splintery, and sometimes inclines to slaty in the large. Fragments rather sharp-edged. Feebly translucent. Soft, passing into semihard. Specific gravity, 2 704, *Breithaupt.* In other characters it agrees with Common Serpentine.

Geognostic and Geographic Situations.—It occurs in the Island of Corsica, and in Bareuth.

Use.—In Corsica, it is cut into snuff-boxes, and other similar articles.

β. Conchoidal precious serpentine, *Jameson.*—Edler Muschlicher Serpentin, *Werner.*

External Characters.—Colour leek green, which sometimes passes into blackish-green; seldom into Pistachio-green, siskin-green, and oil green. Occurs massive, and disseminated. Lustre glistening, passing into glimmering, and is resinous. Fracture flat conchoidal. Fragments sharp-edged. Translucent, but only translucent on the edges in the dark varieties. Intermediate between soft and semi-hard. Specific gravity, 2.561, 2.643, *Breithaupt*. In other characters it agrees with the foregoing.

Constituent Parts.—	Silica,	42.50
	Magnesia,	38.63
	Lime,	0.25
	Alumina,	1.00
	Oxide of Iron,	1.50
	Oxide of Manganese,	0.62
	Oxide of Chrome,	0.25
	Water,	15.20

John, Chem. Untersuchungen, b. ii. s. 218.

Geognostic Situation.—It generally occurs intermixed with foliated granular limestone in beds subordinate to gneiss, mica-slate, and other primitive rocks. It sometimes occurs in cotemporaneous masses in common serpentine, and then it occasionally contains scales of mica.

Geographic Situation.—It occurs at Portsoy in Banffshire, and in the Shetland Islands; in the island of Holyhead.

Uses.—It receives a finer polish than common serpentine, and was much used by the ancients for pillars and other similar ornamental purposes. At present it is also in great esteem as an ornamental stone.

6. Fuller's earth, *Jameson.*—Walkerde. *Werner.*

External Characters.—Colours white, grey, and green. Some varieties exhibit clouded and striped-coloured delineations. Occurs massive. Dull. Fracture coarse and fine-grained uneven; some varieties are large conchoidal; and others incline to slaty. Fragments blunt-edged, and occasionally incline to slaty. Opaque; but when it inclines to steatite it is translucent on the edges. Becomes shining and resinous in the streak. Very soft, sometimes nearly friable. Sectile. Scarcely adheres to the tongue. Feels greasy. Specific gravity, 1.72, *Karsten.*—1.198, *Hoffmann.*—2.198, *Breithaupt.*

Chemical Characters.—It falls into powder in water, without the crackling noise which accompanies the disintegration of bole. It melts into a brown spongy scoria before the blowpipe.

		Fullers' earth of Ryegate.
Constituent Parts.—	Silica,	53.00
	Alumina,	10.00
	Magnesia,	1.25
	Lime,	0.50
	Muriate of Soda,	0.10
	Trace of Potash,	
	Oxide of Iron,	9.75
	Water,	24.00—98.60

Klaproth, Beit. b. iv. s. 338.

Geognostic and Geographic Situations.—In England it occurs in beds sometimes below, sometimes above the chalk formation; at Rosswein, in Upper Saxony, under strata of greenstone-slate; and in different places in Austria, Bavaria, and Moravia, it is found immediately under the soil.

Uses.—This mineral was employed by the ancients for cleaning woollen, and also linen cloth, and they named it *Terra Fullonum*, and *Creta Fullonum;* hence the name *Fuller's Earth.* The *Morochtus* of Dioscorides, which he celebrates on account of its remarkable saponaceous properties, is conjectured to have been a variety of fuller's earth.

Genus VIII. PEARL MICA.

One axis. Cleavage rhomboidal. Streak white. Hardness=3.5. Sp. gravity=3.0.—3.1.

1. Rhomboidal.

Rhomboid unknown. Cleavage parallel with the terminal planes of the regular six-sided prism.

Order VI. SPAR.

No metallic lustre. No adamantine lustre. Streak white. Hardness ranges from 3.5 to 7.0; if above 6, there are single distinct cleavages. Specific gravity ranges from 2.0 to 3.7; if 2.4 and less, it is not amorphous.*

Genus IX. SCHILLER-SPAR.

Schiller Spath, *Mohs.*

Three axes. Cleavage prismatic. Pearly lustre on single cleavages. If common pearly lustre, the specific gravity=3.2 and less, the hardness=5.5 and less, and colour green. Hardness ranges from 4 to 6. Sp. gravity from 3.0 to 3.4.

This genus contains four species, viz. 1. Prismatic, or Green Diallage, 2. Slaty or Common Schiller-spar, 3. Labrador, or Hyperstene, 4. Straight, or Anthophylite.

1. Prismatic Schiller-Spar, or Green Diallage, *Jameson.*—Prismatische Schiller Spath, *Mohs.*—Diallage Verte, *Haüy.*—Korniger Strahlstein, *Werner.*

Prism unknown. Cleavage prismatoidal. Common pearly lustre. Hardness=4.5,—5.5 Sp. gravity=3.0—3.2.

External Characters.—Colour green. Occurs massive and disseminated. Internally shining, glistening, and pearly. Fragments indeterminate angular, and rather sharp-edged. Translucent on the edges, sometimes passing into translucent. Brittle.

Chemical Characters.—It melts before the blowpipe into a grey or greenish enamel.

Constituent Parts.	Silica	50.0
	Alumina	11.0
	Magnesia	6.0
	Lime	13.0
	Oxide of iron,	5.3
	Oxide of Copper	1.5
	Oxide of Chrome	7.5—94.3

Vauquelin, An. d. Chimie, No. 88.

Geognostic and Geographic Situations.—It occurs in the island of Corsica, along with Saussurite; and with the same mineral in Mont Rosa in Switzerland, and at La Rivera, in the Valley of Susa in Piedmont.

Uses.—The compound of green diallage and Saussurite, named *Gabbro*, by the Italians, *Euphotide*, by the French, and by artists, *Verde di Corsica duro*, when cut and polished, has a beautiful appearance, and is much prized as an ornamental stone. It is cut into snuff-boxes, ring-stones, for in-laid work and other similar purposes.

* The cleavage not given, therefore the characters of this order are incomplete.

2. Slaty Schiller-Spar, *Jameson.*—Schiefer Shiller-Spath, *Mohs.*

Prism nearly 100°. Cleavage prismatoidal. Metallic-like pearly lustre. Hardness = 4.0, 5.0. Sp. gravity = 3.0, 3.3.

This species contains two subspecies, viz. Bronzite and Common schiller-spar.

First Subspecies.

Bronzite, *Jameson.*—Blättriger Anthophyllit, *Werner.*—Diallage metalloide fibro-laminaire, *Hauy.*

External Characters.—Colours brown and grey. Occurs massive, and in coarse and small granular distinct concretions. Internally shining, and the lustre is metallic-pearly. Fragments indeterminate angular and blunt-edged. Translucent on the edges, sometimes approaching to translucent. Affords a white streak. Difficultly frangible.

Chemical Characters.—It is infusible before the blowpipe.

Constituent Parts.		
	Silica,	60.00
	Magnesia	27.50
	Iron	10.50
	Water	0.50—98.50

Klaproth. Beit. b. v. s. 34.

Geognostic and Geographic Situations.—It occurs in greenstone in the island of Skye; in large masses in a bed of serpentine near Kraubat in Upper Stiria, &c.

Second Subspecies.

Common schiller-spar, *Jameson.*—Schillerstein, *Werner.*—Diallage metalloide laminaire, *Hauy.*

External Characters.—Colours green, grey, and brown. Seldom occurs massive, generally disseminated, and sometimes in granular distinct concretions. Internally shining and splendent, the lustre pearly, or metallic-pearly. Fragments indeterminate angular or tabular. Faintly translucent on the edges, or opaque. Streak greenish-grey, and dull. Easily frangible, and slightly inclining to sectile.

Geognostic and Geographic Situations.—It occur simbedded in serpentine, in Fetlar, and Unst in Shetland, and at Portsoy in Banffshire; in the greenstone rocks of the island of Skye; also in the greenstone rocks of Fifeshire; in the porphyritic rock of the Calton Hill, and the trap-rocks of Craig Lockhart, near Edinburgh.

3. Labrador Schiller-spar, or Hyperstene. *Jameson.*—Labradorische Schiller-Spath, *Mohs.*—Hypestene, *Hauy.*

Prism nearly 100. Cleavage prismatoidal. Metallic-like pearly lustre. Hardness = 6.0. Sp. gravity = 3.3, — 3.4.

External Characters.—Its colour is intermediate between greyish and greenish-black, nearly copper-red on the cleavage, and brownish-black, or blackish-brown on the fracture surface. Occurs massive, disseminated, also in thin curved lamellar concretions, which are collected into coarse granular. On the cleavage, the lustre shining and glistening, and metallic-pearly, on the fracture glimmering and pearly Fragments indeterminate, angular, or rhomboidal. Opaque, feebly translucent on the edges. Greenish-grey in the streak. Brittle, rather easily frangible.

Chemical Character.—It is infusible before the blowpipe.

Constituent Parts.		
	Silica	54.25
	Magnesia	14.00
	Alumina,	2.25
	Lime	1.50
	Oxide of Iron,	24.50
	Water,	1.00
	Oxide of Manganese, a trace.	—97.50

Klaproth, Beit. b. v. s. 40.

Geognostic and Geographic Situations.—It was first discovered on the coast of Labrador, and afterwards in the island of Skye, and near to Portsoy.

Uses.—When cut and polished, it has a beautiful copper-red colour, and metallic pearly lustre, and is made into ring-stones and brooches.

4. Straight Schiller-Spar, or Anthophyllite,* *Jameson.*—Gerader Schiller-Spath, *Mohs.* Anthophyllith, *Shumacher.* Strahliger Anthophyllit, *Werner.*

Prism nearly 106°. Cleavage in the direction of a rectangular prism. The lustre nearly metallic pearly. Hardness = 5.0, 5.5. Sp. gravity = 3.0, 3.3.

External Characters.—Colour intermediate between dark yellowish-grey and clove-brown. It generally occurs massive; also in narrow or broad prismatic distinct concretions, which are scopiform or promiscuous, and in which the surface is streaked. Rarely crystallized, in reed-like, very oblique four-sided prisms. Surface of the crystals longitudinally streaked. Lustre shining and glistening, and metallic-pearly. Fragments wedge-shaped and splintery; and sometimes rhomboidal. Translucent on the edges, or translucent.

Chemical Characters.—It becomes dark greenish-black before the blowpipe, but is infusible.

Constituent Parts.		
	Silica	56.00
	Alumina,	13.30
	Magnesia,	14.00
	Lime,	3.33
	Iron,	6.00
	Oxide of Manganese,	3.00
	Water,	1.43

John, Chem. Untersuchungen, 1. s. 200, 201.

Geognostic and Geographic Situations.—It occurs in beds in mica-slate at Kongsberg, in Norway, along with common hornblende, mica, and asbestous-tremolite; at Modum cobalt mines, also in Norway, along with common hornblende, cobalt-glance, and copper-pyrites.

Genus II. KYANITE.†

Disthene Spath, *Mohs.*

Three axes. Cleavage prismatic. In the most perfect cleavages, the hardness is = 5; on the angles it is = 7. Sp. gr. = 3.5.—3.7.

This genus contains one species, viz. Prismatic Kyanite.

1. Prismatic Kyanite, *Jameson.*—Prismatischer Disthene Spath, *Mohs.* Kyanite, *Werner.*

Prism = 102° 50′. Cleavage prismatoidal.

External Characters.—Colours blue, bluish-grey,

* This mineral is named *Anthophyllite* on account of the similarity of its colour with that of the anthophyllum.

† *Kyanite*, from the Greek word κυανος, *sky-blue*, a frequent colour of this mineral.

white, sky-blue, celandine-green, and greenish-grey. The varieties are often marked with blue-coloured flame delineations. Occurs massive and disseminated; also in distinct concretions, which are large and longish angulo-granular, and also wedge-shaped prismatic, which are straight or curved, and sometimes disposed in scopiform or stellular directions. It is sometimes regularly crystallized.

1. Oblique four-sided prism, truncated on the two opposite acute lateral edges. 2. Preceding figure, in which all the lateral edges are truncated. 3. Twin-crystal: it may be considered as two flat four-sided prisms joined together by their broader lateral planes.

The narrow lateral planes are longitudinally streaked, and glistening; the broad are smooth, or delicately transversely streaked and splendent. Crystals middle-sized, small, and very small; are singly imbedded, or intersect one another. Lustre splendent and pearly. Fragments splintery, or imperfectly rhomboidal. Massive varieties translucent. Crystals in general transparent. Rather brittle. Easily frangible.

Chemical Character.—It is infusible before the blowpipe.

Constit. Parts.	Silica,	43.00	
	Alumina,	55.50	
	Iron,	0.50	
	Trace of Potash.		——99.00

Klaproth. Beit. b. v. s. 10.

Geognostic Situation.—It has been hitherto found only in primitive mountains, where it occurs in compact granite, mica-slate, and talc-slate, accompanied with several other minerals.

Geographic Situation.—It occurs in primitive rocks near Banchory in Aberdeenshire, and Boharm, in Banffshire; in mica-slate near Sandlodge, in Mainland, the largest of the Shetland Islands.

Uses.—In India it is cut and polished, and sold as an inferior kind of sapphire.

Genus III. SPODUMENE.†

Three axes. Cleavage prismatic. Three cleavages parallel with the axes, nearly of equal perfection. Hardness = 6. Sp. gr. = 3.0.—3.1.

This genus contains but one species, viz. Prismatic Spodumene.

1. Prismatic Spodumene, *Jameson*.—Prismatischer Triphan Spath, *Mohs*. Triphane, *Hauy*.

Prism nearly = 100°. Cleavage three-fold; two of the cleavages parallel with the lateral planes, and a third with the shorter diagonal of the basis of the prism.

External Characters.—Colour intermediate between greenish-white and mountain-grey, and sometimes passes into oil-green. Occurs massive, disseminated, and in large and coarse granular concretions. Cleavage shining. Fracture glistening. Lustre pearly. Fracture fine-grained uneven. Translucent. Uncommonly easily frangible.

Chemical Characters.—Before the blowpipe, it first separates into small golden yellow coloured folia; and if the heat is continued, they melt into a greenish-white coloured glass.

Constit. Parts.	Silica,	64.4	
	Alumina,	24.4	
	Lime,	3.0	
	Potash,	5 0	
	Oxide of Iron,	2.2	——99.0‡

Vauquelin, Hauy's Tabl. p. 168.

Geognostic and Geographic Situations.—This mineral, which occurs in prismatic rocks, was first discovered in Sudermanland, in Sweden, and afterwards in Ireland, and in other countries.

Genus IV. PREHNITE.

Prehn Spath, *Mohs*.

Three axes. Cleavage axifrangible. Hardness = 6.0—7.0. Specific gr. = 2.8—3.0. Not blue.

This genus contains one species, viz. Prismatic Prehnite.

1. Prismatic Prehnite, *Jameson*.—Prismatischer Prehn Spath, *Mohs*. Prehnite, *Werner*.

Prism = 103°. Cleavage axifrangible.

This species is divided into two subspecies, viz. Foliated Prehnite, and Fibrous Prehnite.

First Subspecies.

Foliated Prehnite, *Jameson*.—Blätriger Prehnite, *Werner*.

External Characters.—Colours green, white, and grey. Occurs massive, and in distinct concretions, which are large, coarse, and fine angulo-granular, and also thick and wedge-shaped prismatic. Sometimes crystallized. The following are some of the secondary forms which the species assumes:

1. Oblique four-sided table, sometimes truncated either on all its terminal edges, or only on the acute edges. When the truncations on the edges increase very much, there is formed, 2. An irregular eight-sided table. When the truncations on all the acute edges increase considerably, there is formed, 3. An irregular six-sided table. When these truncating planes increase in magnitude, and when the table at the same time becomes thicker, and the obtuse edges are slightly truncated, there is formed, 4. A broad rectangular four-sided prism, rather flatly bevelled on the extremities, in which the bevelling planes are set on the smaller lateral planes, and the edge of the bevelment is slightly truncated. Externally crystals almost always shining. Internally shining, or glistening, and pearly. Fracture fine-grained uneven. Alternates from translucent, through semi-transparent into transparent. Rather easily frangible.

Chemical Characters.—It intumesces before the blowpipe, and melts into a pale green or yellow, or greenish-black frothy glass, but does not gelatinate with acids.

Physical Characters.—According to the observations of M. De Dree, it becomes electric by heating.

Constituent Parts.—	Silica,	48
	Alumina,	24
	Lime,	23
	Oxide of Iron,	4—99

Vauquelin.

Geognostic and Geographic Situations.—It occurs in veins in primitive and secondary rocks, in France, Tyrol, Greenland, and Cape of Good Hope.

† On exposure to the blowpipe, it first separates into golden-coloured scales, and then into a kind of powder or ash: hence the name *Spodumene*, from ἀποδόω, *I change into ash*, or σποδος, *ashes*.

‡ According to some analyses, it contains 8 *per cent.* of a new alkali named *lithina*.

SECOND SUBSPECIES.

FIBROUS PREHNITE, *Jameson*.—Fasriger Prehnite, *Werner*.

External Characters.—Colours green and greenish-white. Occurs massive, reniform, in straight scopiform and stellular fibrous and radiated distinct concretions, which are collected into large and coarse angulo-granular concretions; also crystallized in acicular four-sided prisms. Internally glistening; lustre pearly. Translucent. Easily frangible.

Chemical Character.—Before the blowpipe it melts into a vesicular enamel.

Physical Character.—It becomes electric by heating.

Constit. Parts.—	Silica,	42 50
	Alumina,	28.50
	Lime,	20.40
	Natron and Potash,	0.75
	Oxide of Iron,	3.00
	Water,	2.00—97.15

Laugier, Annales du Museum, t. xv. p. 205

Geognostic Situation.—This subspecies appears to be confined to secondary mountains; at least it has hitherto been found only in secondary trap rocks, as basalt, amygdaloid, basaltic-greenstone, and common greenstone. It occurs either in cotemporaneous veins, or in amygdaloidal and other shaped cavities in these trap rocks.

Geographic Situation.—In Scotland, it occurs in veins and cavities in trap-rocks near Beith in Ayrshire; Bishoptown in Renfrewshire; also at Hartfield, near Paisley; near Frisky Hall, in Cockney Burn Old Kilpatrick, and Loch Humphrey in Dunbartonshire; in Salisbury Craig, the Castle Rock, and Arthur Seat near Edinburgh; in Berwickshire; and in the islands of Mull and Raasay.

GENUS V. DATOLITE.*

Dattel Spath, *Mohs*. Esmarkite, *Hausmann*.

Three axes. Cleavage prismatic; but detected with difficulty. Internally, lustre resinous. Not blue. Hardness=5.0—5.5. Sp. gr.—2.9—3.0.

This genus contains one species, viz. Prismatic Datolite.

1. PRISMATIC DATOLITE, *Jameson*. Prismatischer Datholit, *Mohs*.

Prism = 109° 28′. Cleavage the same.

This species is divided into two subspecies, viz. Common Datolite, and Botryoidal Datolite.

FIRST SUBSPECIES.

COMMON DATOLITE, *Jameson*.—Datholit, *Werner*.

External Characters.—Colours white and grey, which latter inclines to celandine-green, and rarely to muddy honey-yellow. Occurs in massive portions, which are divided into large coarse and small granular distinct concretions; crystallized. The principal secondary forms are the following:

1. Low oblique four-sided prism. 2. Rectangular four-sided prism, flatly acuminated on the extremities, with four planes which are set on the lateral planes.

Externally shining. Internally intermediate between shining and glistening, lustre resinous. Fracture intermediate between fine-grained uneven and imperfect conchoidal. Translucent, and sometimes transparent. Very brittle. Difficultly frangible.

Chemical Characters.—When exposed to the flame of a candle, it becomes opaque, and may then be easily rubbed down between the fingers. Before the blowpipe, it intumesces into a milk-white coloured mass, and then melts into a globule of a pale rose-colour.

Constit. Parts.—	Silica,	37.0
	Lime,	28.0
	Boracic Acid,	31 0
	Alumina,	1.0
	Iron, Manganese, and Nickel,	1.5
	Water,	1 4—100

Esmark.

Geognostic and Geographic Situations.—It is associated with calcareous-spar, more rarely with fluor-spar, quartz, and sometimes prehnite, in a bed of magnetic ironstone in gneiss, at the mine of Nodebroe, near Arendal in Norway. It is said also to occur in small veins in greenstone, in the Geisalp in Sonthofen; and in the Syseralp.

SECOND SUBSPECIES.

BOTRYOIDAL DATOLITE or BOTRYOLITE, *Jameson*.—Botryolith, *Hausmann*.

This subspecies is divided into two kinds, viz. Fibrous Botryolite, and Earthy Botryolite.

First Kind.

FIBROUS BOTRYOLITE, *Jameson*.—Fasriger Botryolith, *Hausmann*.

External Characters.—Externally grey; internally white, which passes into pale rose-red. The colours are in concentric stripes. Occurs reniform, botryoidal, small globular; in fibrous concretions, which are scopiform and stellular; these concretions are again collected into granular concretions, which are traversed by very thin curved lamellar concretions. Surface granulated or rough, and dull. Internally glimmering and pearly. Fracture splintery. Translucent on the edges.

Geognostic and Geographic Situations.—It occurs in the Kjenlie mine, near Arendal in Norway, along with common quartz, schorl, calcareous spar, and iron pyrites, in a bed of magnetic ironstone, in gneiss.

Second Kind.

EARTHY BOTRYOLITE, *Jameson*.—Erdiger Botryolith, *Hausmann*.

External Characters.—Colour snow-white. Small botryoidal. Dull. Fracture earthy.

Geognostic and Geographic Situations.—It occurs along with the fibrous kind.

GENUS VI.—ZEOLITE.

Schaum Spath, *Mohs*.

Every kind of axis. Hardness ranges from 3.5, to 6.0. Sp. gravity from 2.0, to 2.5.

This genus contains the following species, viz. 1. Dodecahedral Zeolite, 2. Hexahedral Zeolite, 3. Rhomboidal Zeolite, 4. Pyramidal Zeolite, 5. Di-prismatic

* The name *Datolite* refers to the granular concretions which this species exhibits in the massive varieties, and was given to it by its discoverer, M. Esmark.

Zeolite, 6. Prismatic Zeolite, 7. Prismatoidal Zeolite, 8. Axifrangible Zeolite.† * Wavellite.

1. Dodecahedral Zeolite, or Leucite.‡ *Jameson.* Dodecaedricher Schaum Spath, *Mohs.* Leucit, *Werner.*

Tessular. Cleavage hexahedral and dodecahedral. Hardness=5.5—6.0. Specific gravity=2.4, 2.5.

External Characters.—Colours white and grey. Seldom occurs massive, and in granular concretions, most frequently in roundish imbedded grains, and crystallized in acute double eight-sided pyramids, in which the lateral planes of the one are set on the lateral planes of the other, and the summits deeply and flatly acuminated by four planes, which are set on the alternate lateral edges. Surface of the grains rough, and dull, or feebly glimmering; that of the crystals is smooth, seldom slightly streaked, in the direction of the diagonal, and glistening. Internally the lustre is shining, approaching to glistening, and is vitreous, inclining to resinous. Fracture imperfect and flat conchoidal. Translucent, semi-transparent, and some varieties approach to transparent. Refracts single. Brittle. Easily frangible.

Chemical Characters.—Before the blowpipe it is infusible without addition; with borax it forms a brownish transparent glass.

	Mean of different analyses.	
Constituent Parts.—	Silica,	54
	Alumina,	24
	Potash,	21
	Loss	1—100

Klaproth.

Geognostic and Geographic Situations.—It occurs principally in secondary trap rocks, and in lavas, and appears to be almost exclusively a production of Italy.

2. Hexahedral Zeolite, or Analcime, *Jameson.*—Hexadrischer Schaum Spath, *Mohs.* Analcime, *Hauy.* Kubizit, *Werner.*

Tessular. Cleavage hexahedral. Hardness=5.5. Sp. gravity=2.0—2.5.

External Characters.—Colour white, which passes into flesh-red. Seldom occurs massive, and this variety is disposed in coarse and small angulo-granular concretions, which are in general very closely aggregated; generally crystallized, in the following figures. 1. Perfect cube. 2. The cube flatly and deeply acuminated on all the angles with three planes, which are set on the lateral planes. 3. Acute double eight-sided pyramid, deeply and somewhat flatly acuminated on both extremities with four planes, which are set on the alternate lateral edges. Surface of the crystals smooth, and splendent or shining. Internally intermediate between shining and glistening, and the lustre vitreous, inclining to pearly. Fracture small or fine-grained uneven, or conchoidal. Fragments generally indeterminate angular, seldom more or less cubical, owing to the imperfection of the cleavage. Translucent or semi-transparent, and the crystals are transparent. Easily frangible.

Chemical Characters.—It melts with intumescence, before the blowpipe, into a transparent glass.

Physical Characters.—By friction, but not by heating, it becomes electric.

	Analcime of Montecchio-Maggiore.	
Constit. Parts.—	Silica,	58.0
	Alumina,	18.0
	Lime,	2.0
	Natron,	10.0
	Water,	8.5—96.5

Vauquelin, Annal. du Mus. d'Hist. Nat. t. ix. p. 241.

Geognostic Situation.—It occurs in primitive and secondary rocks, but more abundantly in secondary than in primitive rocks.

Geographic Situation.—It occurs in the secondary greenstone of Salisbury Craigs, in the porphyritic rock of the Calton Hill, near Edinburgh, and in many other places in Scotland.

3. Rhomboidal Zeolite, or Chabasite,§ *Jameson.*—Rhomboedrischer Schaum Spath, *Mohs.* Chabasie, *Hauy.* Schabasit, *Werner.*

Rhomboid=93° 48′. Cleavage rhomboidal. Hardness=4.0—4.5. Sp. gravity=1.0—2.1.

External Characters.—Colour greyish-white, approaching to yellowish-white. Seldom occurs massive; almost always crystallized. The following are the most frequent secondary forms: 1. Rhomboid truncated on the six obtuse lateral edges. 2. Rhomboid truncated on the six obtuse lateral edges, and on the six obtuse angles. 3. Rhomboid, in which each of the original planes of the rhomboid is divided into two. The lateral planes of the crystals are streaked in a peculiar manner; the streaks shoot from the shorter diagonal, (the dividing edge of the plane,) and run parallel with the two adjoining lateral edges of the rhomb. The truncating planes are smooth. Externally the crystals are splendent; internally glistening, and the lustre vitreous. Fracture imperfect conchoidal, and also small-grained uneven. Fragments indeterminate angular. Translucent; the crystals sometimes pass into semi-transparent.

Chemical Character.—Before the blowpipe it melts easily into a spongy white enamel.

	Chabasite of the Faroe Islands.	
Constituent Parts.—	Silica,	43.33
	Alumina,	22.66
	Lime,	3.34
	Natron, with Potash,	9.34
	Water,	21.00—99.67

Vauquelin, Annal. du Mus. d'Hist. Nat. t. ix. p. 333.

Geognostic Situation.—It occurs principally in secondary trap rocks; most frequently in cavities of amygdaloid, where it is often associated with agate, calcareous-spar, zeolite, and green-earth.

Geographic Situation.—The vesicular cavities of the trap-rocks of Mull and Skye afford crystals of chabasite; it occurs in similar rocks in the north of Ireland; and beautiful specimens are found in the amygdaloid of Iceland and of the Faroe Islands.

4. Pyramidal zeolite, or Cross-stone, *Jameson.*—Pyramidischer Schaum Spath, *Mohs.* Kreutstein, *Werner* Harmotome, *Hauy.*

Pyramid =121° 58′, 86° 36′? Cleavage is either pyra-

† Mohs names the eighth species *Axentheilender*, because its principal cleavage is perpendicular to the axis of the crystal; and this term is here translated *axifrangible*, until a more appropriate one shall occur.

‡ *Leucite*, from λευκος, *white*, and refers to its frequent white colour.

§ The name *Chabasie*, is from Chabazion, a stone described by Orpheus in his poems, but unknown to us at present.

midal, or is in the direction of the diagonals. Hardness =4 5. Sp. gravity =2 3, 2.4.

External Characters.—Colours white, grey, yellow, and red. Occurs very rarely massive; most frequently crystallized. The following are the principal secondary forms which have been observed: 1. Broad, seldom equilateral, rectangular four-sided prism, rather acutely acuminated on the extremities with four planes, which are set on the lateral edges. 2. Twin-crystal, which is formed by two crystals of No. 1. intersecting each other, in such a manner that a common axis and acumination is formed, and the broader lateral planes make four re-entering right angles. The surface of the smaller lateral planes is double plumosely streaked, the broader lateral planes transversely streaked, and the acuminating planes streaked parallel with the smaller lateral planes. Internally glistening, and the lustre intermediate between vitreous and pearly. Fracture small and perfect conchoidal, passing into uneven. Translucent, sometimes passing into semitransparent.

Chemical Characters.—Before the blowpipe it exhibits a greenish-yellow phosphorescence, and then melts with intumescence into a colourless glass.

Constituent Parts.—	Silica	49
	Alumina	16
	Barytes	18
	Water	15—98

Klap. Beit. b. ii. s. 83.

Geognostic and Geographic Situations.—It has been hitherto found only in mineral veins and in agate balls. At Andreasberg in the Hartz, it occurs in veins that traverse clay-slate and grey-wacke rocks, along with galena or lead-glance; at Kongsberg in Norway, in veins containing native silver, ores of silver, lead, zinc, arsenic, and iron; and Strontian in Argyleshire, in galena veins that traverse gneiss. At Oberstein it occurs in agate balls, in trap rocks, and in a similar situation near the village of Old Kilpatrick in Dunbartonshire.

5. Di-Prismatic Zeolite, or Laumonite, *Jameson.* Di-prismatischer Schaum Spath, *Mohs.* Lomonit, *Werner.*

Vertical prism =90° 12′; horizontal prism in the direction of the smaller diagonal 121° 34′. Cleavage double. Hardness =5. Sp. gr. =2.3—2 4.

External Characters.—Colours yellowish-white, snow-white, and greyish-white. Occurs in massive forms, arranged in large and coarse granular distinct concretions; also crystallized. Internally sometimes shining, sometimes glistening, and lustre pearly. When in a fresh state is transparent, but on exposure to the atmosphere, it very soon becomes opaque. When fresh, is rather harder than fluor-spar; but on exposure to the atmosphere, it soon becomes so soft as to yield to the mere pressure of the finger. Uncommonly easily frangible.

Chemical Character.—It forms a jelly with acids.

Constit. Parts.—	Silica,	94.0
	Alumina,	22.0
	Lime,	9.0
	Water,	17.5
	Carbonic acid,	2.5—100 *Vogel.*

Geognostic and Geographic Situations.—This mineral was first found in the year 1785, in the lead-mines of Huelgoet in Brittany, by M. Gillet Laumont, a distinguished French mineralogist. Since that period, it has been discovered in other parts of the world, as in Scotland, Ireland, Faroe Islands, &c.

6. Prismatic Zeolite or Mesotype, *Jameson.*—Prismatischer Schaum Spath, *Mohs.* Mesotype, *Hauy.*

Prism 91° 25′. Cleavage the same. Hardness =5.0—5.5. Sp. gr. =2 0—2.3.

This species is divided into three subspecies, viz. Fibrous Zeolite, Natrolite, and Mealy Zeolite.

First Subspecies.

Fibrous Zeolite, *Jameson.*—Fasriger Zeolit, *Werner.*

This subspecies is divided into two kinds, viz. Acicular or Needle Zeolite, and Common Fibrous Zeolite.

First Kind.

Acicular or Needle Zeolite, *Jameson.*—Nadelzeolith, *Werner.*

External Characters.—Colours greyish or yellowish-white, and frequently reddish-white. Occurs massive, and in distinct concretions; these are prismatic and granular; the prismatic are thin, sometimes passing into fibrous, straight, and scopiform; the granular include the prismatic, and are large and coarse. It also occurs crystallized, and the following are the secondary figures:

1. Acicular rectangular four-sided prism, very flatly acuminated, with four planes, which are set on the lateral planes. 2. The prism truncated on the edges.

Lateral planes of the crystals are longitudinally streaked, but the acuminating planes are smooth. Externally the crystals are shining, passing into splendent. Internally glistening, and lustre vitreous, inclining to pearly. Fracture small and fine-grained uneven. Translucent; crystals semitransparent and transparent; and it refracts double.

Chemical Characters.—It intumesces before the blowpipe, and forms a jelly with acids.

Physical Characters.—It becomes electric by heating, and retains this property some time after it has cooled. The free extremity of the crystal, with the acumination, shows positive, and the attached end negative electricity.—*Hauy.*

Const. Parts.—	Silica,	50 24
	Alumina	29 30
	Lime	9 46
	Water	10 00—99.00

Vauquelin, Jour. des Mines, N. 44. p. 576.

Geognostic and Geographic Situations.—It occurs in secondary trap rocks, as in basalt, greenstone, and amygdaloid. In this country it occurs near the village of Old Kilpatrick, Dunbartonshire, also in Ayrshire and Perthshire, and always in trap-rocks.

Second Kind.

Common Fibrous Zeolite, *Jameson.* Gemeiner Faser Zeolith, *Werner.*

External Characters.—Colours white, red, yellow, and yellowish-brown. Occurs massive, in blunt angular pieces, in balls, and small reniform, and these forms are composed of distinct concretions, which are fibrous and granular. The fibrous concretions are thin, straight, scopiform, and stellular; the granular, which include the fibrous, are large and coarse longish or angulo-granular, and are very much grown together. Occurs in capillary crystals. Internally it is strongly glimmering, passing into glistening, and lustre pearly. Faintly translucent. Its geognostic and geographic situations are the same with needle zeolite.

Chemical Characters.—It intumesces before the blowpipe, and forms a jelly with acids.

Constituent Parts.—Silica,	.	54.46
Alumina,	.	19.70
Lime,	.	1.61
Soda,	.	15.09
Water	.	9.83—100.63

Gehlen in Schweigger's Journ. viii. 355.

Second Subspecies.

Natrolite, *Jameson.*—Natrolith, *Werner.*

External Characters.—Colours yellow, yellowish-brown, or yellowish-white. Colours generally arranged in narrow striped delineations, which are parallel with the reniform external shape. Occurs massive, in plates, and reniform; also in distinct concretions, which are fibrous, granular, and lamellar; the fibrous are straight, and scopiform or stellular; these are collected into large and coarse granular, and both are intersected by curved lamellar concretions. Internally glistening, passing into glimmering, and lustre pearly. Fracture not visible. Translucent on the edges.

Chemical Characters.—Before the blowpipe it becomes first black, then red, intumesces, and melts into a white compact glass.

Constituent Parts.—Silica,	. .	48.00
Alumina	.	24.25
Natron,	.	16.50
Oxide of iron,		1.75
Water,	.	9.00—99.50

Klaproth. Beit. b v. s. 44.

Geognostic and Geographic Situations.—It occurs in small cotemporaneous veins in clinkstone porphyry, in the hills of Hohentwiel.

Third Subspecies.

Mealy Zeolite, *Jameson.*—Mehlzeolith, *Werner.*

External Characters.—Colours white and red. Occurs massive, reniform, coralloidal, sometimes it forms a crust over the other subspecies of zeolite, or is disposed in delicate fibrous concretions. Internally dull, or very feebly glimmering. Fracture coarse earthy. Opaque. Mass very soft, but the individual parts as hard as fibrous zeolite. Uncommonly easily frangible. Feels rough and meagre; and when we draw our finger across it, it emits a grating sound. Sometimes so light as nearly to swim in water.

Chemical Characters.—It intumesces before the blowpipe, and forms a jelly with acids.

Const. Parts.—Silica,	. . .	60.0
Alumina,	. . .	15.6
Lime,	. . .	8 0
Oxide of iron,	. .	1.8
Loss, by exposure to heat,		11.6—97

Hisinger's Afhandlingar i Fysik, &c. th. 3.

Geognostic Situation.—It occurs in similar repositories with the other subspecies.

Geographic Situation.—It is found near Tantallon Castle in East Lothian, in the islands of Skye, Mull, and Canna, also in the Faroe Islands, Iceland, and Sweden.

7. Prismatoidal Zeolite or Stilbite, *Jameson.*—Prismatoidescher Schaumspath, *Mohs.* Stilbite, *Hauy.*

Prism =90° 22′. Cleavage in the direction of the smaller diagonal very distinct. Hardness =3.5—4.0. Sp. gr. =2.0—2.2.

This species is divided into two subspecies, viz. Foliated Zeolite, and Radiated Zeolite.

First Subspecies.

Foliated zeolite, *Jameson.* Blätter-Zeolith, *Werner.*

External Characters.—Colours white, red, yellowish-grey, and pinchbeck-brown. Occurs massive, disseminated, globular, in amygdaloidal-shaped pieces; also in distinct concretions, which are large, coarse, and small angulo-granular; seldom thin and curved lamellar; which are again collected into granular. Frequently crystallized, and the following secondary forms occur: 1. Low, oblique, sometimes rather broad, four-sided prism. 2. Low six-sided prism. 3. Eight-sided prism.

Lateral planes of the prisms are transversely streaked, the terminal planes smooth. Planes sometimes shining, sometimes splendent, and the lustre vitreous. Internally alternates from shining to splendent, and the lustre pearly: the pinch-beck brown has a semi-metallic lustre. Fracture conchoidal. Massive varieties are strongly translucent: some varieties, particularly the pinchbeck-brown, are only translucent on the edges; but the crystals are generally semitransparent and transparent. Refracts single.

Chemical Characters.—It intumesces and melts before the blowpipe, and during its intumescence emits a phosphoric light. It does not form a jelly with acids.

Constit. Parts.—Silica,	. . .	52 6
Alumina,	. .	17.5
Lime	. . .	9.0
Water	. . .	18 5—97.6

Vauquelin, Jour. des Mines, N. xxxix. p. 164.

Geognostic Situation.—It occurs principally in secondary amygdaloid, either in drusy cavities, along with calcareous-spar and calcedony, or in cotemporaneous veins. It is also met with in primitive and transition mountains.

Geographic Situation.—In Scotland it occurs in drusy cavities or veins in the secondary trap-rocks that abound in the middle division of the country. Very beautiful specimens of the red foliated and radiated zeolites are found at Carbeth in Stirlingshire, and at Loch Humphrey in Dunbartonshire; and the same varieties occur on the coast between Bervie and Stonehaven in Angus-shire; also in the secondary trap-rocks of the Hebrides, as of Canna, Skye, and Mull. In the north of Ireland it is an inmate of secondary trap-rocks.

Second Subspecies.

Radiated zeolite, *Jameson.* Strahl Zeolith, *Werner.*

External Characters.—Occurs almost always white; sometimes grey, yellow, flesh-red, and blood-red. Is found massive, in angular pieces, and globular; also in distinct concretions, which are prismatic and granular; the prismatic are broad and narrow scopiform, and stellular, and are collected into large, coarse, and small angulo-granular concretions. Frequently crystallized. Primitive figure the same as that of foliated zeolite; and it exhibits the following secondary forms:

1. Broad rectangular four-sided prism, rather acutely acuminated on both extremities by four planes, which are set on the lateral edges. 2. Sometimes No. 1. is so thin, that it may be considered as a long six-sided table, bevelled on the shorter terminal planes.

The broader lateral planes of the crystals are smooth, the smaller longitudinally streaked, and the acuminating planes smooth or rough. The surfaces of the broader lateral planes of the crystals, No. 1, 2. are splendent and pearly: the other planes shining and vitreous: internally the lustre more or less shining and pearly. Crystals strongly translucent, sometimes passing into semi-transparent. Hardness same as foliated zeolite. Brittle. Easily frangible.

Its Geognostic and Geographic Situations are the same as those of Foliated Zeolite.

8. Axifrangible Zeolite or Apophyllite, *Jameson*.—Fishaugenstein, *Werner*. Apophyllite, *Hauy*. Ichthyophthalm, *Karsten*.

Pyramid unknown. Cleavage very distinctly axifrangible. Hardness =4.5—5.0. Sp. gr. =2.2—2.5.

External Characters.—Principal colour white. Surface of the cleavage strongly iridescent. Occurs massive, and disseminated; massive varieties are composed of straight and curved lamellar distinct concretions, with feebly streaked splendent pearly surfaces. The following are the secondary forms:

1. Rectangular four-sided prism, sometimes so low as to appear tabular, and resemble a cube. The preceding figure truncated on all the angles: when the truncating planes become so large that they touch each other, the prism appears acuminated with four planes, which are set on the lateral edges, and the apex of the acumination truncated. 3. The rectangular four-sided prism, in which all the lateral edges are truncated, thus forming an eight-sided prism; sometimes the eight solid angles of this figure are truncated. 4. The rectangular four-sided prism bevelled on all the edges, or only on some of them: sometimes one of the bevelling planes is awanting, when the edge appears to be only obliquely truncated. 5. Slightly oblique four-sided prism. Formed when the truncating planes of No. 3. become so large that the original planes disappear. 6. Rectangular four-sided prism, in which the angles are truncated, and the edges bevelled. 7. Rectangular four-sided table, in which the two opposite broader terminal planes are doubly bevelled, and the two smaller planes very flatly acuminated with four planes, of which two are set on the lateral planes, the other two on the terminal planes, and the terminal edges bevelled.

Crystals very small, small, middle-sized, and very rarely large. The surface of the crystals Nos. 1, 2. and 4. is smooth; the surface of Nos. 3. and 5. and the acuminating planes of No. 7. are longitudinally furrowed; the bevelling planes of Nos. 4. 6. and 7. are transversely streaked. All the other planes of the secondary crystals are smooth. The middle point of the end of the crystals is often concave. Lateral planes occasionally bulging, and the terminal planes rose-like. Externally splendent; but only the terminal planes of the prism pearly. Fracture small and perfect conchoidal, and the lustre glistening and vitreous. Semitransparent, passing into transparent, and into translucent. Refracts single.

Chemical Characters.—It exfoliates very readily before the blowpipe, (it even exfoliates when held in the flame of a candle,) and melts easily into a white-coloured enamel.

Physical Characters.—It becomes feebly electric by rubbing.

		Apophyllite of Utön.
Const. Parts.—	Silica,	52.00
	Lime,	24.50
	Potash,	8 10
	Water,	15.00—99.60. *Rose*.

Geognostic and Geographic Situations.—It occurs in the secondary trap-rocks of the island of Skye; in rocks of the same description in the Faroe islands; in the island of Disco in West Greenland, and on the mainland of Greenland. One of the earliest known localities of this mineral is the island of Uton, not far from Stockholm, where it occurs in beds of magnetic-ironstone, along with common felspar, calcareous-spar, and hornblende.

*Wavellite, *Jameson*.

External Characters.—Colours greyish-white, greenish-white, ash-grey, asparagus-green, and sometimes spotted-brown. Occurs botryoidal, globular, stalactitic; and these forms are composed of fibrous or fine prismatic distinct concretions, which are scopiform or stellular; sometimes these prismatic concretions are collected into granular, and both are occasionally traversed by lamellar concretions. Occurs crystallized in the following figures:

1. Very oblique four-sided prism, flatly bevelled on the extremities, the bevelling planes set on the obtuse lateral edges. 2. The preceding figure very deeply truncated on the obtuse lateral edges. Cleavage prismatic. Externally shining; internally shining, passing into splendent; and lustre pearly. Translucent. Hardness =3.5—4.0. Sp. gr. 2.270, *Lucas*.—2.22, 2.253, *Gregor*.—2.25. 2.4, *Aitken*.

Chemical Characters.—It becomes opaque and soft by the action of the blowpipe, but neither decrepitates nor fuses. By the aid of heat it is soluble in the mineral acids and fixed alkalies, with effervescence, and leaves very little residue.

Constituent Parts.

Barnstaple Wavellite.		
Alumina,	71.59	70.0
Oxide of iron,	0.50	—
Lime,		1.4
Water,	28.0	26.2
	100	97.6
	Klap. Beit. b. iv. s. 110.	*Davy*, Nichol. Journ. xii. 157.

Alumina,	35.55
Phosphoric acid,	33.40
Fluoric acid,	2.06
Lime,	0.50
Iron and Manganese,	1.25
Water,	26.80
	99.36
	Berzelius.

From this analysis of Berzelius, wavellite appears to be hydrous phosphat of alumina.

Geognostic and Geographic Situations.—This mineral occurs in veins, along with fluor-spar, quartz, tinstone, and copper-pyrites, in granite, at St. Austle in Cornwall. At Barnstaple in Devonshire, where it was first found by Dr. Wavell, it traverses slate-clay in the form of small cotemporaneous veins. The Secretary of the Wernerian Society, Mr. Neill, found it in a similar situation in Corrivelan, one of the Shiant Isles, in the Hebrides.

Genus VII. FELSPAR.

Rhomboidal, pyramidal, prismatic. Imperfectly axifrangible. Hardness =5.0—6.0. Sp. gr. =2.5—2.8.

I. Rhomboidal Felspar, or Nepheline, *Jameson*. Rhomboedrischer Feldspath, *Mohs*. Nepheline, *Hauy* and *Werner*.

Di-rhomboid =152° 44′; 56° 15′. Cleavage is fourfold. Three of the cleavages are parallel with the lateral planes, and one with the terminal planes, of the six-sided prism. Hardness =6.0. Sp. gr. =2.5—2.6.

External Characters.—Colours white and grey. Occurs massive and crystallized. The secondary forms are the following:

1. Perfect equiangular six-sided prism. 2. The preceding figure, truncated on the terminal edges. 3. Thick six-sided table, in which the lateral edges are truncated.

Externally crystals splendent: internally shining, and lustre vitreous. Fracture conchoidal. Strongly translucent, passing into transparent.

Chemical Characters.—It melts with difficulty before the blowpipe into a dark glass.

Constit. Parts.—Silica,	46	
Alumina,	49	
Lime,	2	
Oxide of Iron,	1—98,	*Vauquelin.*

Geognostic and Geographic Situations.—It occurs in drusy cavities in granular limestone, along with ceylanite, vesuvian, and meionite, at Monte Somma, near Naples; also in fissures of basalt at Capo di Bove, near Rome. It is mentioned also as a production of the Isle of Bourbon.

II. Prismato-Pyramidal Felspar or Meionite, *Jameson.* Prismato-Pyramidischer Feldspath, *Mohs.* Meionite, *Hauy* and *Werner.*

Pyramid =136° 22′, 63° 22′. Cleavage in the direction of the diagonals of the prism. Hardness =5.5. Sp. gr. =2.5—2.7.

External Characters.—Colour greyish-white. Occurs sometimes massive, but more frequently crystallized. The following are the secondary figures:

1. Rectangular four-sided prism, flatly acuminated with four planes, which are set on the lateral edges. 2. The preceding figure, truncated on the lateral edges. 3. No. 1. bevelled on the lateral edges, and the edges of the bevelment truncated; and the edges between the acuminating planes and the lateral planes also truncated.

Externally crystals smooth and splendent, internally splendent and vitreous. Generally transparent or semi-transparent, seldom translucent.

Chemical Characters.—It is easily fusible before the blowpipe; intumesces during fusion, and is converted into a white vesicular glass. It has not hitherto been analysed.

Geognostic and Geographic Situations.—It occurs, along with ceylanite and nepheline, in granular limestone, at Monte Somma, near Naples. It is said also to occur in basalt, along with augite and leucite, at Capo di Bove, near Rome.

III. Prismatic or Common Felspar, *Jameson.*—Prismatischer Feldspath, *Mohs.*

Prism =120°. The most distinct cleavage is that parallel with the terminal planes of the prism; other two, less distinct, parallel with the lateral planes. Hardness =6.0. Sp. gr. =2.5—2.8.

This species is divided into nine Subspecies, viz. 1. Adularia, 2. Glassy-Felspar, 3. Ice-Spar, 4. Common Felspar, 5. Labrador Felspar, 6. Compact Felspar, 7. Clinkstone, 8. Earthy Common Felspar, and, 9. Porcelain Earth.

First Subspecies.

Adularia, *Jameson.* Adular, *Werner.*

External Characters.—Principal colour greenish-white, which sometimes passes into greyish-white and milk-white, and even inclines to asparagus-green. It is frequently iridescent; and the milk-white varieties, in thin plates, when held between the eye and the light, sometimes appear pale flesh-red. Occurs massive, and this variety is composed of granular and thick lamellar concretions; and frequently crystallized. The following are the most frequent secondary figures:

1. Oblique four-sided prism, flatly bevelled on the extremities, and the bevelling planes set on the obtuse lateral edges. 2. Broad six-sided prism, flatly bevelled on both extremities, and the bevelling planes set on the lateral edges, which are formed by the smaller lateral planes. 3. Rectangular four-sided prism, in which the terminal planes are obliquely bevelled.

Lateral planes of the prism longitudinally streaked. Externally splendent; internally cleavage splendent, and the fracture shining and glistening. Lustre intermediate between vitreous and pearly. Semi-transparent, sometimes inclining to transparent, or is translucent. Translucent varieties, when viewed in a certain direction, sometimes exhibit a silvery or pearly light. Refracts double.

Chemical Characters.—It melts before the blowpipe, without addition, into a white-coloured transparent glass.

Constituent Parts.—Silica,	64	
Alumina,	20	
Lime,	2	
Potash,	14—100.	*Vauquelin.*

Geognostic Situation.—It occurs in cotemporaneous veins in drusy cavities in granite and gneiss.

Geographic Situation.—It occurs in the granite of the island of Arran; and in the granite and gneiss rocks of Norway, Switzerland, France, and Germany.

Uses.—The variety of adularia which exhibits the bluish pearly light is valued by jewellers, and is sold by them under the name *Moonstone.* Another variety of adularia, found in Siberia, is known to jewellers under the name *Sunstone.* It is of a yellowish-grey colour, and numberless golden spots appear distributed throughout its whole substance.

Second Subspecies.

Glassy Felspar, *Jameson.* Glasiger Feldspath, *Werner.*

External Characters.—Colour greyish-white, sometimes passing into grey. Occurs always crystallized, in broad rectangular four-sided prisms, bevelled on the extremities. These crystals are often very much cracked; they are generally small, seldom middle-sized, and always imbedded. Internally splendent, and lustre vitreous. Fracture uneven, or small and imperfect conchoidal. Transparent.

Constituent Parts.—Silica,	68.0
Alumina,	15.0
Potash,	14.5
Oxide of iron,	0.5—98.0

Klaproth, Beit. b. v. s. 18.

Geognostic and Geographic Situations.—It occurs imbedded in pitchstone-porphyry in Arran and Rum; in a porphyritic rock in the Siebengebirge; also in a rock composed of white felspar, and very small blackish-brown scales of mica, and fine disseminated magnetic ironstone, in the Drachenfels on the Rhine.

Third Subspecies.

Ice-Spar, *Jameson.*—Eispath, *Werner.*

External Characters.—Colour white. Occurs massive, cellular, and porous; also in large granular concretions, which are composed of thin and straight lamellar concretions. Frequently crystallized in the form of small thin longish six-sided tables, in which the shorter terminal planes are bevelled. Externally crystals shining, and sometimes splendent; internally shining, and lustre vitreous. Massive and other varieties strongly translucent; crystals transparent.

Geognostic and Geographic Situations.—It occurs, along with nepheline, meionite, mica, and hornblende, at Monte Somma, near Naples.

Fourth Subspecies.

Common Felspar, *Jameson*.—Frischer Gemeiner Feldspath, *Werner*.

External Characters.—Most frequent colours white and red, seldom grey, and rarely green and blue. Occurs most frequently massive and disseminated, seldom in blunt angular rolled pieces and grains, and frequently in granular distinct concretions, from the smallest to the largest size; and sometimes crystallized, in the same form nearly as adularia. Internally cleavage shining, and sometimes splendent. Fracture glistening, and frequently not more than feebly glistening. Lustre intermediate between vitreous and pearly, but inclining rather more to the former than to the latter. Fracture uneven or splintery. Fragments rhomboidal, and have only four splendent shining faces. Translucent, or only translucent on the edges.

Chemical Characters.—Before the blow-pipe, it is fusible without addition into a grey semi-transparent glass.

Constituent Parts.

Siberian Green Felspar.		Flesh-red Felspar.	Felspar from Passau.
Silica,	62.83	66.75	60 25
Alumina,	17.02	17 50	22.00
Lime,	3 00	1.25	0.75
Potash,	13.00	12.00	14 00
Oxide of Iron,	1.00	0.75	a trace.
Water,			1 00
	96 85	98.25	98 00
	Vauquelin, Jour. des Mines, n. 49, p. 23.	*Rose*, in Scherer's Jour. der Chimie, b. 7. s. 244.	*Bucholz*, in Von Moll's Neue Jahrb der Berg und Huttenkunde, b 2, s. 361.

Geognostic Situation.—Felspar occurs in most of the primitive rocks; in many of the species of the transition class, and also associated with secondary and volcanic rocks.

Uses.—It is one of the ingredients in the finer kinds of earthen-ware, and is said to be the substance used by the Chinese under the name *Petunse* or *Petunze*, in the manufacture of their porcelain. The green varieties of felspar, which are rare, are considered as ornamental stones, and are cut and polished, and made into snuff-boxes, and other similar articles. When the green varieties are spotted with white, they are named *Aventurine Felspar*, and are prized by collectors.

Fifth Subspecies.

Labrador Felspar, *Jameson*.—Labradorstein, *Werner*.

External Characters.—Most frequent colours light and dark ash-grey, and smoke-grey, seldom yellowish-grey. When light falls on it in determinate directions, it exhibits a great variety of colours; of these the most frequent are blue and green, more seldom yellow and red, and the rarest variety is pearl-grey. Occurs massive, or in rolled pieces, also in large, coarse, seldom in small granular, very seldom in thick and straight lamellar concretions. Cleavage splendent, fracture glistening, and the lustre intermediate between vitreous and pearly. Translucent, but in a low degree.

Chemical Characters.—According to Mr. Kirwan, it is more infusible than common felspar.

Geognostic and Geographic Situations.—It occurs in rolled masses of syenite, in which it is associated with common hornblende, hyperstene, and magnetic ironstone, in the island of St. Paul, on the coast of Labrador, where it was first discovered, upwards of thirty years ago, by the Moravian Missionaries settled in that remote and dreary region. Since that time it has been found in Scotland, Norway, and other countries.

Uses.—On account of its beautiful colours, it is valued as an ornamental stone, and is cut into ring-stones, snuff-boxes, and other similar articles. It receives a good polish; but the streaks caused by the edges of the folia of the cleavage are frequently so prominent as to injure the appearance of the stone.

Sixth Subspecies.

Compact Felspar, *Jameson*. Dichter Feldspath, *Werner*.

External Characters.—Colours white, grey, green, and red. Occurs massive, disseminated, in blunt angular rolled pieces, and in small angulo-granular concretions; also crystallized in rectangular four-sided prisms. Crystals either middle sized, or small, and always imbedded. Internally sometimes glistening, sometimes glimmering. Fracture even and splintery. Feebly translucent, sometimes only translucent on the edges.

Chemical Characters.—Before the blowpipe it melts with difficulty into a whitish enamel.

Constituent Parts.

Compact Felspar of Salberg, in Sweden.

Silica	68.0	Silica	51.00
Alumina	19.0	Alumina	30 50
Lime	1.0	Lime	11.25
Potash	5.5	Iron	1.75
Oxide of Iron	4.0	Natron	4.00
Water	2.5—100	Water	1 26—99.75
Godon de St. Memin, Journal de Physique. t. 63. p. 60.		*Klaproth*. Chem. Abhandl. s. 264.	

Geognostic Situation.—This mineral occurs in mountain-masses, beds and veins, either pure, or intermixed with other minerals, in primitive, transition, and secondary rocks.

Geographic Situation.—The Pentland Hills contain beds of compact felspar, associated with claystone, red sandstone, and conglomerate. It occurs in a similar situation on the hill of Tinto, and in the Ochil Hills; and associated with rocks of the same nature in the Island of Papa Stour, one of the Shetland group.

Seventh Subspecies.

Clinkstone, *Jameson*. Klingstein, *Werner*. Phonolith, *Daubuisson*.

External Characters.—Colours grey, green, and brown. Occurs massive; also in granular, columnar, globular, and tabular distinct concretions. Lustre of the principal fracture glistening and pearly; that of the cross fracture faintly glimmering, almost dull. Principal fracture slaty, generally thick, and often curved slaty, with a scaly foliated aspect; the cross fracture splintery, passing into even, and flat conchoidal. Strongly translucent on the edges, sometimes even translucent. In thin plates, it emits, when struck, a ringing sound.

Chemical Characters.—It melts before the blowpipe into a grey coloured glass, but is more difficultly fusible than basalt.

Const. Parts.	Silica	57.25
	Alumina	23.50
	Lime	2.75
	Natron	8.10
	Oxide of Iron	3.25
	Oxide of manganese	0.25
	Water	3.00—98.10

Klaproth, Beit. b. iii. s. 243.

Geognostic Situation.—This subspecies of felspar generally contains imbedded crystals, when it forms the rock named Clinkstone Porphyry. It is generally associated with secondary trap and porphyry rocks.

Geographic Situation.—The Bass rock at the mouth of the Frith of Forth, North Berwick Law, Traprain Law, and the Girleton Hills, all in East Lothian, and many other hills in Scotland, contain beds and veins of this mineral.

Eighth Subspecies.

Earthy Common Felspar, *Jameson.* Aufgelöster gemeiner Feldspath, *Werner.*

External Characters.—Colours white and grey. Generally occurs massive, and disseminated, and sometimes in imbedded crystals, which agree in form with those of common felspar. Internally sometimes glistening, sometimes glimmering, or even dull. Has sometimes an imperfect cleavage. Fracture coarse and small grained uneven, which approaches to earthy. Breaks into blunt angular pieces. Either translucent on the edges, or opaque. In general, it is so soft as to yield to the nail; sometimes, however, it approaches in hardness to felspar. Sectile, and easily frangible.

The chemical characters and composition of this substance have not been ascertained

Geognostic and Geographic Situations.—It occurs in granite and gneiss districts, as in Cairngorm and Arran in Scotland, and Cornwall in England. It is well known in Saxony, and other countries.

Ninth Subspecies.

Porcelain Earth, or Kaolin, *Jameson.* Porcellanerde, *Werner.*

External Characters.—Most frequent colour reddish white, of various degrees of intensity; also snow-white and yellowish-white. Generally friable, and sometimes approaches to compact. Composed of dull dusty particles, which are feebly cohering. Soils strongly. Feels fine and soft, but meagre. Adheres slightly to the tongue. Specific gravity, 2.216, Karsten.

Chemical Characters.—It is infusible before the blowpipe.

Constituent Parts.

		Porcelain Earth from Aue in Saxony.			
Silica	46 0	Silica	52.00	Silica	55.0
Alumina	39.0	Alumina	47 00	Alumina	42.5
Oxide of Iron	0.25	Iron	0.33	Iron	1.0
Water	14 50			Lime	1.0
	97 75		99.33		99.5
Klaproth, Chem. Abhandl. s. 278.			*Rose.*		*Gehlen.*

Geognostic Situation.—It generally occurs in granite and gneiss countries, either in beds contained in the granite or gneiss, when it appears to be an original deposite, or on the sides and bottom of granite and gneiss hills, when it is certainly formed by the decomposition of the felspar of these rocks.

Geographic Situation.—It occurs in different granite and gneiss districts in Scotland, and in the Shetland Isles; also in England and Ireland, and in many places on the continent of Europe.

Uses.—This mineral forms a principal ingredient in the different kinds of porcelain. It is not used in the state in which it is found in the earth, but is previously repeatedly washed, in order to free it from impurities. After the process of washing, only fifteen parts of pure white clay remain, which is the kaolin of the Chinese. Porcelain has been manufactured in China and Japan from a very early period. The art itself was discovered in Europe, by a German named Bötticher, who made his first porcelain-vessels in Dresden, in the year 1706. These were of a brown and red colour. The white was not attempted until the year 1709; and the famous manufactory at Meissen, the earliest in Europe, was established in 1710.

4. Pyramidal Felspar, or Scapolite † *Jameson.*—Pyramidaler Feldspath, *Mohs.* Scapolit, *Werner.* Paranthine, *Hauy.*

Pyramid = 136° 28′—62° 56′. Cleavage is in the direction of the lateral planes, and of the diagonals of a rectangular four-sided prism. Hardness = 5 0—5.5. Sp. gr. = 2.5—2.8.

This species is divided into four subspecies, viz. Radiated Scapolite, Foliated Scapolite, Compact Red Scapolite, and Elaolite.

First Subspecies.

Radiated Scapolite, *Jameson.*

External Characters.—Most frequent colour grey, seldomer white and green. Occurs massive, and in distinct concretions; concretions radiated or fibrous, scopiform diverging, and are collected into others which are thick and wedge-shaped. It is most frequently crystallized. The secondary forms are the following:

1. Rectangular four sided prism, flatly acuminated on the extremities with four planes, which are set on the lateral planes. 2. The preceding figure, in which the lateral edges are truncated.

Lateral planes of the crystals deeply longitudinally streaked, and shining. Internally intermediate between shining and glistening, and the lustre intermediate between resinous and pearly. Fracture fine-grained uneven. Translucent, and semitransparent in crystals.

Chemical Characters.—Green scapolite, before the blowpipe, becomes white, and melts into a white glass.

Constituent Parts.—Silica,	. .	45.0
Alumina,	. .	33.0
Lime,	. .	17.6
Natron,	. .	1.5
Potash,	. .	0.5
Iron and Manganese,		1.0—98.6

Laugier, Annales du Museum d'Hist. Nat. cah. lx. p. 472.

Geognostic and Geographic Situations.—This mineral occurs in the neighbourhood of Arendal in Norway, where it is associated with magnetic ironstone, felspar, quartz, mica, garnet, augite, hornblende, actynolite, and calcareous-spar.

Second Subspecies.

Foliated Scapolite, *Jameson.*

External Characters.—Principal colours grey, green, and black. Occurs massive, disseminated, and in large, coarse, and long angulo-granular concretions; also crystallized in low eight-sided prisms, flatly acuminated with four planes, which are set on the alternate lateral planes. Externally crystals shining or splendent, and vitreous. Cleavage shining, fracture glistening; lustre intermediate between resinous and pearly. Generally translucent, and passes sometimes into transparent, sometimes to translucent on the edges. Yields a white streak.

Geognostic and Geographic Situations.—It occurs in Sweden, in primitive rocks.

Third Subspecies.

Compact Red Scapolite, *Jameson.* Dichter Scapolite.

External Characters.—Colour dark brick-red, passing into pale blood-red. Seldom occurs massive, more frequently crystallized, in long, frequently acicular, four-sided prisms, which are often curved, and are without terminal crystallizations. Externally crystals rough and dull. Internally very feebly glistening, almost glimmering. Fracture fine-grained uneven, approaching to splintery. Opaque, or very faintly translucent on the edges.

Geognostic and Geographic Situations.—It occurs along with the other subspecies, in metalliferous beds, at Arendal in Norway.

Fourth Subspecies.

Elaolite, *Jameson.*—Eläolith, *Klaproth.* Fettstein, *Werner.* Dichter Wernerit, *Hausmann.*

External Characters.—Colours of this mineral blue, which inclines more or less to green, also flesh-red, which falls more or less into grey, sometimes even inclines to brown. Occurs massive, and in very intimately aggregated granular concretions. Internally shining or glistening, lustre resinous. Fracture principally in the red variety, flat and imperfect conchoidal. Blue variety has an imperfect double cleavage. Translucent in a low degree. Blue variety, when cut in a particular direction, displays a peculiar opalescence, not unlike that observed in the cat's-eye. Has the same degree of hardness as the other subspecies.

Chemical Character.—When pounded, and thrown into acids, it gelatinates. Before the blowpipe it melts into a milk-white enamel.

Constituent Parts.—Silica,	.	44.00
Alumina,	.	34.00
Lime,	.	0.12
Potash and Soda,		16.50
Oxide of Iron,		4.00—98.62

Vauquelin, in Hauy's Tabl. Comparative, p. 178.

Geognostic and Geographic Situations.—The blue variety is found at Laurwig, and the red at Stavern and Friedrichwärn, both in the rock named *zircon syenite.*

Uses.—The pale-blue variety, which has often an opalescence like that of the adularia-moonstone, is cut *en cabochon*, and used for ring-stones. When set, it is difficult to distinguish it from cat's-eye.

Observations.—Few of the newer mineral species have had so many names given to them as Scapolite, as appears from the following enumeration: 1. Paranthine; 2. Wernerite; 3. Arcticite; 4. Sodaite; 5. Natrolite; 6. Fuscite; 7. Gabbronite; 8. Elaolite; 9. Fettstein; 10. Lythrodes; 11. Spreustein; 12. Bergmannite.

* Chiastolite, *Jameson.*—Hohlspath, *Werner.*

External Characters.—Colours white and grey; the white colours yellowish-white, greenish-white, greyish-white, and reddish-white; grey colours pearl-grey, greenish-grey, and yellowish-grey. Occurs always crystallized. Primitive form appears to be an oblique four-sided prism, with lateral edges of 84° 48′, and 95° 12′. The following are the secondary forms:

1. Four-sided prism, in which the lateral edges are rounded. 2. Four prisms arranged in the form of a cross.

These crystals always appear as if they had been at one time hollow, and these hollows filled up with clay-slate, the position of which varies in regard to the crystals. Cleavage double, and in the direction of the lateral planes of the prism. Lustre of the cleavage glistening, that of the fracture glimmering. Fracture splintery. Translucent. Hard. Scratches glass. Rather difficultly frangible. Sp. gr. 2.944, Hauy. 2.944, Karsten.

Chemical Characters.—It is infusible before the blowpipe, and becomes white and nearly opaque.

Its constituent parts have not as yet been ascertained.

Geognostic and Geographic Situations.—It occurs in small acicular crystals in clay-slate in Wolfscrag near Keswick, and near the summit of Skiddaw in Cumberland; also at Aghavanagh, and Baltinglas-hill, in the county of Wicklow. The largest and most beautiful crystals are found in clay-slate near to St. Brieux in Brittany; smaller crystals occur in the clay-slate of St. Jago di Compostella in Gallicia.

Observations.—Chiastolite is placed immediately after the species of the felspar genus, on account of its supposed affinity with them; but its characters are still so imperfectly known, that it cannot be arranged in any of the present genera.

** Sodalite, *Jameson.*—Sodalite, *Thomson.*

External Characters.—Colour intermediate between celandine and mountain-green. Occurs massive, and crystallized in rhomboidal or garnet dodecahedrons. Externally smooth, shining or glistening; internally longitudinal fracture vitreous, cross fracture resinous. Has a double cleavage. Fracture conchoidal. Fragments indeterminate angular, and sharp-edged. Translucent. Hard as felspar. Brittle. Easily frangible. Specific gravity=2.378.

Chemical Characters.—When heated to redness, it does not decrepitate, nor fall to powder, but becomes dark-grey; and is infusible before the blowpipe.

Const. Parts.—Silica,	.	38.52
Alumina,	.	27.58
Lime,	.	2.70
Oxide of Iron,	.	1.00
Soda,	.	25.50
Muriatic Acid,	.	3.00
Volatile Matter,	.	2.10
Loss,	.	1.70—100.00

Thomson, in Tr. R. S. of Ed. vol. vi. p. 394.

Geognostic and Geographic Situations.—It was discovered at Kanerdluarsuk, a narrow tongue of land, upwards of three miles in length, in lat. 61°, in West Greenland, by Sir Charles Giesecké. It is found in a bed from six to twelve feet thick, in mica-slate, and is associated with sahlite, augite, hornblende, and garnet.

Clay and Lithomarge Families.—The minerals included under these titles have no regular form or cleavage, and cannot therefore be connected with any of the mineral species. We place them here on account of their affinity with some of the members of the preceding genus.

* Clay Family.

In this group or family we include the following minerals, 1. Aluminite, 2. Common Clay, 3. Variegated Clay, 4. Slate-Clay, 5. Bituminous Shale, 6. Claystone, 7. Adhesive Slate, 8. Polier Slate, 9. Tripoli.

** Lithomarge Family.

The minerals of this family have many alliances with the preceding, and hence are placed immediately after them.

1. Lithomarge, 2. Mountain Soap, 3. Yellow Earth, 4. Bole.

* Clay Family.

1. Aluminite, *Jameson.*—Reine Thonerde, *Werner.*

External Characters.—Colour snow-white, which verges on yellowish-white. Occurs in small reniform pieces. Dull. Fracture fine earthy; consistence intermediate between friable and solid. Opaque. Soils slightly. Affords a glistening streak. Adheres feebly to the tongue. Passes from very soft into friable. Feels fine, but meagre.

Constituent Parts.—Alumina,	.	31.0
Water,	.	45.0
Sulphuric Acid,		21.5
Lime,	.	2.0—99.5

Bucholz.

Geognostic and Geographic Situation.—It occurs in calcareous loam in the alluvial strata around Halle in Saxony.

2. Common Clay, *Jameson.*

Under this head we include Loam and Potter's-Clay.

Loam, *Jameson.*—Leim, *Werner.*

External Characters.—Colour yellowish-grey, sometimes inclining to greenish-grey, and is spotted yellow and brown. Occurs massive. Dull, and feebly glimmering, when small scales of mica are present. Fracture coarse and small-grained uneven in the large, and in the small earthy. Soils slightly. Very easily frangible. Sectile, and the streak slightly resinous. Intermediate between friable and soft, but inclining more to the first. Adheres slightly to the tongue. Feels rather rough, and very slightly greasy, or meagre.

Geognostic and Geographic Situations.—It occurs in great beds in alluvial districts.

Uses.—The mud-houses we meet with in different countries are built of loam. The use of loam-bricks is of high antiquity; for we are told that the ancient city of Damascus, and the walls of Babylon, were built of bricks of this substance.

Potter's-Clay.—Töpferthon, *Werner.*

a. Earthy Potter's-Clay, *Jameson.*—Erdiger Töpferthon, *Werner.*

There are two kinds of this clay, viz. Earthy and Slaty.

External Characters.—Colours white and grey; very seldom mountain-green. Occurs massive; friable, approaching to solid. Internally dull, or feebly glimmering, from intermixed scales of mica. Fracture in the large coarse-grained uneven; in the small fine earthy. More or less shining in the streak. Fragments very blunt-edged. Opaque. Soils slightly. Very soft, passing into friable. Sectile. Adheres strongly to the tongue; more strongly than loam. Feels rather greasy. Becomes plastic in water.

Chemical Characters.—It is infusible.

Constituent Parts.—Silica,	.	61
Alumina,	.	27
Oxide of Iron,	.	1
Water,	.	11—100

Klaproth, Chem. Abhandl. s. 282.

Geognostic Situation.—It is a frequent mineral in alluvial districts, where it sometimes occurs in beds of considerable thickness; it has also been observed in secondary or flœtz formations.

Geographic Situation.—It occurs in many districts in England, Scotland, and Ireland.

Uses.—It is used in potteries, in the manufacture of the different kinds of earthen-ware; it is also made into bricks, tiles, crucibles, and tobacco-pipes; and is employed in improving sandy and calcareous soils.

(*b.*) Slaty Potter's-Clay, *Jameson.*—Schiefriger Töpferthon, *Werner.*

External Characters.—Most frequent colour dark smoke-grey, seldomer bluish and pearl-grey. Occurs massive. Lustre of the principal fracture glistening; cross-fracture dull. Principal fracture very imperfect slaty; cross-fracture fine earthy. Fragments often tabular. Does not adhere so strongly to the tongue as the earthy kind, but becomes more shining in the streak; feels more greasy.

Geognostic Situation.—It occurs in considerable beds in alluvial districts, along with earthy Potter's-clay.

3. Variegated Clay, *Jameson.*—Bunter Thon, *Werner.*

External Characters.—Colours white, grey, yellow, red, and brown. Occurs massive. Internally dull. Fracture coarse earthy, inclining to slaty. Fragments blunt-edged. Becomes strongly resinous in the streak, more so than the preceding kinds. Soft, inclining to friable. Sectile. Adheres pretty strongly to the tongue. Feels rather greasy.

Geognostic and Geographic Situations.—It occurs in alluvial deposites near Weirau, in Upper Lusatia.

4. Slate-Clay, *Jameson.*—Schiefer Thon, *Werner.*

External Characters.—Colours smoke and ash grey, greyish-black, and sometimes bluish and yellowish-grey, and brownish-red. Occasionally contains impressions of unknown ferns and reeds. Massive, dull, or glimmering, owing to the intermixed scales of mica. Fracture in the large more or less perfect slaty; in the small, earthy. Fragments tabular. Opaque. Intermediate between soft and very soft. Affords a dull grey-coloured streak. Easily frangible. Adheres slightly to the tongue. Feels somewhat greasy. Specific gravity, 2.636, *Karsten* —2.680 *Kirwan.*

Geognostic Situation.—It occurs in beds in all the secondary coal-formations. It passes into claystone, sandstone, and bituminous-shale, and sometimes inclines to clay-slate.

Geographic Situation.—It occurs more or less abundantly in all the coal-districts in this island.

5. Bituminous Shale, *Jameson.*—Brandschiefer, *Werner.*

External Characters.—Colour light brownish-black, which sometimes passes into blackish-brown. Occurs only massive. Internal lustre feebly glimmering. Fracture rather thin and straight slaty. Fragments tabular. Opaque. Becomes resinous in the streak, but the colour not changed. Very soft, approaching to soft. Rather sectile, and easily frangible. Feels rather greasy. Specific gravity, 1.991, 2.049, *Kirwan*, 2.060, *Karsten.*

Geognostic Situation.—It occurs principally in rocks of the coal-formation, where it frequently alternates with, and passes into, slate-clay, and also into coal.

Geographic Situation.—It occurs in all the coal districts in this island, and also in those of Bohemia, Poland, Silesia, and other countries.

6. Claystone. *Jameson.*—Thonstein, *Werner.*

External Characters.—Colours grey, white, blue, and red. Sometimes veined, spotted, and striped. Occurs massive. Internally dull, when it does not contain accidentally mixed glimmering particles. Fracture fine earthy, but sometimes passes to fine-grained uneven, and even inclines to slaty and conchoidal. Opaque. Semi-hard, sometimes soft, and even very soft. Specific gravity, 2.210 *Karsten.*

Geognostic Situation.—It occurs in beds, along with porphyry; also forming the basis of clay porphyry, in beds, along with black coal, and as a constituent of some kinds of tuff.

Geographic Situation.—It occurs along with secondary porphyry in the Pentland Hills; in a similar situation in the island of Arran; on the mountains of Tinto; in the Ochil Hills; and in many other places of Scotland.

Uses.—When of sufficient hardness, it is used as a building-stone; also for lintels and door-posts, and can be formed into water-troughs. It forms an indifferent paving-stone.

7. Adhesive Slate *Jameson.*—Klebschiefer, *Werner.*

External Characters.—Colours grey and white. Massive. Dull. Fractur. straight slaty; thick or thin slaty. Fragments tabular. Soft, passing into very soft. Sectile. Feels somewhat greasy. Adheres strongly to the tongue. Specific gravity, 2.080, *Klaproth.*

Chemical Character.—Infusible before the blowpipe.

Constit. Parts.—	Silica,	58.0
	Alumina,	5.0
	Magnesia,	6.5
	Lime,	1.5
	Iron and Manganese,	9.0
	Water,	19.9—100.

Bucholz.

Geognostic Situation.—It occurs in beds in secondary gypsum, and contains imbedded menilite.

Geographic Situation.—It has hitherto been found only in the gypsum formation around Paris.

8. Polier. or Polishing Slate, *Jameson.*—Polierschiefer, *Werner.*

External Characters.—Colours white, grey, brown, and yellow. Occurs massive. Dull. Principal fracture straight and thin slaty; cross fracture fine earthy. Opaque. Soils slightly. Very soft, passing into friable. Uncommonly easily frangible. Feels fine, but meagre. Specific gravity, 0.590—0.606, *Haberle.*

Constituent Parts.	Silica,	79.0
	Alumina,	1 00
	Lime,	1.00
	Oxide of iron,	4.00
	Water,	14.00—99.00

Bucholz, in Journ. fur d. Chemie et Physik, b. ii. s. 28.

Geognostic and Geographic Situations.—It forms a bed in the neighbourhood of rocks of the coal-formation, at Planitz in Saxony.

IX. Tripoli, *Jameson.* Tripel, Werner.

External Characters.—Colours grey, white, and yellow. Occurs massive, and in whole beds. Dull. Fracture sometimes fine, sometimes coarse earthy, and in the great inclines to slaty. Opaque. Soft, sometimes passing into very soft. Not very brittle, and rather easily frangible. Feels meagre, and rather rough. Does not adhere to the tongue. Specific gravity 2.202, *Bucholz.*

Chemical Character. It is infusible before the blowpipe.

		Rottenstone.
Constituent Parts.	Silica,	4
	Alumina,	86
	Carbon,	10—100

Phillips.

Geognostic Situation. It occurs in beds in coal-fields; also in beds along with secondary limestone, and alternating with clay, under basalt.

Geographic Situation. It is found at Bakewell in Derbyshire, where it is named *Rottenstone*, and in many other parts of the world

Uses. On account of the hardness of its particles, it is used for polishing stones, metals, and glasses.

** Lithomarge Family.

I. Lithomarge. *Jameson.*—Steinmark, *Werner.*

External Characters—Colours white, grey, blue, and yellow. Occurs massive, disseminated, and globular or amygdaloidal. Dull. Fracture fine earthy in the small, and large conchoidal, and sometimes even, in the great. Fragments indeterminate angular, and rather blunt-edged. Opaque. Becomes shining in the streak. Very soft, sectile, and easily frangible. Adheres strongly to the tongue. Feels fine and greasy. Specific gravity, 2 419. *Kopp.*—2.435 —2.492, *Breithaupt.*

Geognostic and Geographic Situations. It occurs in veins in porphyry, gneiss, greywacke, and serpentine:

in drusy cavities in topaz-rock; or nidular, in basalt, amygdaloid, and serpentine; and it is said also in beds, in a coal-formation. It is found in Scotland, England, Germany, &c.

II. Mountain Soap, *Jameson*. Bergseife. *Werner*.

External Characters.—Colour pale brownish-black. Occurs massive. Dull. Fracture fine earthy. Fragments indeterminate angular. Opaque. Becomes shining in the streak. Writes, but does not soil. Very soft, and perfectly sectile. Easily frangible. Adheres strongly to the tongue. Feels very greasy. Light, bordering on rather heavy.

Geognostic and Geographic Situations. It occurs in trap-rocks in the island of Skye.

Use.—It is valued by painters as a crayon.

III. Yellow Earth. *Jameson*. Gelberde, *Werner*. Argile ocreuse jaune graphique, *Hauy*.

External Characters.—Colour ochre-yellow, of different degrees of intensity. Occurs massive. Dull on the cross fracture, but glimmering on the principal fracture. Fracture in the large inclines to slaty; in the small, it is earthy. Fragments tabular, or indeterminate angular. Becomes somewhat shining in the streak. Opaque. Soils and writes slightly. Very soft, passing into friable. Easily frangible. Adheres pretty strongly to the tongue. Feels rather greasy. Specific gravity, 2.240, *Breithaupt*.

Geognostic and Geographic Situations.—It is found at Wehraw, in Upper Lusatia, where it is associated with clay, and clay ironstone.

Uses.—It may be employed as a yellow pigment; and when burnt, it is sold by the Dutch under the name of *English red*. The remains in Pompeii show that it was used as a pigment, both in its yellow and red state, by the ancient Romans. It appears to have been known to Theophrastus as a yellow pigment.

VI. Bole* *Jameson*. Bol, *Werner*.

External Characters.—Colours brown, yellow, and very rarely pale flesh-red, and brownish-black. Sometimes spotted and dendritic. Massive, and disseminated. Internally lustre glimmering, and very rarely dull. Fracture perfect conchoidal. Red variety feebly translucent, the yellow translucent on the edges, and the brown and the black opaque. Very soft, approaching to soft. Rather sectile, and very easily frangible. Feels greasy. Becomes shining and resinous in the streak. Adheres to the tongue. Specific gravity, 1.922, *Karsten*.—From 1 4 to 2 00, *Kirwan*. 1.777, 2.051, *Breithaupt*.

Chemical Characters. When immersed in water, it breaks in pieces with an audible noise, with the evolution of air-bubbles, and falls into powder. Before the blowpipe, it melts into a greenish-grey coloured slag.

Geognostic Situation. The geognostic situation of this mineral is rather circumscribed, it having been hitherto observed only in secondary or flœtz trap-rocks, principally in trap-tuff, wacke, and basalt, in which it occurs in angular pieces, and disseminated.

Geographic Situation. It is found at Strigau in Silesia, and in other places.

Uses.—It was formerly an article of the Materia Medica, and used as an astringent, and in some places is still employed in veterinary practice. It is said that tobacco-pipes are sometimes made of bole, and that it is an ingredient in the glaze of some kinds of earthen ware.

Genus VIII. AUGITE.

Prismatic. Hardness = 4.5,—7. If above 6, the Sp. gr. = 3.2 and more. Sp. gr. = 2 7—3.5. Below 3.2 is easily cleavable according to an oblique prism. No metallic pearly lustre.

This genus contains four species, viz. 1. Oblique-edged Augite. 2. Straight-edged Augite. 3. Prismatoidal Augite 4. Prismatic augite.

I. Oblique-edged Augite, *Jameson*.—Schiefkantiger Augit, *Mohs*.

Prism = 92° 18′. Cleavage indeterminate diagonal. Hardness = 5.0—6.0. Sp. gr. = 3.2 —3.5.

This species contains seven subspecies, viz. Foliated Augite, Granular Augite, Conchoidal Augite, Common Augite, Coccolite, Diopside, and Sahlite.

First Subspecies.

Foliated Augite, *Jameson*.—Blættriger Augit, *Werner*.

External Characters.—Colours black and green. Crystallized in six-sided prisms, bevelled on the extremities, and also in twin crystals. Internally it is shining, inclining to splendent, and the lustre resino-vitreous. Fracture conchoidal. Opaque, or translucent on the edges.

Chemical Characters.—Fusible with difficulty into a black enamel.

		From Ætna.
Constituent Parts.—	Silica, . .	52 00
	Alumina, . .	3.33
	Magnesia, .	10.00
	Lime, . .	13.20
	Oxide of Iron,	14.66
	Oxide of Manganese,	2 00—95.19

Vauquelin, Journ. de Min. N. 39. p. 176.

Geographic Situation.—Occurs only in secondary trap-rocks, and in lava.

Geographic Situation.—It is found in basalt in different districts in Scotland, and abundantly on the continent.

Second Subspecies.

Granular Augite, *Jameson*.—Körniger Augit, *Werner*.

External Characters.—Colour greenish-black. Occurs massive, in coarse and small angulo-granular concretions. Also crystallized in broad six-sided prisms, bevelled or acuminated on the extremities. Surface rough and glistening. Internally glistening and resinous. Fracture uneven. Opaque.

Geognostic and Geographic Situations.—This subspecies of augite has been hitherto found only in primitive rocks at Arendal in Norway, in several of the iron-mines, particularly that named Ulve-Grube.

Third Subspecies.

Conchoidal Augite, *Jameson*.—Muschlicher Augit, *Werner*

External Characters.—Colours black, green, and sometimes even liver-brown. Occurs in imbedded grains. Lustre splendent, and resino-vitreous. Fracture imperfect, and flat conchoidal. Translucent on the edges, or translucent. Agrees in its other characters with the foregoing subspecies.

Geognostic and Geographic Situations.—It occurs only in secondary trap-rocks, and is the rarest of the subspecies of this species. The finest specimens, from two to three inches in diameter, are found in the vesicular basalt of Fulda.

Fourth Subspecies.

Common Augite, *Jameson*. Gemeiner Augit, *Werner*.

External Characters.—Colours blackish-green and velvet-black. Occurs in large and small imbedded grains. Internally its lustre is intermediate between shining and glistening, and is resinous. Fracture coarse, and small-grained uneven. Sometimes inclining to imperfect conchoidal. Translucent on the edges, seldom translucent. Its other characters agree with the foliated subspecies.

Geognostic and Geographic Situations.—It occurs principally in secondary trap-rocks, as basalt and greenstone, and also in lavas. The secondary trap-rocks of France, Germany, and Britain, and the lavas of Vesuvius and Iceland, in many cases abound with this mineral.

Fifth Subspecies.

Coccolite, *Jameson*.—Kokkolith, *Werner*.

External Characters.—Colour green. Occurs massive, also in granular concretions. Sometimes crystallized in the same form as the other subspecies. Internally shining, sometimes approaching to glistening, and lustre vitreous, inclining to resinous. Fracture uneven. Translucent, or translucent on the edges.

Geognostic Situation.—It occurs in mineral beds subordinate to the primitive trap formation, where it is associated with granular limestone, garnet, and magnetic iron-ore.

Geographic Situation.—It occurs at Arendal in Norway; in the iron mines of Hellsta and Assebro in Sudermanland; and in many places in Nericke, in Sweden.

Sixth Subspecies.

Diopside, *Jameson*.—Diopsid, *Werner*.

External Characters.—Colours greenish-white, greenish-grey, and pale mountain-green. Occurs massive, disseminated, in lamellar concretions, which sometimes approach to prismatic; and crystallized in low, oblique four-sided prisms, and also in six and eight-sided prisms. Externally shining, glistening, and pearly; internally shining and vitreous. Fracture uneven, sometimes inclining to imperfect and small conchoidal. Translucent.

Geognostic and Geographic Situations.—It is found in the hill of Ciarmetta in Piedmont; also in the Black Rock at Mussa, near the town of Ala, in veins, along with epidote or pistacite, and hyacinth-red garnets; and in the same district, in a vein traversing serpentine, along with prehnite, calcareous-spar, and iron-glance or specular iron-ore.

Seventh Subspecies.

Sahlite, *Jameson*.—Sahlit, *Werner*.

External Characters.—Colour green. Occurs massive, and in straight lameller and coarse granular concretions; also crystallized in four-sided prisms. Internally the lustre of the principal fracture is shining, splendent and vitreous; that of the cross fracture dull. Fracture uneven. Translucent on the edges.

Geognostic and Geographic Situations.—It occurs in the island of Unst in Shetland; in granular limestone in the island of Tirec, one of the Hebrides; in limestone in Glen Tilt; in Rannoch; in the silver mines of Sala, in Westmanland in Sweden, associated with asbestous actynolite, calcareous-spar, iron-pyrites, and galena; near Arendal in Norway, along with magnetic iron-ore, common hornblende, calcareous-spar, and seldom with felspar and black mica. Some of the varieties of asbestus and actynolite of authors belong to augite, particularly those varieties met with in secondary trap rocks.

2. Straight-Edged Augite, *Jameson*.—Rechtkantiger Augit, *Mohs*.

Prism = 124° 34′. Cleavage indeterminate diagonal. Hardness = 5.0—6.0. Sp. gr. = 2.7—3.2.

This species contains five subspecies, viz. Carinthin, Hornblende, Actynolite, Tremolite, and Asbestus.

First Subspecies.

Carinthin, *Jameson*.—Karinthin, *Werner*.

External Characters.—Colour black. Occurs massive and disseminated; and the massive varieties in coarse granular concretions. Internally splendent, and lustre resino-vitreous. Fracture conchoidal. Greenish-black varieties are strongly translucent on the edges, but the velvet-black opaque.

Geognostic and Geographic Situation.—It occurs in the Saualpe in Carinthia, in a bed in primitive rock, associated with quartz, kyanite, garnet, and zoisite.

Second Subspecies.

Hornblende, *Jameson*.—Hornblende, *Werner*.

This species is divided into three kinds, viz. Common Hornblende, Hornblende-Slate, and Basaltic Hornblende.

First Kind.—Common Hornblende, *Jameson*.—Gemeiner Hornblende, *Werner*.

External Characters.—Colours black and green. Occurs massive, disseminated, and in granular concretions. Rarely crystallized in oblique four-sided prisms, and also in six-sided prisms. Internally the lustre is shining and pearly. Fracture coarse and small grained uneven. Black coloured varieties opaque, but the green generally translucent on the edges. Yields a mountain-green, inclining to a greenish-grey coloured streak. When breathed on or moistened, even when brought from a colder to a warmer place, it yields what is called a bitter smell.

Chemical Characters.—It melts before the blowpipe, with violent ebullition, into greyish-black coloured glass.

Common Hornblende from Nora in Westmanland.

Const. Parts.—	Silica,	42.00	
	Alumina,	12.00	
	Lime,	11.00	
	Magnesia,	2.25	
	Oxide of Iron,	30.00	
	Ferruginous manganese,	0.25	
	Water,	0.75	
	Trace of Potash,		98.25

Klaproth, Beit. b. v. s. 153.

Geognostic Situation.—It occurs in great abundance in primitive rocks, and also in some rocks of the secondary class.

Geographic Situation.—It occurs very abundantly in Scotland, in greenstone and syenite; and imbedded in limestone, gneiss, and mica-slate. It is found in similar rocks in England; and plentifully in the primitive traprocks of Ireland.

Second Kind.—Horneblende-Slate, *Jameson*.—Hornblende Schiefer *Werner*.

External Characters.—Colour green. Occurs massive, and in thin promiscuous prismatic concretions. Internally glistening, passing into shining and pearly. Fracture straight slaty. Opaque. Yields a greenish-grey coloured streak.

Geognostic Situation.—It occurs in beds, in granite, gneiss, mica-slate, quartz-rock, sometimes also in clay-slate, and frequently along with beds of primitive limestone.

Geographic Situations.—In Scotland, it occurs in gneiss, in the districts of Braemar and Aberdeen, in Aberdeenshire; in Banffshire, as near Portsoy; in Argyleshire, as in the islands of Coll, Tiree, &c.; in Inverness-shire, as in the islands of Rona, Lewis, &c.; and in many other parts in Scotland; and also in England and Ireland.

Third Kind.—BASALTIC HORNBLENDE, *Jameson.*—Basaltische Hornblende, *Werner.*

External Characters.—Colour black. Occurs crystallized, in six-sided prisms, variously modified. Lustre of cleavage splendent and vitreous, approaching to pearly; that of the cross fracture glistening. Fracture small-grained uneven, approaching to conchoidal. Opaque. Rather harder than common hornblende. Affords a dark greyish-white streak.

Geognostic and Geographic Situation.—It occurs imbedded in trap-rocks in Scotland, and other countries.

THIRD SUBSPECIES.

ACTYNOLITE, *Jameson.*—Strahlstein, *Werner.*

This subspecies is divided into three kinds, viz. Asbestous Actynolite, Common Actynolite, and Glassy Actynolite.

First Kind.—ASBESTOUS ACTYNOLITE, *Jameson.*—Asbestartiger Strahlstein, *Werner.*

External Characters.—Colours grey, green, blue, and brown. Occurs massive, in distinct concretions, which are fibrous, and sometimes collected into others which are wedge-shaped and granular. Rarely occurs crystallized, in delicate capillary, rigid, moss-like, superimposed crystals. Internally the lustre is glistening and pearly. Opaque, or slightly translucent on the edges. Fibres or concretions in groups are soft, but individually equally hard with the other varieties of actynolite.

Geognostic Situation.—It occurs in beds in gneiss, mica-slate, and granular limestone.

Geographic Situation.—In Scotland, also in Norway, Sweden, &c.

Second Kind.—COMMON ACTYNOLITE.—*Jameson.*—Gemeiner Strahlstein, *Werner.*

External Characters.—Colour green. Occurs massive and disseminated; also in wedge-shaped prismatic concretions, which are scopiform, stellular, and promiscuous; these sometimes pass into angulo-granular concretions. Frequently the prismatic concretions are collected into large granular concretions. Internally shining, inclining to glistening, and pearly inclining to vitreous. Fracture uneven and conchoidal. Generally translucent on the edges.

Geognostic Situation.—It occurs in beds in gneiss, mica-slate, and talc-slate.

Geographic Situation.—It occurs at Eilan Reach in Glenelg, in Inverness-shire; near Fortrose in Cromarty; in the parish of Sleat, in the isle of Skye; different places in the isle of Lewis.

Third Kind.—GLASSY ACTYNOLITE, *Jameson.*—Glasartiger Strahlstein, *Werner.*

External Characters.—Colour green. Occurs massive: also in prismatic distinct concretions, which are fibrous, or radiated, arranged in a scopiform, and rarely in a promiscuous manner; and these are again collected into wedge-shaped prismatic or granular concretions. Internally shining, sometimes splendent, and intermediate between vitreous and pearly. Translucent or semi-transparent. Brittle. Uncommonly easily frangible. Traversed by numerous parallel rents.

Geognostic and Geographic Situations.—It occurs in primitive rocks in the isle of Skye, and other parts of Scotland.

FOURTH SUBSPECIES.

TREMOLITE, *Jameson.*—Tremolith, *Werner.*

This subspecies is divided into three kinds, viz. Asbestous Tremolite, Common Tremolite, and Glassy Tremolite.

First Kind.—ASBESTOUS TREMOLITE, *Jameson.* Asbestartiger Tremolit, *Werner.*

External Characters.—Most common colour greyish-white; it is also yellowish-white, greenish-white, rarely reddish-white, and pale violet blue. Occurs massive; also in fibrous or very thin prismatic distinct concretions. Internally shining, approaching to glistening, and pearly. Translucent on the edges. Rather easily frangible.

Geognostic Situation.—It occurs most frequently in granular foliated limestone, or in dolomite; sometimes in chlorite; and more rarely in secondary trap-rocks.

Geographic Situation.—It occurs in foliated granular limestone in Glen Tilt, in Perthshire, and in Glen Elg in Inverness-shire; in dolomite in Aberdeenshire and Icolmkill; in the Shetland Islands; and in basalt in the Castle Rock of Edinburgh.

Second Kind.—COMMON TREMOLITE, *Jameson.*—Gemeiner Tremolit, *Werner.*

External Characters.—Most frequent colour white, seldom grey, pale asparagus-green, and blue. Occurs massive; also in distinct concretions, which are prismatic, and these are collected into longish granular concretions. Sometimes crystallized in oblique four-sided prisms. Lustre shining, and intermediate between vitreous and pearly. Fracture uneven or conchoidal. Translucent or semi-transparent. Rather brittle. Easily frangible. Powder rough to the feel.

Geognostic Situation.—Like the asbestous subspecies occurs principally in granular limestone, or dolomite, and in metalliferous beds.

Geographic Situation.—It occurs in Glen Tilt, Glen Elg, and in the Shetland Islands; also at Clicker Tor in Cornwall.

Third Kind.—GLASSY TREMOLITE, *Jameson.*—Glasartiger Tremolith, *Werner.*

External Characters.—Colour white. Occurs massive; also in distinct concretions, which are straight and scopiform prismatic, with numerous cross rents, and these are again grouped into thick and wedge-shaped concretions. Frequently crystallized in long acicular crystals. Lustre shining, but in a lower degree than the preceding subspecies, and intermediate between vitreous and pearly. Translucent.

Geognostic Situation.—It is the same as that of the preceding subspecies, occurring principally along with granular limestone.

Geographic Situation.—In Scotland it occurs along with the other kinds.

FIFTH SUBSPECIES.

ASBESTUS, *Jameson.* Asbest, *Werner.*

This subspecies is divided into four kinds, viz. Rock-Cork, Amianthus, Common Asbestus, and Rock-wood.

First Kind. ROCK-CORK, *Jameson.* Berg Cork, *Werner.*

External Characters.—Colours white, grey, and yellow. Occurs massive, in plates that vary in thickness, corroded, and with impressions; and these forms are composed of delicate and promiscuous fibrous concretions. Internally feebly glimmering, or dull. Fracture fine grained uneven, inclining to slaty in the large. Opaque. Very soft. Becomes shining in the streak. Sectile, almost like common cork. Slightly elastic flexible. Difficultly frangible. Adheres slightly to the tongue. Emits a grating sound when we handle it. Feels meagre. So light as to swim on water. Specific gravity, 0.679, 0.991, *Brisson.*—0.991, *Hauy.*

Chemical Characters.—It melts with great difficulty before the blowpipe into a milk-white nearly translucent glass.

Geognostic Situation.—It occurs in cotemporaneous veins in serpentine, and in red sandstone; also in metalliferous veins in primitive and transition rocks; and occasionally in mineral beds.

Geographic Situation.—It occurs in veins in the serpentine of Portsoy, and in the red sandstone of Kincardineshire; in plates, in the lead-veins at Lead Hills and Wanlockhead in Lanarkshire; and in small quantities at Kildrummie in Aberdeenshire.

Second Kind. AMIANTHUS, or FLEXIBLE ASBESTUS, *Jameson.* Amiant, *Werner.*

External Characters.—Colours white, grey, blue, and green. Sometimes blood red, particularly when it occurs in veins in serpentine. Occurs in fibrous distinct concretions. Internally lustre shining and pearly. Translucent on the edges, or opaque. Very soft. Perfectly flexible.

Geognostic Situation.—It occurs frequently along with common asbestus, in cotemporaneous veins in serpentine.

Geographic Situation.—It occurs in serpentine in the islands of Mainland, Unst, and Fetlar in Shetland; and in the same rock at Portsoy.

Uses.—This mineral, on account of its flexibility, and its resisting the action of considerable degrees of heat, was woven into those incombustible cloths, in which the ancients sometimes wrapped the bodies of persons of distinction before they were placed on the funeral pile, that their ashes might be collected free from admixture.

Third Kind. COMMON ASBESTUS, *Jameson.* Gemeiner Asbest, *Werner.*

External Characters.—Colours dark leek-green, and mountain-green; also greenish-grey and yellowish-grey. Occurs massive; and in fibrous distinct concretions. Internally glistening and pearly. Fracture not visible. Translucent, or only translucent on the edges. Soft, approaching to very soft. Rigid or inflexible. Rather brittle. Difficultly frangible. Feels rather greasy. Specific gravity, 2.000, *Karsten.*—2.542, *Kirwan.*—2.591, *Breithaupt.*

Geognostic Situation.—Like amianthus, it occurs in veins in serpentine, and in primitive greenstone.

Geographic Situation.—It occurs in the serpentine of Shetland, Long Island, Portsoy, Anglesey, and Cornwall.

Fourth Kind. ROCK WOOD, or LIGNEOUS ASBESTUS, *Jameson.*—Bergholz, *Werner.*

External Characters.—Colour wood-brown, of various degrees of intensity. Occurs massive, and in plates; also in delicate and promiscuous fibrous concretions. Internally lustre glimmering. Fracture curved slaty. Becomes shining in the streak. Soft, passing into very soft. Opaque. Sectile. Specific gravity, before immersion, 1.534; after immersion, 2.225, *Breithaupt.*

Chemical Characters.—Is infusible before the blowpipe.

Geognostic and Geographic Situations.—It occurs at Sterzing in the Tyrol, in primitive rocks.

3. PRISMATOIDAL AUGITE, *Jameson.* Prismatoidischer Augit, *Mohs.*

Prism =114° 37′. Cleavage sometimes prismatoidal. Hardness =60.70. Specific gravity =3.2,—3.5.

This species contains two subspecies, viz. Epidote and Zoisite.

FIRST SUBSPECIES.

EPIDOTE or PISTACITE, *Jameson.* Epidote, *Hauy.* Pistazit, *Werner.*

External Characters.—Colours green and black. Occurs massive; also in distinct concretions, which are granular and fibrous, which latter are collected into wedge-shaped prismatic concretions. Frequently crystallized in oblique four-sided, and also in six-sided prisms. Externally the lustre alternates from splendent to glistening, and is vitreous; internally it is shining or glistening, and is resinous, inclining to pearly. Fracture conchoidal, sometimes uneven, sometimes even or splintery. Alternates from translucent to translucent on the edges, and to nearly transparent.

Chemical Characters.—Before the blowpipe it is converted into a brown-coloured scoria, which blackens by continuance of the heat.

		Epidote from the Valais.
Constituent Parts.—	Silica . .	37.0
	Alumina .	26.0
	Lime . .	20.0
	Oxide of iron .	13.0
	Oxide of manganese	0.6
	Water . .	1.8
	Loss . .	1.0—100.0

Geognostic Situation.—Occurs in beds and veins, and sometimes as an accidental constituent part of rocks.

Geographic Situation.—In Arran it occurs in syenite and clay-slate; in Mainland in Shetland in syenite, and in other districts in Scotland.

SECOND SUBSPECIES.

ZOISITE, *Jameson.*

This subspecies is divided into two kinds, viz. Common Zoisite and Friable Zoisite.

First Kind.—COMMON ZOISITE, *Jameson.* Zoisite, *Werner.*

External Characters.—Colour grey. Occurs massive; also in large prismatic distinct concretions. Internally it is shining on the cleavage, and glistening on the fracture surface, and the lustre is resino-pearly. Fracture small-grained uneven. Feebly translucent, or only translucent on the edges.

Geognostic and Geographic Situations.—It was first observed in the Saualp in Carinthia; and we have it from Glen Elg in Inverness-shire, and from Shetland.

Second Kind.—Friable Zoisite, *Jameson.* Mürber Zoisit, Karsten.

External Characters.—Colour reddish white, which is spotted with pale peach-blossom red. Massive, and in very fine loosely aggregated granular concretions. Very feebly glimmering. Fracture intermediate between earthy and splintery. Translucent on the edges.

Geognostic and Geographic Situations.—It occurs imbedded in green talk at Radelgraben in Carinthia.

4. Prismatic Augite, or Tabular Spar, *Jameson.* Prismatischer Augitspath, *Mohs.* Schaalstein, *Werner.* Tafelspath, *Karsten.*

Prism =105°. Cleavage indeterminate diagonal. Hardness =4.5—5.0. Sp. gr. =2.7—2.9.

External Characters.—Colour white. Occurs massive, and coarsely disseminated; also in granular and lamellar distinct concretions. Internally the lustre varies from shining to glistening, and is pearly inclining to vitreous. Fracture splintery. Translucent. Brittle, and easily frangible.

Constituent Parts.—Silica,	. . .	50
Lime,	. . .	45
Water,	. . .	5—100

Klaproth, Beit. b. iii. s. 291.

Geognostic and Geographic Situations.—Europe. It occurs in primitive rocks at Orawicza in the Bannat of Temeswar, where it is associated with brown garnets, blue-coloured calcareous-spar, tremolite, actynolite, and variegated copper-ore.

Asia.—It has been lately discovered in the island of Ceylon, associated with cinnamon-stone, in gneiss.

Genus IX. AZURE-SPAR.

Lazur Spath, *Mohs.*

Three axes. Cleavage prismatic and prismatoidal. Blue. Hardness=5,0.0—6.5. Sp. gr.=2.7—3.1.

This genus contains four species, viz. Prismatic Azure-spar, Prismatoidal Azure spar, Dodecahedral Azure-spar, and Calaite.

1. Prismatic Azure-Spar, *Jameson.*—Prismatischer Lazur Spath, *Mohs.*

Pyramid unknown. Cleavage prismatic. Lively Blue colour. Hardness=5.0—5.5. This species contains two subspecies, viz. Azurite and Häuyne.

First Subspecies.

Azurite, *Jameson.*—Lazulit, *Werner.*

External Characters.—Colour blue. Occurs in small massive portions, disseminated, and crystallized in very oblique four-sided prisms, which are rather flatly acuminated on the extremities, with four planes, which are set on the lateral edges. Fracture uneven. Opaque, or very feebly translucent on the edges.

Geognostic Situation.—It occurs imbedded in small portions in quartz: also in fissures in clay-slate, along with sparry-iron. heavy-spar, and quartz.

Geographic Situation.—It occurs principally in the district of Vorau in Stiria.

Second Subspecies.

Hauyne, *Jameson.*—Hauyn. *Karsten.*

External Characters.—Colour blue. Occurs in imbedded grains; rarely crystallized. Externally and internally alternates from splendent to glistening, and lustre vitreous. Has a quintuple cleavage. Fracture imperfect conchoidal. Transparent and translucent. Brittle. Very easily frangible. Scratches glass. Sp. gr. 2.687.

Geognostic and Geographic Situations.—It occurs imbedded in the basalt rocks of Albano and Frascati, along with mica, augite, leucite, and vesuvian; also in the basalt of Andernach.

2. Prismatoidal Azure-Spar, or Blue Spar, *Jameson.*—Prismatoidischer Lazur Spath, *Mohs.* Blauspath, *Werner.*

Pyramid unknown. Cleavage prismatoidal. Pale colours. Hardness=5.5—6.0.

External Characters.—Colour pale smalt-blue, which sometimes passes into sky-blue, and occasionally into milk-white. Occurs massive and disseminated. Internally glistening, approaching to shining. Fracture splintery. Translucent in a low degree. Yields a greyish-white coloured streak.

Chemical Characters.—Before the blowpipe it becomes white and opaque; and affords a black-coloured glass with borax.

Constituent Parts.—Silica,	. .	14.00
Alumina,	.	71.00
Magnesia,	.	5.00
Lime,	. .	3.00
Potash,	. .	0.26
Oxide of Iron,		0.75
Water,	. .	5.00—99.00

Klaproth, Beit. b. iv. s. 85.

Geognostic and Geographic Situations.—It occurs along with quartz, mica, and garnets, in the valley of Murz, near Krieglach, in Stiria.

3. Dodecahedral Azure-Spar or Lapis Lazuli, *Jameson.*—Lasursstein, *Werner.*

Tessular. Dodecahedral. Azure blue. Hardness=5.5—6.0. Sp. gr.=2 95.

External Characters.—Colour azure-blue, of all degrees of intensity. Found massive, disseminated, in rolled pieces, and in rhomboidal dodecahedrons. Internally either glistening or glimmering. Fracture uneven. Feebly translucent on the edges.

Constit. Parts.—Silica,	. . .	46.00
Alumina,	. .	14.50
Carbonate of Lime,	.	28.00
Sulphate of Lime,	.	5.50
Oxide of Iron,	.	3.00
Water,	. . .	2.00—100

Klaproth, b. i. s. 196.

Geognostic and Geographic Situations.—It occurs in primitive limestone, along with iron-pyrites, in Persia, Tartary, and China; in veins that traverse granite, along with quartz, mica, and iron-pyrites, in the Altain mountains; and at the southern end of the Lake Baikal in Siberia, in a vein, associated with garnets, mica, felspar, and iron-pyrites.

Uses.—On account of its beautiful blue colour, and the fine polish it is capable of receiving, it is much prized by lapidaries, and is cut into various ornamental articles. It is highly valued by painters, on account of the fine ultramarine blue colour obtained from it.

4. Calaite, or Mineral Turquois, *Jameson and Fischer.*

External Characters.—Colours blue and green. Occurs massive, disseminated, reniform, and botryoidal. Internally dull, or feebly glistening and resinous. Fracture imperfect conchoidal, or coarse-grained unoven. Opaque. Harder than felspar, but softer than quartz. Streak white. Specific gravity 2.860, 3.0, *Fischer*.

Constituent Parts.—Alumina,	. .	73
Oxide of Copper,		4.50
Water,	. .	18
Oxide of Iron,	.	4.
Loss,	. .	0.50—100.

John, in Fischer's Essai sur la Turquoise, p. 27.

Geognostic Situation.—It occurs in veins in clay ironstone, and also in small pieces in alluvial clay.

Geographic Situation.—It has hitherto been found only in the neighbourhood of Nichabour in the Khorasan in Persia.

Uses.—It is very highly prized as an ornamental stone in Persia and the neighbouring countries.

Order VI.—GEM.

No metallic lustre. Streak white. Hardness ranges from 5.5 to 10.0. At and below 6, the specific gravity is equal to 2.4 and less, and amorphous. The specific gravity ranges from 1.9 to 4.7.

Genus I.—BORACITE.

Many axes. Cleavage tessular. Hardness=7.0. Sp. gr.=2.8—3.0.

I. Hexahedral Boracite, *Jameson.*—Boracite, *Werner.*—Hexaedrischer Boracit, *Mohs.*

Tessular. Cleavage octahedral.

External Characters.—Colours white and grey. Occurs crystallized, in cubes, rhomboidal dodecahedrons, and tetrahedrons. Internally shining and adamantine. Fracture imperfect conchoidal. Translucent, and rarely transparent.

Physical Characters.—It is pyro-electric on all the angles, those that are diagonally opposite, being the one positive, and the other negative. This electricity is uncommonly easily excited, even more so than in tourmaline, or indeed in any other mineral with which we are acquainted.

Chemical Characters.—Fusible with ebullition into a yellowish enamel.

	From Segeberg.	From Luneberg.
Const. Parts.—Magnesia,	36.3	16.6
Boracic Acid,	63.7—100	83.4—100.0
	Pfaff.	*Vauquelin.*

Geognostic and Geographic Situations.—This curious mineral has been hitherto found only in the Kalkberg, at Luneberg in Hanover, where it occurs in a particular bed of gypsum, along with imbedded quartz crystals; and in the same formation, in the Segeberg, near Kiel in Holstein.

Genus II.—ANDALUSITE.

Three axes. Cleavage prismatic, slightly oblique. Hardness=7.5. Sp. gr.=3.0—3.2.

I. Prismatic Andalusite, *Jameson.* Prismatischer Andalusit, *Mohs.*

Prismatic. Pyramid unknown. Cleavage indeterminate diagonal.

First Subspecies.

Common Andalusite, *Jameson.*—Andalusit, *Werner.* Feldspath, Apyre, *Hauy.*

External Characters.—Colour flesh-red, which sometimes inclines to pearl-grey. Occurs massive, and crystallized in slightly oblique four-sided prisms, in which the terminal angles and lateral edges are sometimes truncated. Principal fracture shining, in a low degree; cross fracture glistening, and lustre vitreous. Fracture uneven. Feebly translucent.

Chemical Characters.—It becomes white before the blowpipe, but does not melt.

Constituent Parts.—Silica,	. . .	32
Alumina,	. .	52
Potash,	. .	8
Oxide of Iron,	.	2—94
		Vauquelin.

Geognostic Situation.—It occurs in gneiss, mica-slate, and clay-slate.

Geographic Situation.—It occurs in primitive rocks in Scotland and England.

Second Subspecies.

Saussurite, *Jameson.*

External Characters.—Colours white, grey, and green. Occurs massive, disseminated, and in rolled pieces. Internally dull, or feebly glimmering. Fracture splintery. Faintly translucent on the edges.

Chemical Characters.—Before the blowpipe it melts on the edges and angles, but is not entirely melted.

Geognostic and Geographic Situations.—It occurs in Switzerland and other countries.

Genus III.—CORUNDUM.

One and many axes. Cleavage rhomboidal, prismatic, octahedral. If prismatic, the specific gravity is 3.7 and more, and the hardness 8.5 and more. Hardness=8.0, 9.0. Specific gravity=3 5—4 3.

I. Octahedral Corundum, *Jameson.* Octaedrischer Corund, *Mohs*

Tessular. Cleavage octahedral. Hardness=8. Sp. gr.=3.5—3.8.

This species is subdivided into three subspecies, viz. Automalite, Ceylanite, and Spinel.

First Subspecies.

Automalite, *Jameson.* Authomolite, *Werner.*

External Characters.—Colour green. Crystallized, in octahedrons and tetrahedrons. Externally glistening, and lustre pearly, inclining to semi-metallic. Internally shining on the principal fracture, but glistening on the cross fracture, and the lustre resinous. Fracture flat conchoidal. Opaque, or faintly translucent on the edges.

Chemical Character.—It is infusible before the blowpipe.

Constituent Parts.—Alumina,	. .	42
Silica,	. . .	4
Oxide of zinc,	.	28
Iron,	. . .	5
Sulphur,	. .	17
Undecomposed,	.	3—100

Vauquelin, Annales du Mus. t. vi. p. 33.

Geognostic and Geographic Situations.—It occurs imbedded in talc-slate, along with galena, and has been hitherto found only at Fahlun in Sweden.

Observation.—Appears to be a distinct species.

Second Subspecies.

Ceylanite, *Jameson.* Ceylanit, *Werner.*

External Characters.—Colours green and greyish-black. Occurs crystallized in octahedrons and rhomboidal dodecahedrons. Internally splendent, and lustre vitreous, inclining to semi-metallic. Fracture perfect, and very flat conchoidal. Translucent on the edges.

Geognostic and Geographic Situations.—This mineral was first found in the island of Ceylon, where it occurs in the sand of rivers, along with tourmaline, zircon, sapphire, and iron-sand. It also occurs in the ejected unaltered rocks at Monte Somma, and in other quarters.

Third Subspecies.

Spinel, *Jameson.* Spinell, *Werner.*

External Characters.—Principal colour red; from which there is a transition on the one side into blue, and almost into green; on the other side into yellow and brown, and even into white. The following are its secondary crystallizations:

1. Octahedron. 2. Tetrahedron. 3. Rhomboidal dodecahedron. 4. Various twin crystals.

Externally and internally splendent, and lustre vitreous. Fracture flat conchoidal. Alternates from translucent to transparent, and refracts single. Specific gravity, 3.5, 3.8. *Mohs.*

Chemical Characters.—Infusible before the blowpipe without addition; but is fusible with borax.

Constit. Parts.—Alumina,	. .	82.47
Magnesia,	. .	8.78
Chromic acid,	.	6.18
Loss,	. . .	2.57—100

Vauquelin, J. M. No. 38, p. 89.

Geognostic and Geographic Situations.—*Europe.*—It is found in the gneiss district of Acker in Sudermanland, in a white foliated granular primitive limestone; and in drusy cavities, along with vesuvian and ceylanite, in the ejected foliated granular limestone of Vesuvius.

Asia.—It occurs in the kingdom of Pegu, and at Cannanor in the Mysore country. In the island of Ceylon, so prolific in gems, it is found not only in the sand of rivers, but also imbedded in gneiss.

Uses.—It is an esteemed precious stone, but has neither the hardness nor fire of the red sapphire or oriental ruby.

II. Rhomboidal Corundum, *Jameson.* Rhomboedrischer Corund, *Mohs.*

Rhomboidal. Rhomboid=86° 38′. Cleavage in the direction of the rhomboid, or parallel with the terminal planes of the regular six-sided prism. Hardness=9, Specific gravity=3.8—4.3.

First Subspecies.

Sapphire, *Jameson.* Sapphir, *Werner.*

External Characters.—Blue and red are its principal colours; it occurs also grey, white, green, and yellow. Its crystallizations are six-sided pyramids and six-sided prisms. Internally, lustre splendent and vitreous, sometimes inclining to adamantine. Fracture conchoidal. Alternates from transparent to translucent; and the translucent varieties frequently exhibit a six-rayed opalescence. Refracts double.

	Blue Sapphire.	Red Sapphire, or Oriental Ruby.
Const. Parts.—Alumina,	92.0	90.0
Lime, .	5.25	7.0
Oxide of iron,	1.0	1.2
Loss, . .	1.75	1.8
	100	100
	Chevenix, Phil. Trans. 1802.	*Chevenix*, Phil. Trans. 1802.

Chemical Character.—Infusible before the blowpipe.

Physical Characters.—Becomes electrical by rubbing, and retains its electricity for several hours; but does not become electrical by heating.

Geognostic Situation.—It occurs in alluvial soil, in the vicinity of rocks belonging to the secondary or flœtz-trap formation, and imbedded in gneiss.

Geographic Situation.—It occurs in alluvial soil, in different countries of Europe, but most abundantly in the East, as Ceylon, Pegu, &c.

Uses.—This mineral is, next to diamond, the most valuable of the precious stones. The most highly prized varieties are the crimson and carmine red; these are the *Oriental Ruby* of the jeweller, and, next to the diamond, are the most valuable minerals hitherto discovered. The blue varieties, the *Sapphire* of the jeweller, are next in value to the red. The yellow varieties, the *Oriental Topaz* of the jeweller, are of less value than the blue or true sapphire.

Second Subspecies.

Emery, *Jameson.*—Schmiergel, *Werner.*

External Characters.—Colour intermediate between greyish-black and bluish-grey. Occurs massive and disseminated; and the massive is sometimes intermixed with other minerals. Lustre glistening, passing into glimmering, and adamantine. Fracture fine and small-grained uneven; sometimes splintery. Slightly translucent on the edges.

Geognostic and Geographic Situations.—It is found in talc-slate at Ochsenkopf near Schwartzenberg, and Eibenstock in Saxony. It occurs abundantly in the island of Naxos.

Use.—It is used for polishing hard minerals and metals, and hence is an important article in the arts.

Third Subspecies.

Corundum, *Jameson.*—Korund and Demant-Spath, *Werner.*

External Characters.—Colours white, grey, green, blue, red, and brown. The green, blue, and red colours are generally muddy, and inclining to grey. When cut in a semicircular form, it often presents an opalescent star of six rays. Its principal crystallizations are six-sided prisms and six-sided pyramids. Externally they are dull and rough. Lustre of the cleavage and fracture shining and glistening, and either vitreous inclining to resinous, or pearly inclining to adamantine. Fracture conchoidal, and sometimes uneven. Alternates from strongly translucent to translucent on the edges.

Geognostic and Geographic Situations.—Red and blue corundum occur in dolomite in St. Gothard; also in the Carnatic, on the coast of Malabar; and abundantly in the neighbourhood of Canton in China.

Use.—In its powdered state, it has long been used by the artists of India and China for cutting and polishing precious stones.

III. Prismatic Corundum or Chrysoberyl, *Jameson.* Krysoberyll, *Werner.* Cymophane, *Hauy.* Prismatischer Corund, *Mohs.*

Prismatic. Prism =104° 41′. Cleavage prismatoidal, in the direction of the smaller diagonal of the oblique four-sided prism. Hardness = 8.5. Specific gravity =3.7—3.8.

External Characters.—Chief colour asparagus green. Often exhibits a milk-white opalescence, which appears in general to float in the interior of the mineral. Occurs in blunt angular rolled pieces, that sometimes approach to the cubic form, and crystallized in six-sided prisms. Internally splendent, and lustre intermediate between resinous and vitreous, but more inclining to the first. Fracture perfect conchoidal. Semitransparent, sometimes inclining to transparent, and refracts double.

Constit. Parts.—	Alumina,	71.5
	Silica,	18.0
	Lime,	6.0
	Oxide of iron,	1.5
	Loss,	3.0—100

According to *Klaproth*, b. i. s. 102.

Geognostic and Geographic Situations.—It occurs in Brazil, in alluvial soil with topaz, or in sandstone with diamond; and at Haddam, on Connecticut River, in the United States, in granite, along with garnets, beryl, and tourmaline.

It is found in the island of Ceylon, in the beds of rivers, along with sapphires, rubies and tourmalines.

Uses.—This fine gem was formerly much less prized than it is at present. When cut and polished, it is not inferior in brilliancy and beauty to other gems of the same colour.

Genus IV. DIAMOND.

Tessular. Hardness =10. Sp. gr. =3.4—3.6.

1. Octahedral Diamond, *Jameson.*—Octaedrischer Demant, *Mohs.*

Tessular. Cleavage octahedral.

External Characters.—Most common colours of the diamond are white and grey. Besides these two colours, it occurs blue, red, brown, yellow, and green. Occurs generally crystallized in octahedrons, tetrahedrons, rhomboidal dodecahedrons, and in various twin crystals. Internally, is always splendent, often specular splendent, and the lustre perfectly adamantine. Seldom completely transparent; more generally it rather inclines to semitransparent; but the black variety is nearly opaque. Refracts single.

Constituent Parts.—Is said to be nearly pure carbon.

Geognostic Situation.—It occurs in imbedded grains and crystals, in alluvial soil, sandstone, and, it is said, in secondary trap-rocks.

Geographic Situation.—It occurs in Brazil, Peninsula of India, and the island of Borneo.

Uses.—The diamond, on account of the splendour of its lustre, its peculiar play of colour, its hardness, and, lastly, its rarity, is considered as the most precious substance in the mineral kingdom, and is particularly valued by jewellers. The diamonds purchased by jewellers are generally in grains, or crystals, and sometimes coarsely polished. Vide Article Diamond, for a full account of various sizes of the diamond.

Genus V. TOPAZ.

Prismatic. Axifrangible. Hardness =8. Sp. gr. = 3.4—3.6.

1. Prismatic Topaz, *Jameson.*—Prismatischer Topaz, *Mohs.*

Prismatic. Pyramid =141° 7′: 101° 52′: 90° 55′: Prism =124° 19′. Cleavage axifrangible.

This species contains three subspecies, viz. Common Topaz, Schorlite, and Physalite or Pyrophysalite.

First Subspecies.

Common Topaz. Topaz, *Werner.*

External Characters.—Colours yellow, green, blue, and red. Frequently crystallized, and generally in prisms which are variously bevelled and acuminated. The lateral planes of the crystals are longitudinally streaked; but the acuminating and bevelling planes are smooth; the terminal planes rough. Externally splendent; internally, splendent and vitreous. Fracture small and perfect conchoidal. Alternates from transparent to semitransparent; and refracts double.

Chemical Characters.—Saxon topaz in a gentle heat becomes white, but a strong heat deprives it of lustre and transparency: the Brazilian, on the contrary, by exposure to a high temperature, burns rose-red, and in a still higher violet-blue.

Physical Characters.—When heated, exhibits at one extremity positive, and at the other negative electricity. It also becomes electrical by friction, and retains this property for a considerable time, sometimes more than twenty-four hours.

		Brazilian Topaz.
Const. Parts.—	Alumina,	58.38
	Silica,	34.01
	Fluoric acid,	7.79—100.18

Berzelius, Afhandlingar, vol. iv. p. 236.

Geognostic Situation.—It occurs in various primitive rocks, such as topaz-rock, gneiss, and clay-slate.

Geographic Situation.—It occurs in large crystals, and rolled masses, in an alluvial soil, in the granite and gneiss districts of Mar and Cairngorm, in the upper parts of Aberdeenshire; and in veins, along with tinstone, in clay-slate, at St. Anne's, in Cornwall; also in St. Michael's Mount, and at Trevaunance, in the same county. The finest topazes are those found in Brazil.

Uses.—This gem is much prized by jewellers, and is considered as one of the more beautiful ornamental stones.

Second Subspecies.

Schorlite, or Schorlous Topaz, *Jameson.*—Schorlartiger Berill, or Piknit, *Werner.* Pycnite, *Hauy.*

External Characters.—Colours yellow, white, and grey. Occurs almost always massive, also in parallel, thin, and straight prismatic distinct concretions, which are longitudinally streaked, and crystallized in long six-sided prisms, which are sometimes truncated on the terminal edges and angles, and are generally imbedded. Externally and internally its lustre is shining, approaching to glistening, and is resinous. Fracture small and imperfect conchoidal, or fine-grained uneven. More or less translucent on the edges. Brittle. Uncommonly easily frangible.

Geognostic and Geographic Situations.—It occurs at Altenberg in Saxony, in a rock of quartz and mica which forms an imbedded mass, included in porphyry.

Third Subspecies.

Physalite, or Pyrophysalite. *Jameson.*—Pyrophysalith, *Hisinger.* Physalith, *Werner.*

External Characters.—Colours greenish-white and mountain-green. Massive. Occurs in coarse granular distinct concretions. Lustre of the cleavage splendent, of the cross fracture glistening or dull. Fracture uneven or conchoidal. Translucent on the edges.

Geographic Situation.—It is found imbedded in granite at Finbo, near Fahlun, in Sweden.

Genus VI. EMERALD.

Rhomboidal. Prismatic. Cleavage prismato-rhomboidal, prismatoidal; first axifrangible. Hardness 7.5, 8.0. Sp. gr. =2.6, 3.2.

1. Prismatic Emerald, or Euclase, *Jameson.*—Euclas, *Werner.* Prismatischer Smaragd, *Mohs.*

Prism =133° 26′. Cleavage prismatoidal, in the direction of the smaller diagonal. Hardness=7.5. Sp. gr. =2.9, 3.2.

External Characters.—Colours, white, green, and blue. Crystallized in oblique four-sided prisms variously modified by truncations, and bevelments, and acuminations. Internally splendent. Fracture small conchoidal. Alternates from transparent to translucent, and refracts double.

Chemical Characters.—Before the blowpipe, it first loses its transparency, and then melts into a white enamel.

Const. Parts.—Silica,	.	35
Alumina,	.	18
Glucina,	.	14
Iron,	. .	2
Loss,	. .	31—100. *Vauquelin.*

Geognostic and Geographic Situation.—This rare and beautiful mineral occurs in Peru and Brazil.

2. Rhomboidal Emerald, *Jameson.*—Rhomboedrischer Smaragd, *Mohs.*

Di-rhomboid =138° 35′; 90°. Cleavage most distinct parallel with the terminal planes of the six-sided prism, less distinct in the direction of the lateral planes of the six-sided prism. Hardness =7.5, 8.0 Sp. gr. =2.6, 2.8.

First Subspecies.

Precious Emerald, *Jameson.*—Schmaragd, *Werner.*

External Characters.—Colour emerald green, generally crystallized in equiangular six-sided prisms. Lateral planes smooth; terminal planes rough. Internally lustre intermediate between shining and splendent, and vitreous. Fracture small and imperfect conchoidal. Alternates from transparent to translucent, and refracts double in a moderate degree.

Const. Parts.—Silica,	. .	64.5
Alumina,	. .	16
Glucina,	. .	13
Oxide of Chrome,		3.25
Lime,	. .	1.6
Water,	. .	2.0—100.35

Vauquelin, Jour. des Mines, N. 38, p. 98.

Geognostic Situation.—It occurs in drusy cavities, in veins in clay-slate, and also imbedded in mica-slate; and loose in the sand of rivers and other alluvial deposites.

Geographic Situation.—The most beautiful emeralds are at present brought from Peru; and others of less value are found in Salzburg.

Use.—It is rare to find the colour of this gem pure and of good strength; hence such specimens are very highly valued, and are employed in the most expensive kinds of jewellery. It is valued next to the ruby; and, when of good colour, is set without a foil, and upon a black ground, like brilliant diamonds.

Second Subspecies.

Beryl, *Jameson.*—Edler Beril, *Werner.*

External Characters.—Colours green, blue, and yellow. Occurs massive, and this variety sometimes appears arranged in straight and thin prismatic distinct concretions. Often crystallized in long equiangular six-sided prisms, either perfect, or truncated on the lateral and terminal edges or angles, also sometimes acuminated. Lateral planes deeply longitudinally streaked, but the terminal, acuminating, and truncating planes are smooth. Externally, lustre shining and glistening; internally shining, which sometimes passes into glistening and splendent, and vitreous. Fracture small, and more or less perfect conchoidal. Commonly transparent, and refracts double, but in a feeble degree.

Const. Parts.—Silica,	. .	69.50
Alumina,	. .	14.00
Glucina,	. .	14.00
Oxide of Iron,	.	1.00—98.50

Rose, in Karsten's Tabellen.

Geognostic Situation.—It occurs in veins that traverse granite and gneiss, also imbedded in granite, and dispersed through alluvial soil.

Geographic Situation.—It occurs in alluvial soil along with rock-crystal and topaz, in the upper parts of Aberdeenshire. In Ireland, imbedded in granite, near Lough Bray, in the county of Wicklow, and near Cronebane in the same county.

Uses.—When pure, it is cut into ring-stones, sealstones, brooches, intaglios, and necklaces, but is not so highly valued as emerald.

Genus VII.—IOLITE.

Cleavage rhomboidal. Hardness=7.0—7.5. Sp. gr. =2.5—2.6.

1. Prismato-Rhomboidal Iolite, *Jameson.*—Iolith and Peliom, *Werner.*

Rhomboid unknown. Cleavage in the direction of the lateral planes of the regular six-sided prism.

External Characters.—Colour intermediate between violet-blue and blackish-blue. When viewed in the direction of the axis of the crystals, the colour is dark indigo-blue; but perpendicular to the axis of the crystals, pale brownish-yellow. Occurs massive, disseminated, and rarely crystallized in six-sided prisms.

Internally shining, and the lustre vitreous. Fracture small-grained uneven, and sometimes conchoidal. Translucent in the direction of the axis of the crystal, and transparent at right angles to it. Refracts double.

Const. Parts.—Silica,	. .	43.6
Alumina,	. .	37.6
Magnesia,	. .	9.7
Potash,	. .	1.0
Oxide of Iron,	.	4.5
——— Manganese, a trace		—99.5

Leopold Gmelin.

Geognostic and Geographic Situations.—It is found at Orijarvi, near Abo in Finland; at Bodenmais in Bavaria; in the county of Salzburg; and in other parts of Europe and America.

Use.—It is cut, polished, and worn as a gem.

Genus VII. a. QUARTZ.

Rhomboidal. Cleavage rhomboidal, not axifrangible. Hardness=5 5—7.5. Sp. gr =1.9—2.7.

1. Rhomboidal Quartz, *Jameson.*—Quartz, *Werner.* Rhomboedrischer Quartz, *Mohs.*

Rhomboidal. Rhomboid=76° 2′. Cleavage in the direction of the alternate planes of the double six-sided pyramid, and in the direction of the lateral planes of six-sided prism. Hardness=7.0. Sp gr.=2.5—2.7.

The species contains fourteen subspecies, viz. 1. Amethyst, 2. Rock Crystal, 3. Milk Quartz, 4. Common Quartz, 5. Prase, 6. Cat's-eye, 7. Iron Flint, 8. Hornstone, 9. Flinty Slate, 10. Flint, 11. Calcedony, 12. Heliotrope, 13. Jasper, 14. Floatstone, * Agate.

First Subspecies.

Amethyst.

External Characters.—Colour violet-blue. Occurs massive, and in prismatic and lamellar concretions. Most frequent crystallization is the acute six-sided pyramid; a less frequent form is the six-sided prism with a six-planed acumination. Alternates from translucent to transparent. Internally splendent, or shining, and lustre vitreous. Fracture conchoidal.

Geognostic Situation—It occurs in agate-balls in amygdaloid, greenstone, and porphyry, and in veins in primitive and secondary rocks.

Geographic Situation.—In veins and drusy cavities in secondary greenstone and amygdaloid, in many parts of Scotland. Near Cork in Ireland. In many places on the continents of Europe, Asia, Africa, and America.

Uses.—The most highly valued amethysts are those brought from the continent of India, and the Island of Ceylon. The next in esteem are the Brazilian. When the colour is good, it is cut and polished, and is considered a gem of considerable beauty.

Second Subspecies.

Rock or Mountain Crystal, *Jameson.*—Bergcrystal, *Werner.*

External Characters.—Colours white, brown, yellow, and red. Generally occurs in crystals, which are usually six-sided prisms acuminated, with six planes set on the lateral planes. Externally the crystals are generally splendent or shining. Internally, splendent and vitreous. Fracture almost always perfect conchoidal. Generally transparent.

Chemical Characters.—It is completely infusible before the blowpipe.

Constituent Parts.—Silica,	. .	$99\frac{3}{8}$
Trace of Ferruginous Alumina,		—100

Bucholz, Gehlen's Journ. 1808, p. 150.

Geognostic Situation.—Although rock-crystal occurs more frequently, and in more numerous geognostic relations than amethyst, yet it is not the most common subspecies of quartz. It appears most frequently, and in the largest and most transparent crystals, in primitive rocks, where it occurs in beds, veins, and large drusy cavities.

Geographic Situation.—Crystals of great size and beauty are found in different parts of Scotland; the rock-crystals of the Island of Arran, which occur in drusy cavities in granite, are well known; but the largest and most valuable are found in the district of Cairngorm, in the upper part of Aberdeenshire, where they occur in granite, or in alluvial soil, along with beryl and topaz. On the Continent of Europe it is very widely, and often abundantly distributed, and the same is the case in Asia and America.

Uses.—Rock-crystal is cut and polished as an inferior kind of gem or ornamental stone.

Third Subspecies.

Rose or Milk Quartz, *Jameson.*—Milch Quartz, *Werner.*

External Characters.—Colours rose-red and milk-white. Occurs only massive. Internally shining, sometimes passing to splendent, and vitreous, inclining to resinous. Fracture more or less perfect conchoidal. More or less translucent. The other characters are the same as those of rock-crystal.

Geognostic Situation.—It occurs in masses, included in beds of quartz subordinate to granite and gneiss, and in veins of manganese in granite.

Geographic Situation.—It occurs in primitive rocks in Scotland, Germany, and in Europe, and in various districts in Asia and America.

Uses.—It is employed in jewellery, and the larger masses are cut into vases.

Fourth Subspecies.

Common Quartz, *Jameson.*—Gemeiner Quartz, *Werner.*

External Characters.—Colours white, grey, yellow, brown, red, green, blue, and black. Occurs massive, disseminated, in plates, stalactitic, reniform, botryoidal, globular, specular, corroded, vesicular, ramose, amorphous, cellular, and with impressions. Internally shining, which sometimes borders on glistening, and sometimes approaches to glimmering, and is vitreous. Fracture coarse splintery, and conchoidal. Generally translucent. The other characters the same as those of rock-crystal.

Geognostic Situation.—It is one of the most abundant minerals in nature, and appears in many different geognostic situations. It occurs in primitive, transition, secondary, alluvial, and volcanic rocks, and either as a constituent part of these rocks, or associated with them in the form of beds and veins.

Geographic Situation.—It abounds in all the primitive, transition, secondary, and alluvial districts of Scotland, England, and Ireland; is abundantly distributed throughout the continents of Europe, Asia, Africa, and America.

Uses.—It is employed in the manufacture of glass and artificial gems; also in the preparation of smalt, and as an ingredient in porcelain and different kinds of pottery. The vesicular and corroded variety forms a most excellent millstone, known in commerce under the name of *Buhr-stone.*

Fifth Subspecies.

Prase, *Jameson.*—Prasem, *Werner.*

Colour leek-green. Generally massive, and in prismatic and granular concretions. Sometimes crystallized in same forms as common quartz. Surface of the concretions rough and transversely streaked. Lustre shining, approaching to glistening, and resino-vitreous. Fracture conchoidal, passing into splintery. Translucent.

Geognostic and Geographic Situations.—It occurs in primitive rocks in Scotland, Germany, and other countries. These beds are probably connected with primitive trap.

Uses.—It is sometimes cut and polished as an ornamental stone, but is not highly esteemed.

Sixth Subspecies.

Cat's-eye, *Jameson.*—Katzenauge, *Werner.*

External Characters.—Principal colours grey, red, and brown. Exhibits a beautiful opalescence, particularly when cut in a convex form. Massive. Internally shining, lustre vitreo-resinous. Fracture conchoidal. Translucent, or translucent on the edges.

Geognostic and Geographic Situations.—It occurs imbedded in gneiss in Ceylon.

Uses.—It is generally cut into ring-stones; and the most advantageous form for displaying its peculiar lustre is the oval, with a convex surface.

Seventh Subspecies.

Iron-Flint, *Jameson.*—Eisenkiesel, *Werner.*

External Characters.—Colours brown and red. Massive and crystallized like common quartz. Usually in granular distinct concretions. Externally lustre shining, approaching to glistening; internally glistening, and vitreo-resinous. Fracture conchoidal. Opaque.

Geognostic Situation.—It occurs in veins of ironstone, and also in trap-rocks.

Geographic Situation.—In rocks near Bristol; in trap-rocks that lie over white limestone, island of Rathlin, off the coast of Ireland; and in trap-rocks near Dunbar in Scotland.

Eighth Subspecies.

Hornstone, *Jameson.*—Hornstein, *Werner.*

There are three kinds, viz. Splintery Hornstone, Conchoidal Hornstone, and Woodstone.

First Kind.—Splintery Hornstone, *Jameson.*—Splittriger Hornstein, *Werner.*

External Characters.—Colours grey, red, and green. Massive. Internally dull. Fracture splintery. More or less translucent on the edges.

Geognostic Situation.—Occurs in veins in primitive rocks.

Geographic Situation.—It occurs in primitive districts in Scotland and England, and in various quarters on the continents of Europe, Asia, and America.

Second Kind.—Conchoidal Hornstone, *Jameson.*—Muschlicher Hornstein, *Werner.*

External Characters.—Colours grey, white, and red. Massive. Internally glimmering, sometimes approaching to glistening, and lustre vitreous. Fracture conchoidal. Translucent, but not in a lower degree than splintery hornstone.

Geognostic Situation.—It occurs in metalliferous veins and agate veins; also, in imbedded portions, in pitchstone porphyry, in striped jasper, and along with claystone porphyry.

Geographic Situation.—It is found along with claystone in the Pentland Hills near Edinburgh; also in Saxony and Bohemia.

Third Kind.—Woodstone, *Jameson.*—Holstein, *Wer.*

External Characters.—Colours grey, red, brown, black, and yellow. Occurs in rolled pieces, and in the shape of trunks, branches, and roots. External surface uneven and rough. Internally dull, sometimes glimmering and glistening, according as it is more or less of the nature of the two preceding subspecies. Cross fracture imperfect conchoidal; the longitudinal fracture splintery and fibrous. Generally translucent on the edges; sometimes feebly translucent.

Geognostic Situation.—It is imbedded in sandy loam in alluvial soil; and it is said also in a kind of sandstone-conglomerate and clay-stone.

Geographic Situation.—It occurs at Loch Neagh in Ireland: at Chemnitz and Hilbersdorf in Upper Saxony, and in many other places.

Ninth Subspecies.

Flinty-Slate, *Jameson.*

Two kinds, viz. Common Flinty-Slate, and Lydian Stone.

First Kind.—Common Flinty-Slate, *Jameson.* Gemeiner Kieselchiefer, *Werner.*

External Characters.—Colours grey, red, and black. Often traversed by quartz veins. Occurs massive. Internally faintly glimmering, almost dull. Fracture in the great slaty, and in the small splintery. More or less translucent, and passes into translucent on the edges.

Geognostic Situation.—It occurs in beds and imbedded masses in clay-slate and grey-wacke; and in roundish and angular masses in sandstone.

Geographic Situation.—It occurs in different parts of the great tract of clay-slate and grey-wacke, which extends from St. Abb's Head to Port Patrick; also in the Pentland Hills near Edinburgh.

Second Kind.—Lydian-Stone, *Jameson.*—Lidischerstein, *Werner.*

External Characters.—Colour greyish-black, which passes into velvet-black. Occurs massive. Traversed by quartz veins. Internally glimmering. Fracture generally even, and approaches sometimes to flat conchoidal. Opaque.

Geognostic and Geographic Situations.—It occurs in primitive, transition, and secondary rocks in Scotland, England, and other countries.

Use.—This mineral is sometimes used as a touchstone for ascertaining the purity of gold and silver.

Tenth Subspecies.

Flint, *Jameson.*—Feurstein, *Werner.*

External Characters.—Colours grey, yellow, brown, and red. Besides massive, in plates, in angular grains and pieces, it occurs also in globular and elliptical rolled pieces, in the form of sand, and tuberose and perforated. Sometimes occurs in lamellar concretions, which are either straight or concentrically curved. Internally lustre glimmering. Fracture perfect and large, and rather flat conchoidal. Translucent; the blackish varieties are seldom more than translucent on the edges.

Constituent Parts.—Silica,	98.	
Lime,	0.50	
Alumina,	0.25	
Oxide of Iron,	0.25	
Loss,	1.	—100

Vauquelin, Journ. de Mines, n. xxxiii. p. 702.

Geognostic and Geographic Situations.—Occurs in primitive, transition, secondary, and alluvial rocks in most countries of Europe.

Uses.—The principal use of this mineral is for gun-flints, for which purpose it is excellently fitted, on account of its hardness, the abundance of sparks it affords with steel, and the sharp fragments it gives in breaking.

Eleventh Subspecies.

Calcedony, *Jameson.* Kalzedon, *Werner.*

Four kinds, viz. Common Calcedony, Chrysoprase, Plasma, and Carnelian.

First Kind.—Common Calcedony, *Jameson.*—Gemeiner Kalzedon, *Werner.*

External Characters.—Colours grey, yellow, brown, blue, green, and black. Occurs in lamellar, and also in fibrous distinct concretions. Internally dull; the splintery varieties exhibit a faint degree of lustre. Fracture even, which sometimes passes into imperfect conchoidal, and splintery. Generally semi-transparent; but the black and white varieties are only translucent.

Geognostic Situation.—Occurs in primitive, secondary, and alluvial rocks, in balls, kidneys, angular pieces, short and thick beds, veins, and rolled pieces.

Geographic Situation.—It is frequent in most of the trap districts in Scotland, and also in similar tracts on the continents of Europe, Asia, Africa, and America.

Uses.—As it is hard, susceptible of a fine polish, and exhibits beautiful colours, and considerable transparency, it is employed as an article of jewellery.

Second Kind.—Chrysoprase, *Jameson.* Krisopras, *Werner.*

External Characters.—Characteristic colour apple-green, and greenish-grey. Occurs generally massive, and sometimes in plates. Internally dull, seldom glimmering. Fracture even. Translucent, inclining to semi-transparent.

Geognostic and Geographic Situations.—It occurs in plates, and cotemporaneous veins, in primitive serpentine in Silesia.

Uses.—It is considered as a gem, and is cut into ring-stones, necklaces, bracelets, ear-drops, and brooches.

Third Kind.—Plasma, *Jameson.* Plasma, *Werner.*

External Characters.—Colour grass-green. Internally lustre glistening, inclining to glimmering. Fracture imperfect, and rather flat conchoidal. Translucent, inclining to semi-transparent.

Geognostic and Geographic Situations.—It occurs in beds, associated with common calcedony. Most of the specimens in cabinets have been collected among the ruins of Rome.

Use.—It was considered by the Romans as a gem, and was cut into ornaments; and frequently figures were engraved upon it.

Fourth Kind.—Carnelian, *Jameson.* Carneol, *Werner.*

External Characters.—Colours red, brown, yellow, green, and white. Occurs massive, and in fibrous lamellar concretions. Fracture perfect conchoidal, or splintery in the reniform varieties. Lustre glistening, sometimes passing into shining, and vitreous. Generally semi-transparent; seldom translucent.

Geognostic and Geographic Situations.—It frequently occurs as a constituent part of agate, and in general has the same geognostic situation as common calcedony. The secondary trap-rocks, so abundant in Scotland, often contain carnelian, either alone, or in agate. The most beautiful carnelians are brought to this country from Arabia, India, Surinam, Siberia, and Sardinia.

Uses.—It is cut into seal-stones, ring-stones, bracelets, necklaces, brooches, and crosses; and figures are often engraved on it.

Twelfth Subspecies.

Heliotrope, *Jameson.* Heliotrop, *Werner.*

External Characters.—Colour green, with red and yellow spots. Occurs massive. Internal lustre glistening, and resinous. Fracture conchoidal. Generally translucent on the edges; some varieties translucent.

Geognostic and Geographic Situations.—It is found in rocks belonging to the secondary trap-formation, in Siberia, Tartary, Iceland, and even in Scotland.

Uses.—It is cut and polished, and worn as an ornamental stone.

Thirteenth Subspecies.

Jasper.

Five kinds, viz. Egyptian Jasper, Striped Jasper, Porcelain Jasper, Common Jasper, and Agate Jasper.

First Kind.—Egyptian Jasper, *Jameson.*—Brauner Egyptischer Jaspis, *Werner.*

External Characters.—Colours brown, yellow, and grey, frequently disposed in concentric stripes, alternating with black stripes. In the brown colour there sometimes occur black spots, and similar coloured dendritic delineations. Internally partly glistening, partly glimmering. Fracture conchoidal. Very feebly translucent on the edges, or almost opaque.

Geognostic and Geographic Situations.—It occurs loose in the sands of the desert, and in conglomerate rocks in Egypt.

Uses.—It is cut and worn as an ornamental stone.

Second Kind.—Striped Jasper, *Jameson.* Band Jaspis, *Werner.*

External Characters.—Colours grey, green, yellow, and red, and seldom blue. There are always several colours together, and these are arranged in striped and flamed, and sometimes in spotted delineations. Occurs massive. Internally dull. Fracture conchoidal. Opaque, or very feebly translucent on the edges.

Geognostic and Geographic Situations—It occurs in secondary clay-porphyry in the Pentland Hills near Edinburgh; but the most beautiful varieties are found in Siberia.

Use.—This mineral receives an excellent polish, and hence is used like agate for ornamental purposes.

Third Kind—Porcelain-Jasper, *Jameson.* Porzellan Jaspis, *Werner.*

External Characters.—Colours grey, blue, yellow, and seldom black and red. Occurs most commonly massive, and is frequently cracked in all directions. Internally glistening, sometimes approaching to shining, sometimes to glimmering, and even to dull; and the lustre vitreo-resinous. Fracture conchoidal. Opaque.

Geognostic and Geographic Situations.—It occurs along with pseudo-volcanic rocks in Fifeshire; near Dudley in Warwickshire; and in many other parts of Europe and America.

Fourth Kind.—Common Jasper, *Jameson.* Gemeiner Jaspis, *Werner.*

External Characters.—Colours red, brown, and black. Occurs massive. Internally varies from shining to dull; and lustre resinous-vitreous. Fracture of some varieties is more or less perfect and flat conchoidal, and those have a shining or glistening lustre; in others it is even, with a glimmering lustre, or fine earthy and dull. Opaque, or very faintly translucent on the edges.

Geognostic and Geographic Situations.—It occurs in veins and imbedded masses in primitive, transition, and secondary rocks in Scotland, England and Ireland. It is not unfrequent on the continents of Europe, Asia, Africa, and America.

Uses.—When it occurs in sufficiently large masses, it is cut into various ornamental articles, as vases, snuff-boxes, ringstones, &c.

Fifth Kind.—Agate-Jasper, *Jameson.* Agat-Jaspis, *Werner.*

External Characters.—Colours white, yellow, and red. Several colours generally occur together, and these are arranged either in clouded, flamed, or striped delineations; of these the striped are either disposed in a circular manner, or fortification-wise. Occurs massive. Frequently occurs in distinct concretions, which are either fortification-wise bent, or concentric lamellar. Internally dull. Fracture small and flat conchoidal, approaching to even.

Geognostic Situation.—Occurs principally in layers, in agate-balls, in amygdaloid; likewise in agate-balls and veins in porphyry.

Geographic Situation.—Occurs in the agates of the middle district of Scotland, &c.

Fourtneeth Subspecies.

Float-stone, or Spongiform Quartz, *Jameson.*—Schwimmstein, *Werner.* Quartz nectique, *Hauy.*

External Characters.—Colours white and grey. Occurs in porous, massive, and tuberose forms. Internally dull. Fracture coarse earthy. Feebly translucent on the edges. Soft, but its particles are as hard as quartz.

Geognostic and Geographic Situations.—It occurs incrusting flint, or in imbedded masses in a secondary limestone, at St. Ouen, near Paris.

Agate, *Jameson.*

Agate is not, as some mineralogists maintain, a simple mineral, but is composed of various kinds of the quartz family, intimately joined together, and the whole mass is so compact and hard, that it receives a high polish. Agate is principally composed of calcedony, with flint, hornstone, carnelian, jasper, cacholong, amethyst, and quartz. Of these minerals, sometimes only two, in other instances more than three, occur in the same agate; and these are either massive, disseminated, or in layers.

II. Indivisible or Uncleavable Quartz, *Jameson.* Untheilbarer Quartz, *Mohs.*

This species contains eight subspecies, viz. 1. Quartzy Sinter, 2. Hyalite, 3. Opal, 4 Menilite, 5. Obsidian, 6. Pitchstone, 7. Pearlstone, 8. Pumice.

First Subspecies.

Quartzy or Siliceous Sinter, or Pearl Sinter, *Jameson.* Kieselsinter, *Werner.*

This is the siliceous incrustation met with around hot springs in Iceland, and other volcanic countries.

Second Subspecies.

Hyalite, *Jameson.* Hyalith, *Werner.*

External Characters.—Colours white, grey and green. Generally reniform, botryoidal, and sometimes stalactitic, and in crusts. Internally shining and splendent; and lustre vitreous, slightly inclining to resinous. Fracture conchoidal. Translucent, approaching to semitransparent.

Geognostic and Geographic Situations.—It has been hitherto found principally near Frankfort, on the Mayne, where it occurs in fissures in vesicular basalt and basaltic greenstone.

Third Subspecies.

Opal, *Jameson.* Opal, *Werner.*

This subspecies is divided into seven kinds, viz. Precious Opal, Common Opal, Fire Opal, Mother-of-Pearl Opal or Cacholong, Semi-Opal, Jasper-Opal, and Wood-Opal.

First Kind.—Precious Opal, *Jameson.* Edler Opal, *Werner.*

External Characters.—Most common colour milk-white, which at the same time displays a fine play of beautiful colours. Occurs massive, and disseminated. Internally splendent, and vitreous. Fracture conchoidal. Brittle. Uncommonly easily frangible.

Const. Parts.—	Silica,	90
	Water,	10—100

Opal of Czscherwenitza, according to *Klaproth.*

Geognostic and Geographic Situations.—It occurs in small veins in clay-porphyry, generally accompanied with semi-opal; in Hungary, and some other countries.

Uses.—Few gems are more beautiful than the opal. The elegant play of the richest, purest, and most beautiful colours have procured for it a high rank among the precious stones. It is worked into ringstones, necklaces, ear-drops, and other ornaments.

Second Kind.—Common Opal, *Jameson.* Gemeiner Opal, *Werner*

External Characters.—Colours white, grey, yellow, red, and green. Occurs massive, and disseminated. Internally splendent, passing into shining; and vitreous. Fracture conchoidal. Most commonly semi-transparent.

		Of Telkobanya.
Const. Parts.—	Silica,	93.50
	Oxide of iron,	1 0
	Water,	5.0—99.50

Geognostic and Geographic Situations.—It occurs in veins, along with precious opal, in clay-porphyry, in Hungary and other countries.

Third Kind.—Fire Opal, *Jameson.*—Feur Opal, *Karst.*

External Characters.—Principal colour hyacinth-red, which passes through honey-yellow into wine yellow; and upon lighter places shews a carmine-red and apple-green iridescence. In its interior, dendritic delineations are sometimes to be observed. Internally splendent, and lustre vitreous. Occurs in lamellar distinct concretions. Fracture conchoidal. Completely transparent.

Geognostic and Geographic Situations.—It has hitherto been found only in America, at Zimapan in Mexico, where it was first observed by Sonnenschmid and Humbold, imbedded in porphyry.

Fourth Kind.—Mother-of-Pearl Opal, or Cacholong, *Jameson.* Perlmutter Opal, *Karsten.*

External Characters.—Colour milk white, and sometimes dendritic. Occurs massive, and disseminated. Externally dull; internally alternates from dull to glistening and shining, and pearly. Occurs in granular distinct concretions. Fracture flat conchoidal, but becomes earthy on the action of the atmosphere. Opaque.

Geognostic and Geographic Situations.—It occurs, along with calcedony, in trap rocks in the island of Iceland; in the Faroe islands; also in Greenland; and in Bocharia.

Fifth Kind.—Semi-Opal, *Jameson.* Halb-Opal. *Wer.*

External Characters.—Most common colours white, grey, and brown. Occurs not only massive and disseminated, but also tuberose, small reniform, small botryoidal, and stalactitic. Externally glistening; internally, generally glistening. Fracture conchoidal. More or less translucent, and sometimes passes to translucent on the edges.

Geognostic and Geographic Situations. It occurs in porphyry and amygdaloid, in Scotland, Iceland, France, Germany, &c.

Sixth Kind.—Jasper-Opal, or Ferruginous-Opal, *Jameson.* Opal-Jaspis, *Werner.*

External Characters.—Colours red, yellow, and grey. Occurs massive. Internally lustre shining, approaching to splendent, and intermediate between vitreous and resinous. Fracture perfect conchoidal, and sometimes rather flat conchoidal. Opaque, and sometimes feebly translucent on the edges.

Geognostic and Geographic Situations.—It is found in large and small pieces in porphyry, near Telkobanya and Tokay in Hungary, and in other parts of Europe.

Seventh Kind.—Wood-Opal, *Jameson* —Holz-Opal, *Werner.*

External Characters. Occurs most commonly white, grey, or brown, and sometimes also black. Occurs in pieces which have the shape of branches and stems. Internally lustre shining, and sometimes splendent, glistening, or glimmering. Cross fracture conchoidal; the longitudinal fracture sometimes modified by the remaining fibrous woody texture. More or less translucent; sometimes only translucent on the edges.

Geognostic and Geographic Situations.—It is found in alluvial land at Zastravia in Hungary; and is said to occur in secondary trap-rocks in Transylvania.

Uses.—It is cut into plates, and is then used for snuff-boxes, and other ornamental articles.

Fourth Subspecies.

Menilite, *Jameson.*

First Kind.—Brown Menilite, *Jameson.* Brauner Menilite, *Hoffmann.*

External Characters.—Colour chesnut-brown. On the surface sometimes of a bluish colour. Occurs always tuberose. External surface rough and dull; internally faintly glistening, and lustre intermediate between resinous and vitreous. Fracture very flat conchoidal. Translucent on the edges.

Const. Parts.—	Silica,	85.5
	Alumina,	1.0
	Lime,	0.5
	Oxide of Iron,	0.5
	Water, and Carbonaceous Matter,	11.0
	Klaproth, Beit. b. ii. s. 169.	98.5

Geognostic and Geographic Situations.—It has hitherto been found only at Menil Montant, near Paris, where it occurs imbedded in adhesive-slate, in the same manner as flint is in chalk.

Fifth Subspecies.

Obsidian, *Jameson.* Obsidian, *Werner.*

This subspecies is divided into two kinds, viz. Translucent Obsidian. Transparent Obsidian.

First Kind.—Translucent Obsidian, *Jameson.*—Durchscheinender Obsidian, *Hoffmann.*

External Characters.—Colours black, grey, and green. Occurs massive. Internally splendent, seldom shining, and lustre vitreous. Fracture conchoidal. Alternates from translucent to translucent on the edges. Very brittle. Easily frangible. Streak grey.

Chemical Characters.—The black obsidian of Iceland, according to Da Camara, on charcoal, before the blowpipe, melts into a pale ash-grey, imperfect, vesicular glass.

		American.
Const. Parts.—	Silica,	72.0
	Alumina,	12.5
	Natron and Potash,	10.0
	Lime,	0.0
	Oxide of Iron and Manganese,	2.0
	Collet Descotils.	96.5

Geognostic Situation.—This mineral occurs in beds, and imbedded masses and veins, in porphyry, and in various secondary trap rocks.

Geographic Situation.—It occurs in various parts of Europe, Asia, Africa, and America.

Uses.—It is cut into ornamental articles of different kinds.

Second Kind.—Transparent Obsidian, *Jameson.*—Durchsichtiger Obsidian, *Hoffmann.*

External Characters.—Colours blue, brown, and white. Internally splendent and vitreous. Fracture conchoidal. Perfectly transparent.

Geognostic and Geographic Situations.—It occurs imbedded in pearlstone-porphyry, at Marekan in Siberia.

Sixth Subspecies.

Pitchstone. *Jameson.*—Pechstein, *Werner.*

External Characters.—Colours green, grey, blue, yellow, brown, and black. Occurs massive. Internally shining, and glistening; lustre vitreo-resinous. Feebly translucent on the edges. Fracture conchoidal, coarse-grained uneven, and coarse splintery.

Constit. Parts.—Silica, 73; Alumina, 14.50; Lime, 1.0; Oxide of iron, 1.00; Oxide of manganese, 0.10; Natron, 1.75; Water, 8.50=99.85. *Klaproth.*

Geognostic and Geographic Situations.—It occurs in primitive, transition, and secondary rocks, in Scotland, Ireland, Saxony, &c.

Seventh Subspecies.

Pearl-Stone, *Jameson.* Perlstein, *Werner.*

External Characters.—Colours grey, black, and red. Occurs massive, disseminated; also in roundish granular and curved lamellar concretions. Lustre shining and pearly. Translucent on the edges, or translucent. Very easily frangible.

Constit. Parts.—Silica, 77.; Alumina, 13.0; Oxide of iron and manganese, 2.0; Potash, 2.0; Lime, 1.5; Natron, 0.7; Water, 4=100.2, *Vauquelin.*

Geognostic and Geographic Situations.—It occurs in porphyry, in Hungary, Spain, North of Ireland, Iceland, and Mexico.

Eighth Subspecies.

Pumice, *Jameson.* Bimstein, *Werner.*

External Characters.—Colours white and grey. Occurs vesicular; vesicles much elongated, and contain capillary fibres. Internally glistening or glimmering, and pearly. Principal fracture curved and parallel fibrous; cross fracture uneven. More or less translucent on the edges. Very brittle, and easily frangible.

Constit. Parts.—Silica, 77.50; Alumina, 17.50; Natron and Potash, 3.00; Iron with Manganese, 1.75,= 99.75, *Klaproth.*

Geognostic and Geographic Situations.—Occurs along with various porphyries and obsidians, in the Lipari islands, and other quarters.

Uses.—Is used for polishing glass and soft stones; also by parchment-makers, curriers, and hat-makers, and hence forms a considerable article of trade, and is exported from the Lipari islands in great quantities to the different countries of Europe.

Observations.—Obsidian, pitchstone, pearlstone, and pumice, ought to form a separate group in the species of the Genus Quartz.

Genus VIII. AXINITE, *Jameson.*

Prismatic. Perfect vitreous lustre. Hardness=6.5—7.0. Specific gravity=3.0—3.3.

1. Prismatic Axinite. *Jameson.*—Prismatischer Axinit, *Mohs.*—Thumerstein, *Werner.*

Pyramid unknown. Cleavage prismatic=101°. 30′.

External Characters.—Colours clove-brown, plumb-blue, grey, and black. Seldom massive, most frequently crystallized in very oblique four-sided prisms. Massive varieties occur in curved lamellar distinct concretions. Externally, lustre splendent; internally, alternates from glistening to shining, and is vitreous, slightly inclining to resinous. Fracture fine-grained, uneven, or conchoidal. Alternates from perfectly transparent to feebly translucent.

Chemical Characters.—Easily fusible with ebullition into a bottle-green glass, which by continuance of the heat becomes nearly black.

Constit. Parts.—	Silica,	50.50
	Alumina,	16.
	Lime,	17.
	Oxide of Iron,	9.50
	—— of Manganese,	5.25
	Potash,	0.25—98.50
		Klaproth, t. v. p. 28.

Geognostic Situation.—Occurs in primitive mountains, in rocks of gneiss, mica-slate, clay-slate, and hornblende-rock, and is found in Cornwall, and in various districts on the continent of Europe.

Genus IX. CHRYSOLITE.

Prismatic vitreous lustre. Hardness=6.5—7.0. Sp. gr.=3.3—3.5.

1. Prismatic Chrysolite, *Jameson.*—Prismatischer Krisolith, *Mohs.*—Peridot, *Hauy.*

Prism=131° 48′. Cleavage perfect, in the direction of the shorter diagonal, and less so in direction of the longer diagonal.

Two subspecies, viz. Chrysolite and Olivine.

First Subspecies.

Chrysolite, *Jameson.*—Krisolith, *Werner.*

External Characters.—Colour green. Occurs in angular pieces, roundish pieces, and often crystallized in four and six-sided prisms, variously acuminated, and bevelled, and truncated on the lateral edges. Internally, lustre splendent and vitreous. Fracture conchoidal. Transparent, and refracts double.

Constit. Parts.—	Silica,	39.00
	Magnesia,	43.50
	Iron,	19.00—101.50
		Klaproth Beit. b. i. s. 110.

Geognostic and Geographic Situations.—Is found in alluvial soil in Upper Egypt, and on shores of the Red Sea.

Uses.—It is cut and polished, and made into necklaces, hair ornaments, and ring-stones.

Second Subspecies.

Olivine, *Jameson.*—Olivin, *Werner.*

External Characters.—Colours olive-green and yellow. Occurs massive, in grains, and in roundish pieces.—When crystallized, which is rarely the case, it is in the form of rectangular four-sided prisms, which are always imbedded. Massive varieties occur in small and angulo-granular concretions. Internally, lustre shining and glistening, and vitreo-resinous. Fracture small-grained uneven, sometimes passing into imperfect small conchoidal. Translucent, passing into semi-transparent, seldom transparent.

Geognostic and Geographic Situations.—It occurs imbedded in basalt, greenstone, porphyry and lava, generally accompanied with augite, in Scotland, Germany, Italy, and other countries.

Genus X. TOURMALINE.

One axis. Rhomboidal. Hardness=7.0—7.5. Sp. gr.=3.0—3.2.

This genus contains one species, viz. Rhomboidal Tourmaline.

I. Rhomboidal Tourmaline.—Rhomboedrischer Turmalin, *Mohs.*

Rhomboidal. Rhomboid=133° 26′. Cleavage rhomboidal, and in direction of sides of a six-sided prism.

It is divided into two subspecies, viz. Tourmaline and Schorl.

First Subspecies.

Tourmaline, *Jameson.*—Turmalin, *Werner.*

External Characters.—Its principal colours are green, brown, red, blue, yellow, and white. Occurs very seldom massive, or in prismatic concretions; scarcely ever disseminated; oftener in rolled pieces; but most frequently crystallized in three, four, six, and nine-sided prisms, variously accuminated. The lateral planes are generally cylindrical convex, and deeply longitudinally streaked; the acuminating planes are mostly smooth and shining; sometimes the planes on one extremity are smooth, but on the other rough. Internally, lustre splendent and vitreous. Fracture nearly perfect, and small conchoidal. Alternates from nearly opaque to completely transparent. Refracts double in a middling degree. When viewed perpendicular to the axis of the crystal, it is more or less transparent, but in the direction of the axis, even when the length of the prism is less than the thickness, it is opaque.

Physical Characters.—By friction, it exhibits signs of vitreous electricity; by heating, vitreous electricity at one extremity, and resinous electricity at the other.

Chemical Characters.—Before the blowpipe it melts into a greyish-white vesicular enamel; but the red-coloured Siberian tourmaline is infusible.

		Green Tourmaline from Brasil.
Constituent Parts.—	Silica,	40.
	Alumina,	39.
	Lime,	3.84
	Oxide of Iron,	12 5
	Oxide of Manganese,	2.
	Loss,	2.66—100

Vauquelin, Ann. de Chim. N. 88. p. 105.

Geognostic and Geographic Situations.—Tourmaline occurs in primitive rocks in Scotland, England, Germany, Norway, Italy, and many other countries.

Uses.—The green, blue, and brown varieties are sometimes cut and polished, and worn as ornamental stones.

Second Subspecies.

Common Schorl, *Jameson.*—Gemeiner Schorl, *Werner.*

External Characters.—Colour velvet-black, of various degrees of intensity. Occurs massive, disseminated, and frequently crystallized, in three, six, and nine-sided prisms, that present various acuminations, truncations, and bevelments. Occurs in granular and prismatic concretions. Internally its lustre is intermediate between shining and glistening, and is vitreous. Fracture intermediate between conchoidal and uneven. Opaque. Affords a grey streak.

		Common Schorl from Eibenstock.
Constituent Parts.—	Silica,	36.75
	Alumina,	34.50
	Magnesia,	0.25
	Oxide of Iron,	21.0
	Potash,	6.0 —98.50

Klaproth, Beitrage, b. 5. s. 148, 149.

Physical Characters.—Exhibits the same electrical properties as tourmaline.

Geognostic and Geographic Situations.—Occurs in primitive mountains in most extensive alpine districts in Europe; and also in Asia, Africa, and America.

Genus XI.—GARNET.

Tessular, pyramidal, prismatic. If red, the Sp. gr. =3.7. and more. If black, sp. gr.=3.9 and less. No pure vitreous lustre. If prismatoidal, the hardness is= 7 and more, and no pure vitreous lustre. Hardness ranges from 6 5 to 7.5. If 7.5, it is red or brown. Sp. gravity=3.3—4.3.

1. Pyramidal Garnet or Vesuvian, *Jameson.*—Pyramidaler Granat, *Mohs.*—Vesuvian, *Werner.*—Idocrase, *Hauy.*

Pyramidal. Pyramid=129° 30′, 74° 14′. Cleavage in the direction of the lateral planes of the prism; in the direction of the diagonals of the prism; and also in the direction of the terminal planes of the prism. Hardness =6.5. Sp. gravity=3 3—3 4.

External Characters.—Colours green and brown. Occurs massive, disseminated, and in granular concretions; but more frequently crystallized, in rectangular four-sided prisms, variously acuminated, truncated, and bevelled. Lateral planes of the prisms are longitudinally streaked; but the truncating and terminal planes are smooth. Externally the crystals are splendent; internally glistening, approaching to shining, and the lustre is vitreo-resinous. Fracture is small-grained uneven. Alternates from translucent to translucent on the edges, and refracts double.

Chemical Characters.—Before the blow-pipe it melts without addition into a yellowish and faintly translucent glass.

		Vesuvian of Vesuvius.
Constit. Parts.—	Silica,	35 5
	Lime,	33.0
	Alumina,	22.25
	Oxide of Iron,	7.5
	Oxide of Manganese,	0.25
	Loss,	1.5—100

Klaproth, *Beit.* b. ii. s. 32. & 38.

Geognostic and Geographic Situations.—Occurs in various primitive rocks, in Ireland, Italy, Norway, Switzerland, &c.

Uses.—At Naples it is cut into ring-stones, and is sold under various names: the green-coloured varieties are denominated Volcanic Chrysolite; and the brown, Volcanic Hyacinth.

Obervation.—The *Egeran* of Werner is a variety of this species.

2. Dodecahedral Garnet, *Jameson.*

Tessular. Cleavage dodecahedral. Hardness=6.5—7.5. Sp. gravity=3.5—4.3.

This species contains nine subspecies, viz. 1. Pyreneite; 2. Grossulare; 3. Melanite; 4. Pyrope; 5. Garnet; 6. Allochroite; 7. Colophonite; 8. Cinnamon-stone; 9. Helvin.

First Subspecies.

Pyreneite, *Jameson.*—Pyreneit, *Werner.*

External Characters.—Colour greyish-black. Occurs massive, and crystallized in the form of rhomboidal dodecahedrons. Externally glistening, inclining to shining, and metallic-like. Internally glistening and vitreous. Fracture small-grained uneven. Opaque.

Geognostic and Geographic Situations.—Occurs in primitive limestone in the Pic of Eres-Lids, near Bareges, in the French Pyrenees.

Second Subspecies.

Grossulare, *Jameson.*—Grossular, *Werner.*

External Characters.—Colour asparagus-green. Crystallized in acute double eight-sided pyramids, flatly acuminated on both extremities by four planes; the acuminating planes set on the alternate edges of the double eight-sided pyramid. Planes of the crystals are smooth.

Externally shining; internally shining, and lustre resinous. Fracture intermediate between conchoidal and uneven. Translucent.

Geognostic and Geographic Situations.—Occurs imbedded in small crystals, along with vesuvian, in a pale greenish-grey claystone, near the river Wilui in Siberia; also in the Bannat of Temeswar.

Third Subspecies.

Melanite. *Jameson.*—Melanit, *Werner.*

External Characters —Colour velvet-black. Generally crystallized in rhomboidal dodecahedrons, truncated on the edges. Internally shining, inclining to glistening, and resino-vitreous. Fracture conchoidal. Opaque.

Geognostic and Geographic Situations.—Occurs in primitive and secondary rocks in Italy, Germany, and Norway.

Fourth Subspecies.

Pyrope, *Jameson.*—Pyrope, *Werner.*

External Characters.—Colour dark blood-red. Occurs in roundish and angular grains. Lustre splendent, and vitreo-resinous. Fracture conchoidal. Is transparent, and refracts double.

Geognostic and Geographic Situation.—It occurs in serpentine and trap, in Bohemia.

Use.—This beautiful gem is employed in almost every kind of jewellery, and is generally set with a gold foil.

Fifth Subspecies.

Garnet, *Jameson.*

This subspecies is divided into two kinds, viz. Precious Garnet and Common Garnet.

First Kind.—Precious Garnet, *Jameson.*—Edler Granat, *Werner.*

External Characters.—All the colours of this gem are dark-red, which generally fall into blue. Occurs in roundish grains, and crystallized in rhomboidal dodecahedrons, and in the form of the leucite. Internally it is shining, bordering on splendent; and vitreous, inclining slightly to resinous. Fracture conchoidal. Sometimes occurs in lamellar distinct concretions. Alternates from completely transparent to translucent.

Constit. Parts.—Silica,	.	39 66
Alumina,	.	19 66
Black oxide of Iron,		39.68
Oxide of Manganese,		1 80—100.80

Berzelius, in Afhandlinger, vol. iv. p. 385.

Chemical Character.—Before the blowpipe it melts pretty easily into a black scoria or enamel.

Geognostic and Geographic Situations.—Occurs imbedded in primitive rocks, in Scotland, England, Ireland, Germany, Norway, Sweden, and many other countries.

Use.—This beautiful gem is not so highly valued at present as it was a century ago. The larger kinds are used as ring stones, and, after cutting and polishing, are set either *au jour*, or are provided with a silver or violet-blue foil.

Second Kind —Common Garnet, *Jameson.*—Gemeiner Granat, *Werner.*

External Characters.—Brown and green are its most common colours. Occurs most commonly massive: sometimes crystallized, and possesses all the figures of the precious garnet. Occurs in angulo-granular distinct concretions. Lustre shining, or glistening, very rarely splendent. Internally lustre glistening, seldom shining, and intermediate between resinous and vitreous. Fracture fine-grained uneven, sometimes slightly inclining to imperfect conchoidal, or to splintery.

Geognostic and Geographic Situations.—It occurs massive or crystallized in primitive rocks in Scotland, England, Ireland, Norway, Sweden, Germany, Italy, and many other countries.

Use.—On account of its easy fusibility and richness in iron, it is frequently employed as a flux in smelting rich iron-ores, and as an addition to poor ores.

Sixth Subspecies.

Allochroite, *Jameson.*—Allochroit, *Werner.*

External Characters.—Colours grey, brown, and green. Occurs massive. Internally glimmering, rarely glistening, and lustre resinous. Fracture uneven, sometimes even passing to conchoidal. Feebly translucent on the edges.

Geognostic and Geographic Situations.—It has hitherto been found only in Viuls iron-mine near Drammen in Norway, where it is associated with calcareous spar, reddish-brown garnet, and magnetic iron-ore.

Seventh Subspecies.

Colophonite, or Resinous Garnet, *Jameson.*

External Characters.—Colours brown, red, and green. Occurs massive, in angulo-granular concretions; and crystallized in rhomboidal dodecahedrons, either perfect, or truncated on the edges. Appears as if melted. Internally shining; externally splendent. Lustre resino-adamantine. Fracture imperfect conchoidal. Translucent, or only translucent on the edges.

Geognostic and Geographic Situations.—It occurs in beds of magnetic iron-ore, which are subordinate to gneiss, at Arendal in Norway; and in talc-slate at Salvagnengo in Piedmont. It is also found in the Island of Ceylon.

Eighth Subspecies.

Cinnamon Stone, *Jameson.*—Kanelstein, *Werner.*—Essonite, *Hauy.*

External Characters.—Principal colour intermediate between hyacinth-red and orange-yellow. Occurs massive, and in granular distinct concretions. Internally shining, approaching to glistening; and lustre resino-vitreous. An indistinct cleavage sometimes visible, indicating an oblique prism of 102° 40′. Fracture in every direction rather imperfect, and flat conchoidal. Transparent and semi-transparent; generally so impure and full of cracks, that faultless specimens rarely occur. Refracts single. Hardness 7, 7.5. Sp. gr. 3.5, 3.7.

Geognostic and Geographic Situation.—It is found in alluvial deposites, and associated with quartz, tabular spar, and iron-ore, in gneiss, in the island of Ceylon.

Use.—It is cut as a precious-stone, and, when free of flaws, is of considerable value.

Observation.—Appears to be a distinct species.

NINTH SUBSPECIES.

HELVINE, *Jameson*.—Helvin, *Werner*.

External Characters.—Colour wax-yellow. Occurs disseminated, and crystallized in tetrahedrons, which are perfect or truncated on the angles. Internally glimmering or shining. Externally vitreous; internally it inclines to resinous. Fracture small-grained uneven. Crystals strongly translucent.

Geognostic and Geographic Situation.—It occurs in gneiss, near Schwarzenberg in Saxony.

Observation.—Probably a distinct species.

3. PRISMATIC GARNET or GRENATITE, *Jameson*.—Prismatischer Granat, *Mohs*. Granatit, *Werner*. Staurotide, *Hauy*.

Prismatic. Prism=129° 30′. Cleavage prismatoidal, in the direction of the shorter diagonal of the prism. Hardness=7.0, 7.5. Sp. gr=3.3, 3.9.

External Characters.—Colour dark reddish-brown. Occurs only crystallized, and in the form of oblique four-sided prisms, sometimes truncated on the lateral edges. Internally the cleavage is shining and splendent; fracture glistening and glimmering, with a resino-vitreous lustre. Fracture small-grained uneven, which sometimes approaches to small conchoidal. Often opaque, sometimes translucent, and very rarely semi-transparent.

		St. Gothard.
Const. Parts.—	Alumina, . .	41.
	Silica, . .	37.5
	Oxide of Iron, .	18.25
	Oxide of Manganese,	0.5
	Loss, . .	2.75—100

Klap. Bullet des Scien. de la Soc. Phil. t. i. p. 171.

Geognostic and Geographic Situations.—The geognostic relations of this mineral are nearly the same with those of precious garnet. It occurs in Aberdeenshire, the Shetland Islands, county of Wicklow in Ireland, &c.

GENUS XII.—ZIRCON.

Pyramidal. Hardness=7.5. Sp. gr.=4.5, 4.7.

PYRAMIDAL ZIRCON, *Jameson*.—Pyramidaler, Zircon, *Mohs*.

Pyramidal. Pyramid=123° 19′; 84° 20′. Cleavage pyramidal, or in the direction of the lateral planes of the oblique prism.

This species is divided into two subspecies, Common Zircon, and Hyacinth.

FIRST SUBSPECIES.

COMMON ZIRCON, *Jameson*.—Zirkon, *Werner*.

External Characters.—Colour grey, also white, green, and brown; and rarely yellow, blue, and red. Occurs crystallized in rectangular four-sided prisms, acuminated with four or eight planes. Internally splendent, passing into shining, and lustre intermediate between adamantine and resinous. Fracture perfect and flat conchoidal. Alternates from transparent to opaque. Refracts double in a high degree.

Chemical Character.—It is infusible, without addition, before the blowpipe.

		Zircon of Ceylon.
Const. Parts.—	Zirconia, . .	69.00
	Silica, . .	26.50
	Oxide of Iron, .	0.50—96.00

Klaproth, Beit. i. s. 222.

SECOND SUBSPECIES.

HYACINTH, *Jameson*.—Hiacinth, *Werner*.

External Characters.—Colours red, brown, yellow, grey, green, and white. Occurs crystallized, in rectangular four-sided prisms acuminated with four planes, set on the lateral edges. Internally specular splendent, and lustre intermediate between resinous and vitreous. Fracture perfect and small conchoidal. Alternates from transparent to semi-transparent. Refracts double.

Geognostic and Geographic Situations of the Zircon species, including Common Zircon and Hyacinth.—It occurs in grains and crystals, imbedded in gneiss and syenite; also imbedded in basalt and lava, and dispersed through alluvial soil, in Shetland Islands, Sutherlandshire, Inverness-shire, Galloway, &c. The finest specimens are brought from the East, principally from Ceylon.

GENUS XIII.—GADOLINITE.

Three axes. Prismatic. Black. Streak greenish grey. Hardness=6.5—7.0. Sp. gr. 4.0—4.3.

This genus contains but one species, viz. Prismatic Gadolinite.

I. PRISMATIC GADOLINITE, *Jameson*.—Prismatischer Gadolonit, *Mohs*.—Gadolinit, *Karsten*.

Prism 100 nearly.

External Characters.—Colours velvet-black; very rarely hyacinth-red. Occurs massive and disseminated; the massive varieties sometimes composed of granular or prismatic concretions, the surfaces of which have frequently a whitish or bluish aspect, and vary from glistening to dull. It very rarely occurs crystallized in six-sided prisms. Internally shining; lustre resinous, inclining to vitreous. Fracture generally conchoidal; seldom uneven.

Constituent Parts.—Silica, 25,80; Yttria, 45.0; Oxide of Cerium, 16.69; Oxide of iron, 10.26; Volatile matter, 0.60. =98.35. *Berzelius*.

Geognostic and Geographic Situations.—Occurs in beds of felspar in mica-slate, at Ytterby near Waxholm in Roslagen, and in granite at Finbo near Fahlun, in Sweden.

ORDER VIII.—ORE.

If metallic, the colour is dark. If not metallic, lustre adamantine, or imperfect metallic. If the streak is yellow or red, the hardness =3.5 and more. If the specific gravity =4 8 and more, and the streak brown, or black, the hardness =5. and more, or very perfectly prismatoidal. Hardness =2.5.—7. If 4.5 and less, the streak is red, yellow, or black. If 6.5 and more, and white streak, the specific gravity=6.5 and more. Sp. gr. =3.4.—7.4.

GENUS I.—TITANIUM ORE.

Pyramidal, prismatic. Hardness =5.0,—6.5. Sp. gr. =3.4,—44. If less than 4.2, the streak is white.

I. Prismatic Titanium Ore, or Sphene, *Jameson*.—Prismatisches Titan-erz, *Mohs*.

Vertical prism =136° 50′. Horizontal prism in the direction of one of the diagonals, =120°. Streak white. Hardness =5.0.—5.5. Sp. gr. =3.4,—3.6.

This species is divided into two subspecies, viz. Common Sphene, and Foliated Sphene.

First Subspecies.

Common Sphene, *Jameson*.—Braun Manakerz, *Werner*. Titane Siliceo Calcaire, *Hauy*.

External Characters.—Colours brown, green, grey, and white. Occurs in granular distinct concretions, and crystallized in oblique four-sided prisms, variously modified by bevelments, truncations, and acuminations. Internally shining or glistening; lustre adamantine, sometimes inclining to resinous, sometimes to vitreous. Fracture imperfect conchoidal, which inclines to uneven. Alternates from opaque to translucent.

		St. Gothard.
Constituent Parts.—	Oxide of Titanium	33.3
	Silica, . .	28.0
	Lime, . .	32.2
	Water, . .	0—93.5

Cordier in Jour. des Mines, N. 73, 70.

Geognostic and Geographic Situations.—It occurs in small and very small crystals, imbedded in the syenite of the Criffle and other hills in Galloway; in the syenite of Inverary; and in various other quarters in Scotland.

Second Subspecies.

Foliated Sphene. *Jameson*.—Gelb Manakerz, *Werner*. Titane siliceo-calcaire, *Hauy*.

External Characters.—Occurs yellow, brown, and grey. Occurs massive, in straight lamellar concretions, and crystallized in the same figures as the preceding subspecies. Lustre on the cleavage splendent or shining; on the imperfect conchoidal and uneven fractures only shining or glistening, and resinous. Fracture imperfect conchoidal, inclining to uneven. Translucent, or only translucent on the edges.

Geognostic and Geographic Situations.—Occurs in primitive rocks in Italy, Bohemia, Norway, and other countries.

II. Prismato Pyramidal Titanium-Ore *Jameson*.—Prismato-Pyramidales Titan-erz. *Mohs*.

Pyramidal. Pyramid =117° 2′; 84° 48′. Most distinct cleavage in the direction of the lateral planes of the rectangular four-sided prism; and another less distinct, parallel with the diagonals of the prism. Streak brown. Hardness =6.0—6.5. Sp. gr. =4.2—4.4.

This species is divided into three subspecies, viz. Rutile, Iserine, and Menachanite.

First Subspecies.

Rutile, *Jameson*.—Rutil, *Werner*. Titane Oxide, *Hauy*.

External Characters.—Colours brown, red, and yellow. Occurs massive, disseminated, in membranes, and in four and six-sided prisms. Internally the lustre is intermediate between adamantine and semi-metallic, and is splendent on the surface of the cleavage, but only shining or glistening in the conchoidal or uneven fractures. Fracture uneven and conchoidal. Streak brown. Transparent or only translucent on the edges.

Geognostic and Geographic Situations.—It is found imbedded, in veins and in drusy cavities, in granite, syenite, gneiss, mica-slate, limestone, chlorite-slate, and hornblende slate, in Scotland, England, and in various countries on the continents of Europe, Asia, and America.

Second Subspecies.

Iserine, *Jameson*.—Iserin, *Werner*.

External Characters.—Colour iron-black, inclining to brownish-black. Occurs in rolled pieces. Internally it alternates from splendent to glistening, and the lustre is metallic. Fracture more or less perfect conchoidal. It is completely opaque.

Constituent Parts.—	Oxide of Titanium,	28
	Oxide of Iron .	72—100

Klaproth, Beit. b. v. s. 206.

Geognostic and Geographic Situations.—In sand of the river Iser.

Third Subspecies.

Menachanite, *Jameson*.—Menacan, *Werner*.

External Characters.—Colour greyish black, inclining to iron black. Occurs only in very small flattish angular grains, which have a rough glimmering surface. Internally it is glistening or glimmering, or the lustre is adamantine, passing into semi-metallic. Opaque.

Geognostic and Geographic Situations.—It is found, accompanied with fine quartz-sand, in the bed of a rivulet which enters the valley of Manaccan in Cornwall.

III. Pyramidal Titanium-Ore, or Octahedrite, *Jameson*.—Pyramidales Titan-erz, *Mohs*. Octaedrit, *Werner*.

Pyramid =97° 38′; 137° 10′. The least perfect cleavage in the direction of the faces of the pyramid; and the most perfect is parallel to the common base of the pyramids. Streak white. Hardness =5.5—6.0. Sp. gr. =3.8—3.9.

External Characters.—Colours blue and brown. Occurs crystallized in double four-sided pyramids. Internally splendent, and lustre adamantine, inclining to semi-metallic. Is strongly translucent or transparent.

Geognostic and Geographic Situations.—It is found at Bourg d'Oisans in Dauphiny, in primitive rocks, and in transition clay-slate in Norway.

Genus II. RED COPPER ORE.

Tessular. Hardness =3.5,—4. Sp. gr. =5.6,—6.0.

This genus contains but one species, viz. Octahedral Red Copper-Ore.

1. Octahedral Red Copper-Ore.—*Jameson*. Octaedrisches Kupfer-erz. *Mohs*.

Tessular. Cleavage octahedral. Streak red.

This species is divided into four subspecies, viz. Foliated Red Copper-ore, Compact Red Copper-ore, Capillary Red Copper-ore, and Tile-ore.

First Subspecies.

Foliated Red Copper-Ore, *Jameson*.—Blättriches Rothkupfererz, *Werner*.

External Characters.—Colour red. Occurs massive, disseminated, in membranes, corroded; also in granular concretions, and crystallized in variously modified octahedrons. Internally alternates from shining to glistening; lustre adamantine, inclining to semi-metallic. Fracture coarse and small-grained uneven. Ranges from opaque to translucent.

Second Subspecies.

Compact Red Copper-Ore, *Jameson.*—Dichtes Rothkupfererz, *Werner.*

External Characters.—Colour red. Occurs massive, disseminated, and in a kind of reniform shape. Internally glimmering, inclining to glistening; lustre semimetallic. Fracture even, inclining to flat conchoidal. Opaque.

Third Subspecies.

Capillary Red Copper-Ore, *Jameson.*—Haarformiges Roth Kupfererz, *Werner.*

External Characters.—Colour red. Occurs in small capillary crystals, also in thin tables, which are sometimes aggregated into amorphous and scopiform flakes. Shining. Lustre adamantine. Translucent.

			Cornwall.
Constituent Parts.	Copper	.	88.5
	Oxygen,	.	11.5——100.0

Chenevix, Phil. Trans.

Geographic and Geognostic Situations.—It occurs in veins in primitive transition and secondary rocks, as Cornwall, and in several mines on the continents of Europe, Asia, and America.

Fourth Subspecies.

Tile-Ore, *Jameson.*—Ziegelerz, *Werner.*

This subspecies is divided into two kinds, viz. Earthy Tile-ore, and Indurated Tile-ore.

First Kind. Earthy Tile-Ore, *Jameson.*—Erdiches Ziegelerz, *Werner.*

External Characters.—Colours red and brown. Occurs massive, disseminated, and incrusting copper-pyrites. Composed of dull dusty particles, which are more or less cohering. Soils slightly. Feels meagre.

Geognostic and Geographic Situations.—Occurs in veins in the Hartz, Tyrol, &c.

Second Kind.—Indurated Tile-Ore, *Jameson.*—Festes Ziegelerz, *Werner.*

External Characters.—Colours red, brown, grey, and black. Occurs massive, disseminated; also in curved lamellar and fibrous concretions. Internally glimmering or glistening, and resinous. Fracture conchoidal.

Constituent Parts.—Werner considers it to be an intimate combination of red copper-ore and brown ironochre. It contains from ten to 50 per cent. of copper.

Geognostic and Geographic Situations.—Occurs in veins in Cornwall and other countries.

Genus III. TIN-ORE.

Zinnerz, *Mohs.*

Pyramidal. Streak not black. Hardness =6.0—7.0. Sp. gr. =6.3—7.0.

This genus contains one species, viz. Pyramidal Tin-Ore.

1. Pyramidal Tin-Ore, *Jameson.*—Pyramidales Zinnerz, *Mohs.*

Pyramidal. Pyramid =133° 36′, 67° 42′. The most perfect cleavage is in the direction of the lateral planes of a rectangular four-sided prism, and another, less perfect, in the direction of the diagonals of the same prism Streak white and brown.

This species is divided into two subspecies, viz. Common Tin-Ore or Tinstone, and Cornish Tin-Ore.

First Subspecies.

Common Tin-Ore or Tintstone, *Jameson.*—Zinstein, *Werner.*

External Characters.—Colours brown, black, green, white, yellow, and red. Occurs most frequently crystallized, and in the form of rectangular prisms, variously modified by truncations and acuminations. Internally alternates from splendent to glistening. Lustre intermediate between resinous and adamantine. Fracture uneven, inclining to conchoidal. Alternates from semitransparent to opaque. Yields a greyish-white streak.

			From Alternon.
Constituent Parts.	Tin,	.	77.50
	Iron,	.	0.25
	Oxygen,	.	21.50
	Silica,	.	0.75——100

Klaproth, Beit. b. ii. s. 256.

Geognostic and Geographic Situations.—Occurs disseminated, in granite, gneiss, mica-slate, clay-slate, porphyry, and in an alluvial form, in what are in Cornwall named *Stream Works.* Cornwall contains the greatest European tin mines, and Banca in India the most extensive beyond Europe.

Second Subspecies.

Cornish Tin-Ore, or Wood-Tin, *Jameson.*—Kornisch Zinnerz, *Werner.*

External Characters.—Colour hair brown, woodbrown, and reddish-brown. Occurs reniform, botryoidal, and globular; and in fibrous distinct concretions. Internally feebly glistening or glimmering, and lustre resinous. Opaque. Streak grey, inclining to brown.

Geognostic and Geographic Situations.—It occurs loose, and in small quantities, along with stream tin, in alluvial deposites (stream-works) in Cornwall.

Genus IV. WOLFRAM ORE.

Scheel-erz, *Mohs.*

Prismatic. Hardness =5.0—5.5. Sp. gr. =7.1.—7.4.

This genus contains one species, viz. Prismatic Wolfram.

1. Prismatic Wolfram, *Jameson.*—Prismatisches Scheel-erz, *Mohs.*—Wolfram, *Werner.*

Prism =120°. Cleavages in the direction of the diagonals of the oblique four-sided prism. Streak dark reddish brown.

External Characters.—Colour black, and rarely a temper-steel tarnish. Occurs massive, and crystallized in oblique four-sided prisms, variously modified by truncation, bevelment, and acumination. Cleavage shining or splendent; fracture glistening; lustre resinous, inclining to adamantine. Fracture coarse and small grained uneven. Opaque.

Constituent Parts.—	Tungstic Acid		67.00
	Oxide of Manganese,		6.25
	Oxide of Iron,		18.10
	Silica,	. .	1.50—92.75

Vauquelin, in Journ. d. Min. N. 19. 18.

Geognostic and Geographic Situations.—Occurs in primitive rocks, in the island of Rona, one of the Hebrides, also in Cornwall and other counties.

Genus V. TANTALUM-ORE.

Tantal-Erz, *Mohs.*

Prismatic. Streak brownish black. Hardness = 6. Sp. gr. =6, 6.3.

This genus contains one species, viz. Prismatic Tantalum-ore.

1. Prismatic Tantalum-Ore.—Prismatisches Tantal-erz, *Mohs.*

Prismatic. Prism unknown.

External Characters.—Colours greyish and brownish black. Occurs massive, disseminated, and crystallized in oblique four-sided prisms, the dimensions of which are unknown. Externally and internally shining or glistening, and lustre resinous, inclining to semi-metallic adamantine. Fracture uneven, or conchoidal. Opaque.

		Finland.
Constituent Parts.—	Oxide of Tantalum,	83
	Oxide of Iron, .	12
	Oxide of Manganese,	8—103

Vauquelin, in Hauy, Tabl. p. 308.

Geognostic and Geographic Situations.—It occurs disseminated in a coarse red granite, at Brokärns.

Genus VI. URANIUM-ORE.

Uran-Erz, *Mohs.*

Form unknown. Streak black. Hardness = 5.5. Sp. gr. = 6.4,—6.6.

This genus contains one Species, viz. Indivisible Uranium-Ore.

1. Indivisible or Uncleavable Uranium-Ore, *Jameson.*—Untheilbares Uran-Erz, *Mohs.*—Uranpecherz, *Werner.*

Uncleavable. Reniform. Massive.

External Characters.—Colour black. Generally occurs massive, seldom disseminated, sometimes reniform; also in granular, lamellar, and prismatic concretions. Internally shining, lustre resinous, inclining to semi-metallic. Fracture conchoidal, which passes into coarse-grained uneven. Opaque.

		Joachimsthal.
Constit. Parts.—	Oxide of Uranium,	86.5
	Black Oxide of Iron,	2.5
	Galena or Lead-glance,	6.0
	Silica, . . .	5.0

Klaproth, Beit. b. ii. s. 221.

Geognostic and Geographic Situations.—It occurs principally in veins in primitive rocks in Cornwall, and other countries.

Genus VII. CERIUM-ORE.

Cerer-erz, *Mohs.*

Cleavage either prismatic or invisible. No metallic lustre. Streak white, grey. Hardness = 5.5. Sp. gr. = 3 5 —5.0.

1. Prismatic Cerium-Ore, *Jameson.*

Prism = 117°. Sp. gr. = 4.0—5.3.

External Characters.—Colour brownish-black. Occurs massive, and crystallized in oblique four, and in six-sided prisms. Internally shining, and resino-metallic. Fracture conchoidal. Opaque. Affords a greenish-grey coloured streak.

Geognostic and Geographic Situations.—Occurs in a granite rock in West Greenland, where it was first discovered by Professor Giesecké of Dublin.

2. Uncleavable Cerium-Ore, or Cerite, *Jameson.*—Untheilbares Cerer-erz, *Mohs.*

Massive. Hardness = 5.5. Sp. gr. = 4.6, 5 0.

External Characters.—Colour red and brown. Occurs massive, and disseminated. Internally glimmering and resinous. Fracture fine splintery. Opaque. Its streak is greyish-white.

Constituent Parts.—	Oxide of Cerium,	54.50
	Silica, . .	34.50
	Oxide of Iron,	3.50
	Lime, . .	1.25
	Water, .	5.00—98.75

Klaproth, Beit. b. iv. s. 147.

Geognostic and Geographic Situations.—Occurs in a bed of copper-pyrites, in Westmanland in Sweden.

Genus VIII. CHROME-ORE.

Chrom-erz, *Mohs.*

Prismatic. Streak brown. Hardness = 5.5. Sp. gr. = 4.4,—4.5.

This genus contains one species, viz. Prismatic Chrome-Ore.

1. Prismatic Chrome-Ore, *Jameson.*—Prismatisches Chrom-erz, *Mohs.*

Prismatic. Pyramid unknown. Cleavage prismatoidal.

External Characters.—Colour between steel-grey and iron-black. Occurs massive, disseminated, and in granular distinct concretions; also crystallized in oblique four-sided prisms, acuminated with four planes. Internally shining or glistening, and the lustre imperfect metallic. Fracture small and fine-grained uneven, sometimes passing into small and imperfect conchoidal. Opaque.

Physical Characters.—Some varieties are magnetical, others are not.

Chemical Characters.—It is infusible before the blowpipe. Melted with borax, it forms a beautiful green-coloured mass, very different from the dark green-coloured glass formed when borax and magnetic iron-ore are melted.

		Stiria.
Constituent Parts.—	Oxide of Iron,	33.00
	Oxide of Chrome,	55.50
	Alumina, .	6.00
	Silica, . .	2.00
	Loss by heating,	2.00—98.50

Klaproth, Beit. b. iv. s. 132.

Geognostic and Geographic Situations.—Occurs in serpentine and talc in the Shetland islands, and in various quarters in the continents of Europe, Asia, and America.

Uses.—When the chromic acid, which this ore contains, is combined with lead, it forms an uncommonly beautiful yellow pigment.

Genus IX.—IRON-ORE.

Eisen-erz, *Mohs.*

Tessular, rhomboidal, prismatic. Hardness = 5, 6.5. Sp. gr. = 3.8, 5.2. If the streak is brown, the Sp.

gr. is below 4.2, or above 4.8. If the streak is black, the Sp. gr. is above 4.8.

1. Octahedral Iron-Ore.—Octaedrisches Eisenerz, *Mohs*. Fer Oxydulé, *Hauy*.

Tessular. Cleavage octahedral. Streak black. Hardness = 5.5, 6.5. Sp. gr. = 4.8,—5.2.

This species is divided into two subspecies, viz. Common Magnetic Iron-Ore, and Granular Magnetic Iron-Ore.

First Subspecies.

Commom Magnetic Iron-Ore, *Jameson*.—Gemeiner Magneteisenstein, *Werner*.

External Characters.—Colour iron-black. Occurs massive, disseminated, in distinct concretions, and crystallized in octahedrons and rhomboidal dodecahedrons. Externally shining, glistening, or splendent. Internally intermediate between shining and glistening, and lustre metallic. Fracture uneven.

Physical Characters.—Highly magnetic, with polarity.

Constituent Parts.—	Peroxide of Iron,	69
	Protoxide of Iron,	31—100
		Berzelius.

Geognostic and Geographic Situations.—Occurs principally in beds, in primitive mountains in Norway, Sweden, Lapland, and other countries.

Uses.—When pure, it affords excellent iron.

Second Subspecies.

Granular Magnetic Iron-Ore, or Iron-Sand, *Jameson*.—Eisensand, *Werner*.

External Characters.—Colour very dark iron-black. Occurs in grains, and also in octahedral crystals. The grains have a feeble glimmering, and rough surface. Internally intermediate between shining and splendent, and lustre imperfect metallic. Fracture conchoidal.

Geognostic and Geographic Situations.—Occurs imbedded in trap rocks in different parts of Scotland, and in many countries on the continent of Europe.

2. Rhomboidal Iron-Ore, *Jameson*.—Rhomboedrisches Eisen-erz, *Mohs*. Fer Oligiste, *Hauy*.

Rhomboid = 85° 58′. Cleavage rhomboidal, and parallel with terminal planes of six-sided prisms. Streak red, reddish-brown. Hardness = 5.5.—6.5. Sp. gr. = 4.8.—5.2.

This species is divided into three subspecies, viz. 1. Specular Iron-ore, or Iron-glance, 2. Red Iron-ore, 3. Red Clay Iron-ore.

First Subspecies.

Specular Iron-Ore, *Jameson*.

This Subspecies is divided into two kinds, viz. Common Specular Iron-ore, and Micaceous Specular Iron-ore.

First Kind.—Common Specular Iron-Ore, *Jameson*.—Gemeiner Eisenglanz, *Werner*.

External Characters.—Colour dark steel-grey, which frequently borders on iron-black, and sometimes inclines to brownish-red. Occurs very frequently tarnished on the external surface. Occurs massive, disseminated, in concretions, and also crystallized in rhomboids and in six-sided pyramids. Internally glistening, but sometimes passes into shining and splendent, and the lustre metallic. Fracture conchoidal.

		From Grengesberget.
Constit. Parts.—	Reddish-brown Oxide of iron,	94.38
	Phosphate of Lime, . .	2.75
	Magnesia, . . .	0.16
	Mineral Oil, . . .	1.25
	Loss by heating, . .	0.50
		98.94

Hisinger, Afhandlingar, iii. p. 32, 33.

Geognostic and Geographic Situations.—Generally occurs in beds, in primitive and secondary rocks; as in England, and in many mines in the continents of Europe, Asia, and America.

Uses.—When it occurs in quantity, it is smelted as an ore of iron, and affords excellent malleable iron.

Second Kind.—Micaceous Specular Iron-Ore, *Jameson*.—Eisenglimmer, *Werner*.

External Characters.—Colour iron-black. Occurs most commonly massive and disseminated. Internally splendent, which in some varieties passes into shining, and the lustre is metallic. Slightly translucent on the edges; but translucent in thin plates, and it then appears blood-red.

Geognostic and Geographic Situations.—Generally occurs in primitive rocks, and it is met with in Scotland, England, Norway, Germany, &c.

Uses.—It melts better than common specular iron-ore, but requires a greater addition of limestone. The iron which it affords is sometimes cold-short, but is well fitted for cast-ware.

Second Subspecies.

Red Iron-Ore, *Jameson*.—Rotheisenstein, *Werner*.

This species is divided into four kinds, viz. Scaly Red Iron-ore, Ochry Red Iron-ore, Compact Red Iron-ore, and Fibrous Red Iron-ore or Red Hematite. Of these the principal kinds are the compact and fibrous.

Compact Red Iron-ore, *Jameson*.—Dichter Rotheisenstein, *Werner*.

External Characters.—Colour intermediate between dark steel-grey and blood-red. Occurs most commonly massive, sometimes also disseminated, specular, with impressions; and in supposititious crystals. Fracture usually uneven.

Constituent Parts.—	Oxide of Iron,	70.50
	Oxygen,	29.50—100.00

Bucholz in Ghelen's Journ. b iii. s. 158.

Geognostic and Geographic Situations.—Occurs in beds and veins in primitive mountains in England, Norway, Sweden, Germany, &c.

Uses.—It affords good cast and bar-iron.

Fibrous Red Iron-Ore, or Red Hematite, *Jameson*.—Rother Glaskopf, *Werner*.

External Characters.—Colours blood red and dark steel-grey. Occurs most frequently massive, reniform, botryoidal, stalactitic, and globular; also in fibrous and lamellar distinct concretions.

Const. Parts.—	Oxide of Iron, . .	90
	Trace of Oxide of Manganese,	
	Silica, ...	2
	Lime, ...	1
	Water, ...	3—96

Daubuisson, Ann. de Chimie, Sept. 1810.

Geognostic and Geographic Situations.—These are the same as the preceding.

Uses.—It affords excellent malleable and cast-iron.

THIRD SUBSPECIES.

RED CLAY IRON-ORE or STONE, *Jameson.*

This subspecies is divided into four kinds, viz. Ochry Red Clay Iron-ore, Columnar Red Clay Iron-ore, Lenticular Red Clay Iron-ore, and Jaspery Red Clay Iron-ore.

First Kind. OCHRY RED CLAY IRON-ORE, or RED CHALK. *Jameson* —Roethel, *Werner.*

External Characters.—Colour brownish-red. Occurs massive. Principal fracture glimmering; cross fracture dull. Principal fracture thick slaty; cross fracture fine earthy. Fragments sometimes tabular, and sometimes splintery.

Geognostic and Geographic Situations.—It occurs in thin beds in clay-slate and grey-wacke-slate in Hessia, Thuringia, &c.

Uses.—It is principally used for drawing. The coarser varieties are used by the carpenter, the finer by the painter.

Second Kind. COLUMNAR RED CLAY IRON-ORE, *Jameson.*—Stänglicher Thoneisenstein, *Werner.*

External Characters.—Colour brownish-red. Occurs massive, and in columnar distinct concretions.

Geognostic and Geographic Situations.—It is a rare mineral, and is in general a pseudo-volcanic production. It is found in Germany and other countries.

Third Kind. LENTICULAR RED CLAY IRON-ORE, *Jameson.*—Linsenförmiger Thoneisenstein, *Werner.*

External Characters.—Colours brownish-red and reddish-brown. Occurs massive, and in lenticular concretions.

Geognostic and Geographic Situations.—It occurs principally in beds in an amygdaloid, subordinate to clay-slate and grey-wacke in Bohemia.

Fourth Kind. JASPERY RED CLAY IRON-ORE, *Jameson.*—Jaspisartiger Thoneisenstein, *Werner.*

External Characters.—Colour reddish-brown. Occurs massive. Internally feebly glimmering, sometimes approaching to glistening. Fracture large and flat conchoidal.

Geognostic and Geographic Situations.—It occurs at Fischau in Austria, where it forms considerable beds in a flœtz or secondary formation.

3. PRISMATIC IRON-ORE, *Jameson.*—Prismatisches Eisen-erz, *Mohs.* Braun Eisenstein, *Werner.*

Prismatic. Pyramid unknown. Streak yellowish-brown. Hardness = 5.5. Sp. gr. = 3.8.—4.2.

This species is divided into four subspecies, Ochry Brown Iron-ore, Compact Brown Iron-ore, Fibrous Brown Iron-ore or Brown Hematite, Brown Clay Iron-ore. * Bog Iron-ore.

FIRST SUBSPECIES.

OCHRY BROWN IRON-ORE, *Jameson.* Ockriger Brauneisenstein, *Werner.*

External Characters.—Colour light yellowish-brown. Occurs massive and disseminated. Internally dull. Fracture coarse earthy. Soils slightly.

Geognostic and Geographic Situations.—It occurs along with the compact and fibrous subspecies, in England, Germany, France, &c.

Use.—It affords excellent bar-iron.

SECOND SUBSPECIES.

COMPACT BROWN IRON-ORE, *Jameson.* Dichter Brauneisenstein, *Werner.*

External Characters.—Colours yellowish-brown and clove-brown. Occurs massive, and disseminated; very rarely in supposititious crystals. Internally dull, or semimetallic glimmering. Fracture even, sometimes also fine-grained uneven. Streak yellowish-brown.

		Bergzabern.
Constit. Parts.—	Peroxide of Iron, .	84
	Water, . . .	11
	Oxide of Manganese, .	1
	Silica, ...	2—98

Daubuisson, Annal. de Chim.

Geognostic and Geographic Situations.—It occurs in the same geognostic and geographic situations as the following subspecies.

Uses.—It affords about 50 *per cent.* of Iron. It is easily fusible. It affords excellent bar-iron.

THIRD SUBSPECIES.

FIBROUS BROWN IRON-ORE, or BROWN HEMATITE, *Jameson.* Brauner Glaskopf, *Werner.*

External Characters.—Colour brown. Seldom occurs massive, more frequently stalactitic, coralloidal, reniform, botryoidal, tuberose; sometimes also cylindrical, fructicose, and in distinct concretions, which are fibrous, granular and lamellar. Internally glimmering; lustre intermediate between pearly and resinous.

		Fibrous Bergzabern.
Constit. Parts.—	Peroxide of Iron, .	79
	Water, . . .	15
	Oxide of Manganese,	2
	Silica, . . .	3—99

Geognostic and Geographic Situations.—Occurs in primitive, transition, and secondary mountains, in England, Germany, Italy, &c.

FOURTH SUBSPECIES.

BROWN CLAY IRON-ORE, *Jameson.*

This subspecies is divided into five kinds, viz. Common Brown Clay Iron-ore, Pisiform Brown Clay Iron-ore, Reniform Brown Clay Iron-ore, Granular Brown Clay Iron-ore, and Umber.

First Kind. COMMON BROWN CLAY IRON-ORE. *Jameson.*

External Characters.—Colours brown and yellow. Occurs massive. Internally dull or feebly glimmering. Fracture conchoidal; also even and uneven. Streak brown.

Constituent Parts.—	Oxide of Iron, .	69
	Oxide of Manganese,	3
	Water, . . .	13
	Silica, . . .	10
	Alumina, . .	3—98

Daubuisson, Annal. de Chim. Sept. 1810.

Geognostic and Geographic Situations.—It occurs in England; also in Saxony, Bohemia, Silesia, and Westphalia, in beds in secondary rocks.

Second Kind. PISIFORM BROWN IRON-ORE or PEA-ORE, *Jameson.* Bohnerz, *Werner.*

External Characters.—Colour yellowish-brown. Occurs in small spherical round grains, which are not hollow, and these are composed of concentric curved lamellar concretions.

Geognostic and Geographic Situations.—It occurs in hollows in secondary rocks, as at Galston in Ayrshire, and in many places on the Continent of Europe.

Uses.—It yields from 30 to 40 *per cent.* of Iron.

Third Kind. RENIFORM OR KIDNEY-SHAPED BROWN CLAY IRON-ORE, *Jameson.* Eisenniere, *Werner.*

External Characters.—Colour yellowish-brown. Occurs massive, in irregular single balls, also in reniform, lenticular and elliptical forms, which are sometimes hollow. These forms are composed of concentric lamellar concretions, which often include a loose nodule.

Geognostic and Geographic Situations.—It occurs imbedded in ironshot clay, in secondary rocks of different kinds, and also in loam and clay beds that lie over black coal.

Uses.—It is one of the best kinds of ironstone, yields an excellent iron, and is smelted in many places.

Fourth Kind. GRANULAR BROWN CLAY IRON-ORE, *Jameson.*

External Characters.—Colours yellowish and reddish brown. Occurs massive, and in small globular united grains.

Geognostic and Geographic Situations.—It occurs in beds between the red sandstone of the salt formation and the lias limestone. It often contains petrifactions of shells. It is found in Bavaria, Salzburg, the Tyrol, and France.

Uses.—It affords about 40 *per cent.* of good iron.

Fifth Kind. UMBER, *Jameson.*

External Characters.—Colours clove-brown and yellowish-brown. Occurs massive. Internally dull or glimmering, and resinous. Fracture flat conchoidal.

Geognostic and Geographic Situations.—It occurs in beds in the Island of Cyprus.

Use.—It is used as a pigment.

*BOG IRON-ORE, *Jameson.* Raseneisenstein, *Werner.*

There are three kinds of this ore, viz. Morass-ore, Swamp-ore, and Meadow-ore.

First Kind. MORASS-ORE, OR FRIABLE BOG IRON-ORE, *Jameson.* Morasterz, *Werner.*

External Characters.—Colour brown. Sometimes friable, sometimes nearly coherent. Coherent varieties occur massive, corroded, in grains, and sometimes tuberose. The friable is composed of dull dusty particles. Coherent varieties externally and internally dull. Fracture earthy.

Observations.—It is characterised by colour, dull earthy aspect, and low specific gravity.

Second Kind. SWAMP-ORE, OR INDURATED BOG IRON-ORE, *Jameson.* Sumpferz, *Werner.*

External Characters.—Colour yellowish-brown. Occurs corroded and vesicular, also amorphous. Internally dull, but the darker varieties glimmering, and sometimes even glistening. Fracture earthy, sometimes passing into fine-grained uneven. Specific gravity, 2.944, from Sprottau, *Kirwan.*

Observations.—It is distinguished from the preceding kind, by its greater specific gravity, and greater compactness.

Third Kind. MEADOW-ORE, OR CONCHOIDAL BOG IRON-ORE, *Jameson.* Weisenerz, *Werner.*

External Characters.—On the fresh fracture it is blackish-brown, which sometimes passes into brownish-black. Occurs massive. Internally shining; glistening; lustre resinous. Fracture conchoidal. Yields a light yellowish-grey streak.

Constituent Parts.

Oxide of Iron,	61.0
Oxide of Manganese,	7.0
Phosphoric Acid, with a trace of Sulphur,	2.5
Water,	19.0
Silica,	6.0
Alumina,	2.0—97.5

Daubuisson, Annal. de Chim. 1800.

Geognostic and Geographic Situations of Bog-iron ore.—It is found in various places in the Highlands of Scotland, in the Hebrides, and Orkney and Shetland Islands, in alluvial soil. Also abundantly on the continents of Europe and America.

Uses.—Affords good iron on smelting.

GENUS X. MANGANESE-ORE.

Mangan-erz, *Mohs.*

Prismatic. Hardness =2.5—6. Sp. gr. =4.3—4.8.

This genus contains but one species, viz. Prismatic Manganese ore.

1. PRISMATIC MANGANESE-ORE, *Jameson.*—Prismatisches Mangan-erz, *Mohs.*

Prism nearly 100°. Most perfect cleavage in direction of the longer diagonal.

This species contains three subspecies, viz. Grey Manganese-ore, Black Manganese-ore, and Scaly Brown Manganese-ore.

FIRST SUBSPECIES.

GREY MANGANESE-ORE, *Jameson.*—Grau Braunsteinerz, *Werner.*

External Characters.—Colour dark steel-grey, inclining more or less to iron-black. Occurs massive, in various particular external shapes, in fibrous and radiated concretions, and crystallized in four-sided prisms. Lustre shining, glimmering, and metallic; fracture conchoidal and earthy. Streak black.

Const. Parts.—Black Oxide of Manganese,		90.50
	Oxygen,	2.25
	Water,	7.00
	Klaproth,	100.

Geognostic and Geographic Situations.—Occurs in veins and imbedded masses in primitive rocks in Scotland, England, France, and Germany.

Uses.—It is added to glass, in small quantity, when we wish to destroy the brown colour which that material receives from intermixed inflammable substances, or in larger quantity, when we wish to give to it a violet blue colour. It affords a fine brown colour, which is used for painting on porcelain. It is employed in the laboratory, as the cheapest and most convenient material from which to procure oxygen gas. All the oxymuriatic acid used in bleacheries, and for the purpose of destroying contagious matter, is prepared from manganese, and the usual materials of muriatic acid.

SECOND SUBSPECIES.

BLACK MANGANESE-ORE, *Jameson.*

External Characters.—Colours bluish-black and steel-grey. Occurs massive, tuberose, fruticose, reniform, and botryoidal; also in fibrous and lamellar concretions. Internally glimmering, glistening, and metallic. Fracture conchoidal. Opaque. Streak blackish-brown.

Geognostic and Geographic Situations.—Occurs in veins in primitive, transition, and secondary rocks, in Saxony, Hanover, &c.

THIRD SUBSPECIES.

SCALY BROWN MANGANESE-ORE, *Jameson.*—Brauner Eisenrahm, *Werner.*

External Characters.—Colour intermediate between steel-grey and clove-brown. Occurs in crusts, massive, spumous, fruticose, and irregular dendritic. Friable, or friable passing into solid. Composed of scaly particles, which are intermediate between shining and glistening, with metallic lustre. Soils strongly. Feels greasy.

Geognostic Situation.—Occurs in drusy cavities in brown hematite.

Geographic Situation.—It is found near Sandlodge in Mainland, one of the Shetland Islands; and in various iron mines on the Continent of Europe.

ORDER IX.—NATIVE METALS.

Metallic. Not black. If grey, is ductile; and Sp. gr. =7.4. and more. Hardness =0. — 4, or malleable. Sp. gr. =5.7—2.0.

GENUS I. ARSENIC.

Form unknown. Tin white. Hardness =3.6. Sp. gr. =5.7—5.8.

1. NATIVE ARSENIC, *Jameson.* Gediegen Arsenik, *Werner and Mohs.*

Reniform and massive.

External Characters.—Colour tin white. Internally, on the fresh fracture, usually glistening, inclining to glimmering, sometimes to shining, and the lustre metallic. Fracture small, and fine-grained uneven.

Chemical Characters.—Before the blowpipe it yields a white smoke, diffuses an arsenical odour, burns with a blue flame, is gradually and almost entirely volatilized, and deposits a white coating on the coal.

Const. Parts.—It usually contains a small portion of iron, and when it occurs with gold or silver, a little gold or silver.

Geognostic and Geographic Situations.—It occurs in veins in primitive rocks, as in gneiss, mica-slate, and clay-slate, and less frequently in transition and secondary rocks, in Norway, Germany, France, Spain, &c.

GENUS II. TELLURIUM.

Form unknown. Tin-white. Hardness = 2—2.5. Sp. gr. =6.1, 6.2.

This genus contains one species, viz. Native Tellurium.

1. NATIVE TELLURIUM, *Jameson.* Hexahaedrisches Tellur, *Mohs.* Gediegen Sylvan, *Werner.*

Massive.

External Characters.—Colour tin-white. Occurs massive. Internally shining, and lustre metallic.

Constit. Parts.—	Tellurium,	92.55
	Iron,	7.20
	Gold,	0.25—100.00

Klaproth, Beit. b. iii. s. 8.

Geognostic and Geographic Situations.—It occurs in veins in grey-wacke, in Transylvania.

GENUS III. ANTIMONY.

Tessular, prismatic. Not ductile. White. Hardness =3—3.5. Sp. gr. =6.5—10.

This Genus contains two species, viz. Dodecahedral Antimony, and Octahedral Antimony.

1. DODECAHEDRAL ANTIMONY, *Jameson.*—Dodecaedrisches Spiesglas, *Mohs.* Gediegen Spiesglas, *Werner.*

Tessular. Cleavage octahedral and dodecahedral. Hardness =3—3.5. Sp. gr. =6.5—6.8.

External Characters.—Colour perfect tin-white. Occurs massive, disseminated, reniform; also in granular and lamellar distinct concretions. Crystallized, in octahedrons and rhomboidal dodecahedrons. Splendent and metallic.

Geognostic and Geographic Situations.—It is found in argentiferous veins in the gneiss mountain of Chalanches in Dauphiny.

2. OCTAHEDRAL ANTIMONY, *Jameson.*—Octaedrisches Spiesglas, *Mohs.*

Tessular. Cleavage octahedral. Hardness 3.5. Sp. gr. =8.9,—10.

Two Subspecies, viz. 1. Antimonial Silver, 2. Arsenical Silver.

FIRST SUBSPECIES.

ANTIMONIAL SILVER, *Jameson.*—Spiesglas Silber, *Werner.*

External Characters—Colour intermediate between silver-white and tin-white. Occurs massive, and crystallized in oblique four and in six-sided prisms. Internally shining and splendent, with metallic lustre.

Geognostic and Geographic Situations.—It occurs in veins, in primitive and transition rocks, in Germany and France.

Observations.—The oblique prism, if accurately given, would refer this subspecies to the prismatic series.

SECOND SUBSPECIES.

ARSENICAL SILVER, *Jameson.* Arsenik Silber, *Werner.*

External Characters.—Colour on the fresh surface tin-white, which tarnishes greyish-black. Occurs massive, reniform, and in lamellar concretions. Internally glistening and metallic. Fracture uneven.

Const. Parts.	Arsenic,	35.00
	Iron,	44.25
	Silver,	12.75
	Antimony,	4.00—96.00

Klaproth, Beit. b. i. s. 187.

Geognostic and Geographic Situations.—It occurs in veins in primitive and transition rocks, in Germany and Spain.

GENUS IV.—BISMUTH.

Tessular. Silver-white, inclining to red. Hardness =2.0,—2.5. Specific gravity=8.5, 9.

This genus contains one species, viz. Octahedral Bismuth.

1. OCTAHEDRAL BISMUTH, *Jameson.* Octaedrisches Wismuth, *Mohs.* Gediegen Wismuth, *Werner.*

Tessular. Cleavage octahedral.

External Characters.—Colour silver-white, which inclines to red. Seldom massive, generally disseminated, and in leaves having plumosely-streaked surfaces, and crystallized in octahedrons, cubes, and tetrahedrons. Internally splendent, and lustre metallic. Malleable.

Geognostic and Geographic Situations.—It occurs in veins in primitive rocks in Cornwall, and other countries.

Uses.—It enters as an ingredient into the composition of printing types, and of pewter; is used as solder, in the construction of mirrors, and for the refining of gold and silver; its oxide is used as a white pigment, as an essential ingredient in a kind of salve, which is used for giving a black colour to the hair, and as an ingredient in sympathetic ink. All the bismuth of commerce is obtained from Saxony.

Genus. V. MERCURY.

Tessular, liquid. Not malleable. White. Hardness =0—3. Specific gravity=10.5—15.

This genus contains two species, viz. 1. Fluid Mercury, 2. Dodecahedral Mercury.

1. Liquid Native Mercury. *Jameson.* Tropfbares Gediegen Quecksilber, *Mohs.* Gediegen Quecksilber, *Werner*

Liquid. Tin-white. Hardness=0. Specific gravity=12—15.

External Characters.—Colour tin-white. Perfectly liquid. Splendent, and lustre metallic.

Geognostic and Geographic Situations.—This mineral occurs principally in rocks of the coal formation, and either disseminated, or in veins traversing them, as in Spain and Germany.

2. Dodecahedral Mercury, or Native Amalgam, *Jameson.* Natürliches Amalgam, *Werner.*

Tessular. No cleavage. Silver-white. Hardness= 1—3 Specific gravity=10 5—12.5

External Characters.—Colour silver-white. Occurs usually in small roundish portions; and crystallized in rhomboidal dodecahedrons. Internally shining and metallic. Fracture small-grained uneven. When pressed between the fingers, or cut with a knife, it emits a creaking sound like artificial amalgam.

Constituent Parts.—Mercury . 74
Silver . 25—99
Heyer, in Crell's Annalen, 1790, b. ii. s. 36. 44.

Geognostic and Geographic Situations.—It is generally associated with native mercury and cinnabar. It is found at Moschellandsberg in Deux-Ponts; and, it is said, also at Rosenau in Hungary.

Genus VI. SILVER.

Tessular. Malleable. Silver-white. Specific gravity=10—10.5.

1. Hexahedral Silver, *Jameson.* Hexaedrisches Silber. *Mohs.*

Tessular. No cleavage.

This species is divided into two subspecies, viz. Common Native Silver, and Auriferous Native Silver.

First Subspecies.

Common Native Silver, *Jameson.*

External Characters.—Colour pure silver-white. Seldom occurs massive, more frequently disseminated, and in various particular external shapes, or crystallized in cubes, octahedrons, rhomboidal, dodecahedrons, and tetrahedrons. Lustre splendent to glimmering. Fracture fine hackly.

Geognostic and Geographic Situations.—Occurs in veins in various silver-mines in Europe, Asia, Africa, and America.

Uses.—Its various uses, in coinage, and for other useful and ornamental purposes, will be considered in a separate article.

Second Subspecies.

Auriferous Native Silver, *Jameson.* Guldischesgediegen Silber. *Werner*

External Characters.—Colour intermediate between brass-yellow and silver-white.

Constituent Parts. Silver . 72.00
Gold . . 28.00—100 00
Fordyce. Phil. Trans. 1799, p. 523.

Geognostic and Geographic Situations.—It occurs in veins in primitive rocks at Kongsberg in Norway; at Rauris in Salsburg; and at Schlangenberg in Siberia.

Genus VII. GOLD.

Tessular. Yellow. Specific gravity=12—20.

This genus contains only one species, viz. Hexahedral Gold.

1. Hexahedral Gold *Jameson.* Hexaedrisches Gediegen Gold, *Mohs.* Gediegen Gold, *Werner.*

Tessular. No cleavage.

External Characters.—Colour perfect gold-yellow, which varies in intensity; in some varieties inclines to brass-yellow. Seldom occurs massive, often disseminated, and sometimes crystallized in octahedrons, cubes, rhomboidal dodecahedrons, and tetrahedrons. Internally shining, glistening, and metallic. Fracture hackly.

Geognostic and Geographic Situations.—It occurs in veins, and disseminated in primitive transition and secondary rocks, abundantly in alluvial deposites, and is not confined to any particular quarter of the globe, being found in Europe, Asia, Africa, and America.

Genus VIII. PLATINA.

Form unknown. Steel-grey. Sp. gr. = 16—20.

1. Native Platina.—*Jameson.*—Gediegen Platin, *Werner*

In grains and rolled pieces.

External Characters.—Colour very light steel-grey, which approaches to silver-white. Occurs in grains and rolled pieces. Roundish. Externally shining, glistening, or glimmering, and lustre metallic.

Geognostic and Geographic Situations.—Occurs principally in alluvial deposites in South America.

Genus IX. IRON.

Tessular. Pale steel-grey. Sp. gr.=7.4—7.8.

This genus contains one species, viz. Octahedral Iron.

1. Octahedral Iron.—*Jameson.*—Octaedrisches Eisen, *Mohs.*—Gediegen Eisen, *Werner.*

Tessular. No cleavage.

This species is divided into two subspecies, viz. Terrestrial Native Iron, and Meteoric Native Iron.

First Subspecies.

Terrestrial Native Iron, *Jameson.*—Tellureisen, *Werner.*

External Characters.—Colour steel-grey. Occurs massive, in plates, and in leaves. Internally glistening, and lustre metallic. Fracture hackly.

Constituent Parts.—Iron,	. .	92.50
Lead,	. .	6.00
Copper,	.	1.50—100.00

Klaproth, Beit. b. iv. s. 106.

Geognostic and Geographic Situation.—It is said to have been found associated with brown ironstone, sparry iron, and heavy-spar, at Kamsdorf in Saxony.

SECOND SUBSPECIES.

METEORIC NATIVE IRON, *Jameson.*—Meteoreisen, *Karsten.*

External Characters.—Colour pale steel-grey. Occurs ramose, imperfect globular, and disseminated in meteoric stones. Internally intermediate between glimmering and glistening, and lustre metallic. Fracture hackly. Yields a splendent streak. It is flexible, but not elastic.

		Agram.
Constituent Parts.—Iron,	.	96.5
Nickel,	.	3 5—100.0

Klaproth, Beit. b. iv.

Geographic Situation.—This subspecies of iron falls from the air in all parts of the world, and appears to be formed in the atmosphere by some process hitherto unknown to us.

GENUS X. COPPER.

Tessular. Copper red. Sp. gr. = 8.4 — 8.9.

1. OCTAHEDRAL COPPER, *Jameson.*—Octaedrisches Kupfer, *Mohs.* Gediegen Kupfer, *Werner.*

Tessular. No cleavage.

External Characters.—Colour copper-red. Occurs massive, disseminated, in various particular forms, and crystallized in cubes, octahedrons, and rhomboidal dodecahedrons. Internally glistening, and lustre metallic. Fracture hackly.

Geognostic and Geographic Situations.—It occurs in veins, and imbedded in various primitive, transition, and secondary rocks; also in large blocks in alluvial districts in Europe, Asia, Africa, and America.

ORDER X. PYRITES.

Metallic. Hardness = 3.5—6.5. If hardness 4.5, and less, the sp. gr. is less than 5. Sp. gr. = 4.1 — 7.7. If 5 3, and less, it is yellow-red.

GENUS I. NICKEL PYRITES, OR COPPER-NICKEL, *Jameson.*—Nickelkies, *Mohs.*

Prismatic. Pyramid unknown. Hardness=5—5.5. Sp. gr. =7 5—7.7.

This Genus contains one species, viz. Prismatic Nickel Pyrites.

1. PRISMATIC NICKEL PYRITES, *Jameson.*—Prismatischer Nickelkies, *Mohs.* Kupfer Nickel, *Werner.*

Prismatic. Pyramid unknown. Copper-red.

External Characters.—Colour copper-red. Occurs most frequently massive and disseminated; seldom in particular external forms, and rarely crystallized in oblique four-sided prisms. Internally alternates from shining to glistening, and lustre metallic. Fracture conchoidal, sometimes passing into uneven.

Constit. Parts.—It is a compound of Nickel and Arsenic, with accidental intermixtures of cobalt, iron, and sulphur.

Geognostic and Geographic Situations.—It occurs in primitive, transition, and secondary rocks, in Scotland, and in several different mining districts in Germany and Spain.

GENUS II. ARSENICAL PYRITES.

Prismatic. If white, the sp. gr. 6 2 and less; if grey, sp. gr. above 6.8. Hardness = 5—6. Sp. gr. = 5.7—7.4.

1. PRISMATIC ARSENICAL PYRITES, *Jameson.* Prismatischer Arsenikkies, *Mohs.* Arsenikkies, *Werner.*

Prism unknown. Cleavage unknown. Steel-grey. Hardness = 5.0—5.5 Sp. gr. = 6.9—7.4.

External Characters.—Colour pale steel-grey. Occurs massive, and in the form of oblique four-sided prisms. Lustre metallic and shining.

2. DI-PRISMATIC ARSENICAL PYRITES, *Jameson.*—Di-prismatischer Arsenikkies, *Mohs.*

Prismatic. Hardness=5.5—6.0. Sp. gr.=5.7—6.2.

External Characters.—Colour silver-white. Occurs massive, and disseminated; also in prismatic distinct concretions, and crystallized in oblique four-sided prisms, variously modified by bevelments and truncations. Externally shining or splendent; internally shining, seldom glistening, and lustre metallic. Fracture uneven.

Geognostic and Geographic Situations.—It occurs in primitive, transition, and secondary rocks in Scotland, England, Saxony, Spain, and other countries.

Use. It is from this ore that the White Oxide of Arsenic is principally obtained, and Artificial Orpiment is also prepared from it. A variety named Argentiferous contains a portion of silver.

GENUS III. COBALT-PYRITES.

Tessular. Hardness = 5.5. Sp. gr. 6, = 6 6.

1. HEXAHEDRAL COBALT-PYRITES, OR SILVER-WHITE COBALT, *Jameson.* Hexaedrischer Kobalt-Kies, *Mohs.* Glanz Kobold, *Werner.*

Tessular. Cleavage hexahedral and perfect. White, inclining to red. Hardness = 5.5. Sp. gr. = 6.1—6.3.

External Characters.—Colour silver-white, slightly inclining to copper-red. Occurs commonly massive, and disseminated; also crystallized in cubes, octahedrons, pentagonal dodecahedrons, and icosahedrons. Internally shining and glistening, and lustre metallic. Fracture conchoidal.

Geognostic and Geographic Situations.—It occurs in primitive rocks, in Norway, Sweden, and Silesia.

Use. This is one of the most common species of cobalt, and is that from which the cobalt of commerce is principally obtained.

2. OCTAHEDRAL COBALT-PYRITES, *Jameson.* Octaedrischer Cobalt-Kies, *Mohs.*

Tessular. Cleavage tessular. White, inclining to steel-grey. Hardness = 5.5. Sp. gr. = 6—6.6.

External Characters.—Colours tin-white, inclining more or less to steel-grey. Occurs massive, in various particular external forms, in radiated and lamellar concretions, and crystallized in cubes, octahedrons, and rhomboidal dodecahedrons. Lustre varies, from splendent to glimmering, and is metallic. Fracture uneven, and conchoidal.

		From Riegelsdorf.
Const. Parts.—Arsenic,	.	74.2174
Cobalt, .	.	20.3135
Iron, .	.	3.4257
Copper, .	.	0.1586
Sulphur,	.	0.8860—100

Strohmeyer.

Geognostic and Geographic Situations.—It occurs in veins and beds in primitive, transition, and secondary rocks, and is found in Cornwall, Germany, France, Poland, Norway, and Sweden.

Genus IV. IRON PYRITES.

Tessular, rhomboidal, prismatic. Yellow. Hardness =3.5—6.5. Sp. gr.=4.4—5.

1. Hexahedral Iron-Pyrites, or Common Iron-Pyrites, *Jameson.*—Hexahaedrischer Eisen-Kies, *Mohs.* Gemeiner Schwefelkies, *Werner.*

Tessular. Cleavage hexahedral. Bronze yellow. Hardness=6—6.5. Sp. gr.=4.7—5.

External Characters.—Colour bronze-yellow. Occurs most commonly massive, disseminated, and globular; also in distinct concretions, and crystallized, in cubes, octahedrons, and in the leucite-form. Internally shining and glistening, and lustre metallic. Fracture uneven, and sometimes conchoidal.

Geognostic and Geographic Situations.—It occurs in primitive, transition, and secondary mountains, in every country.

Uses.—It is never worked as an ore of Iron; it is principally valued on account of the sulphur which can be obtained from it by sublimation, and the iron-vitriol which it affords by exposure to the air, either with or without previous roasting.

2. Prismatic Iron-Pyrites, or Radiated Pyrites, *Jameson.* Prismatischer Eisenkies, *Mohs.*

Prism=106° 36′. Cleavage the same. Bronze yellow. Hardness=6, 6.5. Sp. gr.=4.7—5.

External Characters.—Colour bronze-yellow. Occurs massive, in various particulars, external shapes, in radiated fibrous and lamellar concretions, and crystallized in oblique four-sided prisms, variously modified by bevelling and truncating planes. Lustre varies from shining to glimmering, and is metallic. Fracture uneven, or conchoidal.

Constit. Parts.—Sulphur,	.	53.60
Iron,	.	46.40—100

Hatchett, Phil. Trans. for 1804.

Geognostic and Geographic Situations.—It occurs in primitive, transition, secondary, and alluvial formations; and the different principal varieties are met with in England, Germany, Spain, and other countries.

3. Rhomboidal Iron Pyrites, or Magnetic Pyrites, *Jameson.* Magnetkies, *Werner.*

Di-rhomboidal. Rhomboid unknown. Cleavage in the direction of the terminal planes of a regular six-sided prism; another less distinct parellel with the lateral planes of a six-sided prism. Colour bronze-yellow, inclining to copper-red. Hardness=3.5—4.5. Sp. gr.=4.4—4.7.

External Characters.—Colour intermediate between bronze-yellow and copper-red. Occurs massive, disseminated, in coarse granular concretions; and very rarely crystallized in six-sided prisms and six-sided pyramids. Internally splendent, to glistening, and lustre metallic. Fracture conchoidal, or uneven.

Geognostic and Geographic Situations.—It occurs in beds, and imbedded in primitive and transition mountains along with common iron-pyrites, magnetical iron-ore, and blende, in Scotland, Wales, Germany, &c.

Genus V. COPPER-PYRITES.

Many axes. Cleavage tessular. Brass yellow. Steel grey. Iron black. Hardness=3.0—4.0. Sp. gr.=4.1—4.9.

This genus contains two subspecies, viz. Octahedral Copper-Pyrites, and Tetrahedral Copper-Pyrites.

1. Octahedral Copper-Pyrites, or Yellow Copper Pyrites, *Jameson*—Octaedrischer Kupferkies, *Mohs.*—Kupferkies, *Werner.*

Tessular. Cleavage probably octahedral. Brass yellow. Hardness=3.0—4.0. Sp. gr.=4.1—4.3.

External Characters.—Colour brass-yellow. Occurs massive, disseminated, in various particular external forms, and crystallized in octahedrons and tetrahedrons. Internally shining, which in some varieties passes into glimmering. Lustre metallic. Fracture commonly uneven, sometimes even and conchoidal.

		Cornwall.	
Constit. Parts.—Copper,	.	30	
Iron, .	.	53	
Sulphur,	.	12—95	*Chenevix.*

Geognostic and Geographic Situations.—Is one of the most abundant metalliferous minerals; occurs in almost every kind of repository, in all the great classes of rocks, and has a very extensive geographical range.

Uses.—Nearly one-third of the copper which is obtained by metallurgic operations is extracted from this species.

2. Tetrahedral Copper-Pyrites, *Jameson.*—Tetraedrischer, Kupferkies, *Mohs.*

Tessular. Cleavage probably octahedral. Steel-grey and iron-black. Hardness=3.0—4.0. Sp. gr.=4.4—4.9.

This species is subdivided into two subspecies, viz. Grey Copper and Black Copper.

First Subspecies.

Grey-Copper, *Jameson.*—Fahlerz, *Werner.*—Cuivre gris arsenifère, *Hauy.*

External Characters.—Colour steel-grey. Occurs massive, disseminated, and crystallized in tetrahedrons variously modified. Internally glistening and metallic lustre. Fracture uneven, sometimes conchoidal.

		Freyberg.
Constituent Parts.—Copper,	.	42.50
Iron,	.	27.60
Sulphur,	.	10.00
Arsenic,	.	15.60
Silver,	.	0.90
Antimony,	.	1.50—98.00

Klaproth, Beit. b. iv. s. 52.

Geognostic and Geographic Situations.—It occurs in beds and veins, in primitive, transition, and secondary rocks, in different parts of Scotland and England, and also in many mining districts in other countries.

Uses.—It is valued as an ore of copper; and when it contains silver, is worked as an ore of that metal.

Second Subspecies.

Black Copper, *Jameson.*—Schwarzerz, *Werner.*—Cuivre gris antimonifère, *Hauy.*

External Characters.—Colour iron-black, which sometimes inclines to steel-grey. Occurs massive, disseminated, and crystallized in tetrahedrons variously modified. Internally shining and splendent. Lustre metallic. Fracture conchoidal.

		Kapnik in Transylvania.
Constit. Parts.—Copper,	.	37 75
Antimony,	.	22 00
Sulphur,	.	28.00
Silver,	.	0.25
Iron, .	.	3.25
Zinc, .	.	5.00
Loss, .	.	3.75—100.00

Klaproth, Beit. b. iv. s. 56, 68, 73, and 80.

Geognostic and Geographic Situations.—Occurs in veins that traverse transition rocks at Zilla, in the Clausthal in the Hartz, and in other districts.

Use.—It is worked, both as an ore of copper and as an ore of silver.

Genus VI.—TIN-PYRITES.

Steel-grey, inclining to brass-yellow. Sp. gr.=4.3—5.0.

This genus contains but one species, viz. Common Tin Pyrites.

I. Common Tin Pyrites, *Jameson.*—Zinnkies, *Wer.*

External Characters.—Massive. Colour intermediate between steel-grey and brass-yellow. Occurs massive and disseminated. Internally glistening or shining, and lustre metallic. Fracture uneven, and sometimes conchoidal.

Constituent Parts.—Tin,	.	26.50
Copper,	.	30.00
Iron, .	.	12.00
Sulphur,	.	30.50—99

Klaproth, Beit. b. v. s. 230.

Geognostic and Geographic Situations.—It has been hitherto found only in Cornwall, where it occurs in primitive rocks.

Order IV.—GLANCE.

Metallic. Grey, black. Hardness=1—4. Sp. gr. =4—7.6. If the specific gravity is under 5, with single imperfect cleavages, the colour is lead-grey. If above 7.4, is lead-grey.

Genus I.—COPPER-GLANCE, or VITREOUS COPPER, *Jameson.*

Kupfer-Glanz, *Mohs.*

Cleavage rhomboidal. Blackish lead-grey. Sectile, and nearly malleable. The intensity of the lustre increased in the streak. Hardness=2.5—3.0. Sp. gr.= 5.5—5 8.

This genus contains one species, viz. Rhomboidal Copper glance. * Variegated Copper.

I. Rhomboidal Copper Glance, or Vitreous Copper Ore, *Jameson.*—Kupferglas. *Werner.*

Rhomboid unknown. Cleavage in the direction of lateral planes of a six-sided prism.

External Characters.—Colour blackish lead-grey. Occurs massive, disseminated, and crystallized on six-sided prisms and six-sided pyramids. Internally shining, glistening and glimmering, and metallic. Fracture uneven and conchoidal.

		Siberia.
Constituent Parts.—Copper,	.	78.05
Iron, .	.	2.25
Sulphur,	.	18.50
Silica,	.	0.75—100.00

Klaproth, Beit. b. ii. s. 179.

Geognostic and Geographic Situations.—It occurs in veins and beds in primitive rocks; also in beds in bituminous marl-slate, and in flœtz amygdaloid; and is found in Scotland, England, Germany, Sweden, Hungary, &c.

* Variegated Copper, *Jameson.*—Buntkupfererz, *Werner.*

External Characters.—Its fresh colour is intermediate between copper-red and pinchbeck-brown: it, however, soon acquires a variegated tarnish. Occurs massive, disseminated, and crystallized in six-sided prisms. Internally shining or glistening, and lustre metallic. Fracture conchoidal.

		From Rudelstadt in Silesia.
Constituent Parts.—Copper,	.	58
Sulphur,	.	19
Iron, .	.	18
Oxygen, .	.	5—100

Klaproth, Beit. b. ii. s. 286.

Geognostic and Geographic Situations.—It occurs in veins in primitive, transition, and secondary rocks, in various mining countries, as Cornwall, Arendal, Kongsberg, Thuringia, &c.

Uses.—Copper is extracted from it, but it is not so easily reduced as copper-glance. It yields from 50 to 70 *per cent.* of copper.

Genus II.—SILVER-GLANCE, or VITREOUS SILVER, *Jameson.*

Silber-Glanz, *Mohs.*

Cleavage rhomboidal, or not discernible. Blackish lead-grey, and iron-black. If blackish lead-grey, the specific gravity=6.9 and more. Hardness 2.0—2.5. Sp. gr.=5.7—7.2.

This genus contains two species, viz. Hexahedral Silver Glance, and Rhomboidal Silver Glance.

I. Hexahedral Silver Glance, *Jameson.* Hexaedrischer Silber Glanz, *Mohs.*

Tessular. Cleavage not discernible. Sp. gr.=6.9—7.2.

External Characters.—Colour dark blackish lead-grey. Generally occurs massive, sometimes in various particular external shapes, and crystallized in cubes, octahedrons, and rhomboidal dodecahedrons. Externally shining and glistening. Internally shining and glistening, and lustre metallic. Fracture uneven, conchoidal. Completely malleable. Flexible, but not elastic.

	From Himmelsfürst.
Constituent Parts.—Silver,	85
Sulphur,	15—100. *Klaproth.*

Geognostic and Geographic Situations.—It is one of the most frequent of the ores of silver, and there are few formations of that metal which do not contain it. It occurs in Scotland, England, Germany, and many other mining countries.

Uses.—It is highly valued as an ore of silver.

II. Rhomboidal Silver Glance, or Brittle Silver Glance, *Jameson.*—Sprödglaserz, *Werner.*

Rhomboid unknown. Sp. gr.=5.7—6.1.

External Characters.—Colour intermediate between iron-black and blackish lead-grey. Generally disseminated, and sometimes crystallized in equiangular six-sided prisms, and six-sided pyramids. Externally highly splendent. Internally shining, inclining to glistening, and lustre metallic. Fracture alternates from small conchoidal to fine-grained uneven. Lustre not increased in the streak. Sectile.

Constit. Parts.—Silver,	.	66.50
Sulphur,	.	12.00
Antimony,	.	10.00
Iron, .	.	5.00
Copper and Arsenic,		0.50
Earthy substances,		1.00—95.00

Klaproth. Beit. b. i. s. 166.

Geognostic and Geographic Situations.—It occurs in veins that traverse gneiss, clay-slate, and porphyry, in Saxony, Bohemia, and Hungary.

Genus III.—GALENA, or LEAD-GLANCE.

Tessular. Pure lead-grey. Hardness=2.5. Sp. gr. 7.0—7.6.

This genus contains but one species, viz. Hexahedral Galena.

1. Hexahedral Galena, or Lead-Glance, *Jameson.*—Hexaedrischer Bleiglanz, *Mohs.*

Tessular. Cleavage hexahedral. Hardness=2.5. Sp. gr.=7.0—7.6.

This species is divided into two subspecies, viz. Common Galena, and Compact Galena.

First Subspecies.

Common Galena, or Lead-Glance, *Jameson.*—Gemeiner Bleiglanz, *Werner.*

External Characters.—Colour lead-grey. Occurs massive, in various particular forms, and crystallized in cubes, and octahedrons. Internally specular, splendent, and glistening, and lustre metallic. Fragments cubical. Perfectly sectile. Uncommonly easily frangible.

			Durham.
Constituent Parts.—Lead,	.	.	85.13
Sulphur, .		.	13.02
Iron,	.	.	0.50—98.65

Thomson.

Geognostic and Geographic Situations.—It occurs in veins, beds, and imbedded masses, in primitive, transition, and secondary mountains, in many of the mining districts in Europe, Asia, and America.

Uses.—Nearly all the lead of commerce is obtained from galena.

Second Subspecies.

Compact Galena, or Lead-Glance, *Jameson.*—Bleischweif, *Werner.*

External Characters.—Colour lead-grey. Occurs massive, disseminated, and specular. Internally glimmering, and lustre metallic. Fracture even, which in some varieties passes into flat conchoidal.

Geognostic and Geographic Situations.—It occurs in the same formations, and in the same countries, as Common Galena.

Genus IV.—BLACK TELLURIUM, or TELLURIUM GLANCE.—*Jameson.*

Blätter Glanz, *Mohs.*

Cleavage perfect, according to one direction. Not malleable. Hardness=1—1.5. Sp. gr.=7.0.—7.2.

I. Prismatic Black Tellurium, *Jameson.*—Prismatischer Blätter-glanz, *Mohs.* Nagyagerz, *Werner.*

Blackish lead-grey. Cleavage prismatoidal or axifrangible.

External Characters.—Colour between blackish lead-grey, and iron-black. Occurs massive, disseminated, in leaves, crystallized, in oblique four-sided prisms and four-sided pyramids. Externally splendent, and lustre metallic. Internally shining. It is sectile.

Const. Parts.—Tellurium,	.	.	.	32.2
Lead, .	.	.	.	54.0
Gold, .	.	.	.	9.0
Sulphur,	.	.	.	3.0
Copper,	.	.	.	1.3
Silver,	.	.	.	5—100

Klaproth, Beit. b iii. s. 32.

Geognostic and Geographic Situations.—It occurs in veins that traverse porphyry, at Nagyag in Transylvania.

Use.—It is worked for the gold it contains.

Genus V.—MOLYBDENA.

Molydan Glanz, *Mohs.*

Rhomboidal. Very flexible. Hardness=1.—1.5. Sp. gr.=4.4.—4.6.

I. Rhomboidal Molybdena, *Jameson.*—Rhomboedrischer Molybdän, *Mohs.* Wasserblei, *Werner.*

Di-rhomboidal. Rhomboid unknown. Cleavage parallel with terminal planes of a six-sided prism. Pure lead-grey.

External Characters.—Colour fresh lead-grey. Occurs usually massive, disseminated, in plates, and sometimes crystallized in six-sided prisms. Internally splendent or shining, and lustre metallic. It writes with a bluish-grey streak on paper, but with a greenish-grey streak on porcelain.

Const. Parts.—Molybdena,	.	.	.	60
Sulphur,	.	.	.	40—100

Bucholz in Gehlen's Journ. de Chem. u. Phys. b. iv. s. 603.

Geognostic and Geographic Situations.—It occurs disseminated in granite, gneiss, mica-slate, and chlorite-slate, in Inverness-shire, Aberdeenshire, Cornwall, and Cumberland. Also in Norway and other countries.

Genus VI.—GOLD GLANCE.

Prismatic: not axifrangible. Pure steel-grey. Hardness=1.5—2.0. Sp. gr.=5.7—5.8.

I. Prismatic Gold Glance, *Jameson.*—Prismatischer Gold Glanz, *Mohs.*

Prism unknown. Cleavage prismatic.

External Characters.—Colour steel-grey. Occurs massive, disseminated, in leaves, and crystallized in oblique four-sided prisms. Externally splendent, and lustre metallic. Internally glistening, and lustre metallic. Fracture fine-grained uneven.

Const. Parts.—Tellurium,	.	.	.	60
Gold, .	.	.	.	30
Silver, .	.	.	.	10—100

Klaproth, Beit. b. iii. s. 20.

Geognostic and Geographic Situation.—It occurs in veins in porphyry, in Transylvania.

Use.—It is worked as an ore of gold, and as an ore of silver.

Genus VII.—BISMUTH GLANCE.

Prismatic. Lead-grey. Hardness=2.0—2.5. Sp. gr.=6 1—6.4.

Prismatic Bismuth Glance, *Jameson.* Prismatischer Wismuth Glanz, *Mohs.* Wismuth Glanz, *Werner.*

Prismatic pyramid unknown. Lead-grey. Hardness =2.0—2.5. Sp. gr.=6.1—6.4.

External Characters.—Colour pale lead-grey. Occurs massive, disseminated, in granular and radiated concretions, and crystallized in oblique four-sided prisms. Internally splendent and metallic. Soils. Brittle, inclining to sectile.

Const. Parts.—Bismuth,	. . .	60
Sulphur,	. . .	40—100

Sage in Mem. de l'Acad. d. Sc. 1782, p. 307.

Geognostic and Geographic Situations.—It occurs in veins in Cornwall, Saxony, and other countries.

Genus VIII.—ANTIMONY GLANCE.

Three axes. Prismatic. Lead-grey, inclining to blackish and steel-grey. If it passes into steel-grey, the cleavage is axifrangible, inflexible, sectile. If it passes into lead-grey, is brittle. Hardness=2.0—3.0. Sp. gr. 4.0—5.8.

I. Prismatoidal Antimony Glance, or Grey Antimony. Grau Spiesglaserz, *Werner.* Prismatoidischer Antimon-Glanz, *Mohs.*

Prismatic. Pyramid unknown. Cleavage prismatic. Lead-grey. Hardness=2. Sp. gr.=4.0.—4.6.

External Characters.—Colour lead-grey. Occurs massive, disseminated, in distinct concretions, which are radiated, fibrous, and granular; also crystallized in oblique four-sided prisms, and in six-sided prisms. Lustre from glistening to splendent and metallic. Fracture uneven and even.

Const. Parts.—Antimony 74; Sulphur 26=100. *Bergman.*

Geognostic and Geographic Situations.—Occurs in veins and beds in primitive and transition rocks. In Dumfries-shire there are veins of it in grey-wacke, and in Banffshire it is distributed among rocks of the primitive class. There are considerable deposits of it on the Continent, and also in America.

2. Axifrangible Antimony Glance, or Bournonite. Axentheilender Spiesglas Glanz, *Mohs.*

Prism unknown. Axifrangible. Colour Blackish, lead-grey, passing into steel-grey. Hardness=2.0—2 5. Sp. gr.=5.5—5.8.

External Characters.—Colour blackish lead-grey, passing into steel-grey. Occurs massive, disseminated, and crystallized in oblique four-sided prisms. Externally shining and metallic; internally glistening and metallic. Fracture conchoidal or uneven.

Constituent Parts.—Lead, 42.62; Antimony, 24 23; Copper, 18 20; Iron, 1.20; Sulphur, 17.00 = 100. Hatchett, *Phil Trans* 1804. p. 63.

Geognostic and Geographic Situations.—Found in Cornwall in veins in clay-slate; also in Germany, Siberia and Peru.

3. Prismatic Antimony Glance. Prismatischer Spiesglas-glanz, *Mohs.*

Prism unknown. Cleavage in direction of the shorter diagonal. Blackish lead-grey. Hardness 2.5.—3.0. Sp. gr.=5.7—5.8.

External Characters.—Colour blackish lead-grey. Crystallized in oblique four-sided prisms. Lustre shining and metallic.

Order XII.—BLENDE.

If metallic, the colour is black with a green streak. If not metallic, the lustre is adamantine. If the streak is brown or white, it is tessular, with a hardness between 4 0 and 4.2. If the streak is red, the specific gravity is 4.5. and more, and the hardness 2.5. and less. Hardness= 1. and 4. Sp. gr.=3.9—8.2. If 4.3, and more, the streak is red.

Genus I.—MANGANESE-BLENDE.

Glanz-Blende, *Mohs.* Mangan-Blende, *Werner.*

Three axes. Prismatic. Streak greenish. Hardness =3.5—4 0. Sp. gr.=3.9—4.0.

1. Prismatic Manganese Blende, *Jameson.*—Prismatischer Glanz Blende, *Mohs.*

Prismatic. Pyramid unknown. Cleavage prismatic, but very imperfect. Metallic.

External Characters.—Colour on the fresh fracture iron-black, but on exposure it becomes tarnished of a brownish-black colour. Occurs massive, disseminated, in granular concretions, and crystallized on oblique four-sided prisms. Lustre splendent or shining, and semi-metallic. Opaque. Streak of a greenish colour.

Const. Parts.—Oxide of Manganese,	.	85
Sulphur,	. . .	15—100

Vauquelin, Annal. d. Mus. vi. s. 405.

Geognostic and Geographic Situations.—It is found in Cornwall, and at Nagyag in Transylvania, along with ores of tellurium, blende, copper-pyrites, compact red manganese, and brown-spar.

Genus II.—ZINC-BLENDE, or GARNET-BLENDE.

Granat-Blende, *Mohs.*

Many axes. Tessular. Streak brown and white. Hardness=3.5—4 0. Sp. gr=4.0—4 2.

1. Dodecahedral Zinc-Blende.—Dodecaedrischer Granat-Blende, *Mohs.* Blende, *Werner.*

Tessular. Cleavage dodecahedral. Streak white or reddish-brown.

External Characters.—Colours yellow, brown, and black. Occurs massive, disseminated, in granular concretions, and crystallized in rhomboidal dodecahedrons, octahedrons, and tetrahedrons. Lustre splendent and adamantine, inclining more or less to metallic. Alternates from opaque to transparent.

			Northumberland
Const. Parts.—Zinc,	. . .		58.8
Sulphur,	. . .		23.5
Iron,	. . .		8 4
Silica,	. . .		7.0—97.7
			Thomson.

Geognostic and Geographic Situations—It occurs in veins in primitive, transition, and floetz rocks, where it is generally associated with galena or lead-glance. Occurs in all the lead mines in Scotland and England, and also in those on the continent.

Uses.—It is principally valuable as an ore of Zinc.

Genus III.—ANTIMONY-BLENDE, or RED-BLENDE.

Nadel-Blende, *Mohs.*

Three axes. Prismatic. Streak red. Hardness=1.0—1.5. Sp. gr.=4.5—4.6.

1. Prismatic Antimony-Blende, or Red Antimony, *Jameson.*—Prismatische Nadel-Blende, *Mohs.*—Rothspiesglas-erz, *Werner.*

Prismatic. Pyramid unknown. Cleavage prismatoidal. Streak red.

External Characters.—Colour cherry-red. Occurs massive, disseminated, in flakes; in scopiform and stellular, fibrous, and granular distinct concretions; and crystallized in oblique four-sided prisms. Externally and internally shining. Lustre nearly adamantine. Opaque, or translucent on the edges. Colour not changed in the streak.

Const. Parts.—From the mine called Neue Hoffnung Gottes at Brünsdorf:

Antimony,	. . . .	67.50
Oxygen,	. . . .	10.80
Sulphur,	. . . .	19.70—98.00

Klaproth. Beit. b. iii. s. 182.

Geognostic and Geographic Situations.—This rare mineral occurs in veins, in primitive rocks, in Saxony, France, and Hungary.

Genus IV.—RUBY-BLENDE.

Rubin-Blende, *Mohs.*

One axis. Rhomboidal. Hardness=2.0—2.5. Sp. gr.=5.2—8.2.

Two species. viz. Rhomboidal and Prismato-Rhomboidal *Red Zinc.

1. Rhomboidal Ruby-Blende, or Red Silver, *Jameson.*—Rhomboedrische Rubin-Blende, *Mohs.*

Rhomboidal. Rhomboid=109° 28′. Cleavage rhomboidal. Streak red. Hardness=2.5. Sp. gr.=5.2.—5.8

External Characters.—Colour intermediate between cochineal-red and dark lead-grey, and sometimes inclines to carmine-red. Occurs massive, disseminated, in membranes; and crystallized in six-sided prisms, and six-sided pyramids. Externally alternates from shining to splendent; lustre semi-metallic or adamantine. Internally alternates from shining to glimmering; lustre sometimes adamantine, sometimes semi-metallic. Fracture uneven or conchoidal. Opaque, or more or less translucent. Streak cochineal-red.

Const. Parts.—	Silver,	. . .	60.0
	Antimony,	. .	20.3
	Sulphur,	. .	14.7
	Oxygen,	. .	5.0—100.0

Klaproth. Beit. b. v. s. 200.

Geognostic and Geographic Situations.—It occurs in veins in gneiss, mica-slate, porphyry, and grey-wacke, in various mining districts, as Cornwall, Hartz, Hungary, Mexico, and Peru

2. Prismato-Rhomboidal Ruby-Blende, or Cinnabar, *Jameson.*—Prismato-Rhomboedrische Rubin-Blende, *Mohs.*

Rhomboidal. Rhomboid about 8° 5′. Cleavage in direction of lateral planes of six-sided prism. Streak red. Hardness =2.0.—2.5. Sp. gr. 6.7.—8.2.

Is divided into two subspecies, viz. Common and Hepatic Cinnabar.

First Subspecies.

Common Cinnabar, *Jameson.*

External Characters.—Colours cochineal-red, scarlet-red, and carmine-red. Besides massive, disseminated, dendritic, and in granular concretions; it also occurs crystallized in six-sided prisms. Internally alternates from shining to glimmering; lustre adamantine, verging on semi-metallic. Fracture fine-grained uneven, even conchoidal, and earthy. Alternates from opaque to transparent. Yields a scarlet-red shining streak.

			Japan.
Constit. Parts.	Mercury,	.	84.50
	Sulphur,	.	14.75——99.25

Klaproth. Beit. b. iv. s. 17—19.

Geognostic and Geographic Situations.—It occurs most abundantly in the coal formation, and less plentifully in beds and veins in primitive rocks. There are considerable mines of this mineral at Idria in Carniola, and in other parts of Europe; also in Asia and America.

Uses.—It is from this mineral that most of the mercury of commerce is obtained.

Second Subspecies.

Hepatic Cinnabar, *Jameson.*—Quecksilber Lebererz, *Werner.*

External Characters.—Colour intermediate between dark cochineal-red and dark lead-grey. Occurs massive, disseminated, and in globular concretions. Internally alternates from glimmering to splendent. Lustre semi-metallic. Fracture even or slaty. Opaque.

Const. Parts.	Mercury	. .	81.80
	Sulphur,	. .	13 75
	Carbon,	. .	2.30
	Silica,	. . .	0.65
	Alumina,	. .	0.55
	Oxide of Iron,	.	0.20
	Copper,	. .	0.02
	Water,	. .	0.73——100

Klaproth, Beit. b. iv. s. 24.

Geognostic and Geographic Situations.—This mineral occurs in considerable masses in clay-slate and bituminous-shale, at Almaden in Spain, in Deux Ponts, and Siberia.

* Red Zinc, or Red Ore of Zinc, *Jameson.*—Red Oxide of Zinc. *Bruce.*

External Characters.—Colours blood-red and aurora-red. Occurs massive, and disseminated. Internally fresh fracture shining; after long exposure to the air it becomes dull, and even covered with a pearly crust. Cleavage undetermined. Fracture conchoidal. Translucent on the edges, or opaque. Easily scratched by the knife. Brittle. Affords a streak which is brownish-yellow, approaching to orange. Specific gravity 6.220.

Con. Parts.	Zinc,	. . . .	76
	Oxygen,	. . . .	16
	Oxides of Manganese and Iron,		8—100

Bruce, American Min. Jour. p. 99.

Geognostic and Geographic Situations.—This mineral has been hitherto found only in North America, where it occurs in several of the iron-mines in Sussex county, New Jersey; as at the Franklin, Sterling, and Rutgers mines, and near Sparta. In some instances it is imbedded in foliated granular limestone; while in others, it serves as a basis in which magnetic ironstone occurs, either in crystals or grains. At Franklin, it also assumes a micaceous form, and is imbedded in a whitish oxide of zinc, which is often, in the same specimen, found adhering to the black oxide of iron.

Uses.—This ore occurs abundantly in the United States of America, and promises to be a valuable acquisition to that country.

Order XIII. SULPHUR.

Schwefel, *Mohs.*

Three axes. Prismatic. Hardness =1.5.—2.5. Sp. gr. =1.9.—3.6.

Genus I.

1. Red Orpiment, or Ruby Sulphur, or Hemi-Prismatic Sulphur, *Jameson.*—Hemi-prismatisches Schwefel, *Mohs.* Rothes Rauschgelb, *Werner.*

Prism 107° 42′. Cleavage in the direction of the diagonals of the prism, but not perfect. Streak orange-yellow and aurora-red. Hardness =1.5.—2.0. Sp. gr. =3 3.—3 4.

External Characters.—Colour aurora-red. Occurs massive, disseminated, in flakes or membranes, and crystallized in oblique four-sided prisms, variously modified by acuminations, truncations, and bevelments. Internally shining. Lustre resinous, inclining to adamantine. Fracture uneven, sometimes passing into conchoidal. Translucent; crystals semi-transparent. Yields an orange-yellow coloured streak.

			Bannat.
Constit. Parts.	Arsenic	. .	69
	Sulphur,	. .	31——100

Klaproth, Beit. b. v. s. 238.

Geognostic and Geographic Situations.—It occurs most frequently in veins in primitive rocks, less frequently in secondary rocks. Different mining districts in Germany afford this mineral, and it is also a production of Japan, the north west coast of America, and of volcanoes.

Uses.—It is used as a pigment.

2. Yellow Orpiment, or Prismatoidal Sulphur, *Jameson.*—Prismatoidescher Schwefel, *Mohs.* Gelbes Rauschgeld, *Werner.*

Prismatic. Pyramid unknown. Cleavage prismatoidal. Streak lemon-yellow. Hardness =1.5.—2.0. Sp. gr. 3.4—3.6.

External Characters.—Colour lemon-yellow. Occurs massive, disseminated, stalactitic, reniform, botryoidal, in crusts, in granular and concentric curved lamellar concretions, and crystallized in oblique four-sided prisms, and in flat double four-sided pyramids. Splendent. Lustre intermediate between adamantine and semi-metallic. Translucent, but in small leaves transparent. Colour not altered in the streak. Sectile. Flexible, but not elastic.

			Turkey.
Constit. Parts.	Arsenic,	. .	62
	Sulphur,	. .	38——100

Klaproth, Beit. b. v. s. 238.

Geognostic and Geographic Situations. It occurs in veins in secondary and primitive rocks in Germany, Hungary, China, Mexico, and the United States.

3. Prismatic Sulphur, *Jameson.*—Prismatischer Schwefel, *Mohs.* Natürlicher Schwefel, *Werner.*

Prismatic. Pyramid =107° 19′; 84° 24′; 143° 8′. Cleavage pyramidal, and in the direction of prism 102° 41′. Streak white or sulphur-yellow. Hardness =1.5—2.5. Sp. gr. 1.9.—2.1.

First Subspecies.

Common Sulphur, *Jameson.*—Gemeiner Naturlicher Schwefel, *Werner.*

External Characters.—Colour yellow. Occurs massive, disseminated, in granular concretions, and crystallized in acute double six-sided pyramids. Internally varies from shining to glimmering. Lustre intermediate between adamantine and resinous. Fracture uneven. Translucent. Crystals semi-transparent and transparent, and refract double. Brittle, and easily frangible.

Chemical Characters.—It is easily inflammable, burning with a lambent bluish flame, and a suffocating odour.

Geognostic and Geographic Situations.—Common sulphur occurs in considerable abundance in primitive mountains, in a state of combination with metals; but rarely pure or uncombined; while in secondary mountains, it is more abundant in the pure uncombined state than in combination with metals. It is also met with in alluvial districts, particularly near sulphureous springs. It abounds in Iceland, Spain, Italy, &c.

Second Subspecies.

Volcanic Sulphur, *Jameson.*—Vulcanischer Natürlicher Schwefel, *Werner.*

External Characters.—Colour pale sulphur-yellow. Occurs massive, stalactitic, vesicular, corroded, perforated; crystallized in pyramidal figures. Glistening. Lustre resinous, inclining to adamantine. Fracture uneven. Translucent. In other characters it agrees with the preceding subspecies.

Geognostic and Geographic Situations.—It occurs only in volcanic countries, where it is found more or less abundantly among lavas. Solfatara, in the vicinity of Vesuvius, is one of the most famous repositories of volcanic sulphur, and it is there collected in considerable quantities for the purposes of commerce.

Uses.—When burnt, it affords sulphuric acid; it enters into the composition of gunpowder; is used in various metallurgic processes, and in bleaching; it forms a constituent part of some cements; is employed in taking casts; and is an article in the materia medica.

CLASS III.

If liquid, bituminous smell. If solid, tasteless. Specific gravity under 1.8.

Order I.—RESIN.

Liquid. Solid. Streak white, yellow, brown, black. Hardness =0—2.5. Sp. gr. =0.7—1.6. If 1.2, and more, the streak is white.

Genus. I. HONEYSTONE.

Crystal-Harz, *Mohs.*

Pyramidal. Hardness =2.—25. Sp. gr. =1.4—1.6.

1. Pyramidal Honeystone, *Jameson.*—Pyramidales Crystal-Harz, *Mohs.* Honigstein, *Werner.*

Pyramidal. Pyramid =118° 4'.--93° 22'. Cleavage pyramidal and imperfect.

External Characters.—Colour yellow. Rarely massive. Generally crystallized in flat double four-sided pyramids. Lustre shining or splendent. Fracture conchoidal. Semi-transparent, or translucent, and refracts double.

Constituent Parts.	Alumina,	16
	Mellilitic Acid,	46
	Water of Crystallization,	38--100

Klaproth, Beit. b. iii. s. 114.

Geognostic and Geographic Situations.—It occurs superimposed on bituminous wood and earth-coal, and is usually accompanied with sulphur. It has been hitherto found only at Artern in Thuringia.

Genus II.--MINERAL RESIN.

Erd-Harz, *Mohs.*

Amorphous. Hardness =0—2.2. Sp. gr.=0.8—1.2.

This genus contains two species, viz. Yellow Mineral Resin, and Black Mineral Resin.

1. Yellow Mineral Resin, or Amber, *Jameson.*—Gelbes Erdharz, *Mohs.*

Solid. Yellow. White. Streak White. Hardness =2.0--2.5. Sp. gr. =1.0--1.1.

External Characters.—Colours yellow and white. Occurs in massive pieces, disseminated, and often incloses insects. Externally dull; internally splendent, shining or glistening, and lustre resinous. Fracture conchoidal. Transparent or translucent.

Chemical Characters.—It burns with a yellow-coloured flame, and fragrant odour, at the same time intumescing, but scarcely melting.

Physical Characters.—When rubbed, it gives out an agreeable smell, and becomes strongly resino-electric. This latter property was known to the ancients, who termed amber *electrum;* from whence is derived the word *electricity.*

Constituent Parts.—It is composed of carbon, hydrogen, and oxygen. An acid named *Succinic* is obtained from it by distillation.

Geognostic and Geographic Situations.—It occurs in beds of bituminous wood and moor coal; also in a conglomerate formed by the aggregation of fragments on sea-shores; in sandy soil; frequently floating on the sea; and it is said to have been observed imbedded in secondary limestone. It is found on the shores of Scotland and England, of the Baltic, and in Germany, Poland, and other countries.

Uses.—On account of its beautiful colour, great transparency, and the fine polish it receives, it is considered as an ornamental stone, and is cut into necklaces, bracelets, snuff-boxes, and other articles of dress.

2. Black Mineral Resin, *Jameson.* Schwarzes, Erd-Harz, *Mohs.*

Solid, liquid. Black, brown, red, grey. Streak black, brown, yellow, grey. Hardness =0.2. Sp. gr. =0.8—1.2.

This species is divided into three subspecies, viz. Naphtha, Mineral Oil or Petroleum, and Mineral Pitch or Bitumen.

First Subspecies.

Naphtha, *Jameson.*

External Characters.—Colours yellowish-white, yellowish-grey, and wine-yellow. Perfectly liquid. Shining and resinous. Feels greasy. Exhales an agreeable bituminous smell.

Chemical Characters.—Takes fire on the approach of flame, affording a bright white light.

Constituent Parts.—Is a compound of carbon, hydrogen, and a little oxygen.

Geognostic and Geographic Situations.—This mineral is seldom found in a pure state. It is said to occur in considerable springs on the shores of the Caspian Sea, in the Caucasus, and other places.

Uses.—In Persia, Japan, and some parts of Italy, where it occurs in considerable quantity, it is used in lamps, in place of oil, for lighting streets, churches, &c.

Second Subspecies.

Mineral Oil, or Petroleum, *Jameson.* Erdöl, *Werner.*

External Characters.—Colour dark blackish brown, which sometimes inclines to green. Liquid, but approaches more or less to the viscid state. Shining and resinous. Feels greasy. Semi-transparent, translucent, and opaque. Exhales a strong bituminous odour.

Geognostic and Geographic Situations.—It generally flows from rocks of the coal formation, and usually from the immediate vicinity of beds of coal; also from limestone rocks. It occurs in marshes, on the surface of spring water; or it flows or trickles unmixed from its mineral repository. Is found at St. Catherine's well, near Edinburgh, in the Orkney Islands, in Shropshire in England, &c.

Uses.—In Piedmont, Persia, Japan, and other countries, it is used in lamps in place of oil, for lighting streets and churches.

Third Subspecies.

Mineral Pitch, or Bitumen, *Jameson.*

This species is divided into three kinds, viz. Earthy Mineral Pitch, Slaggy Mineral Pitch, and Elastic Mineral Pitch.

First Kind.—Earthy Mineral Pitch, *Jameson.*—Erdiges Erdpech, *Werner.*

External Characters.—Colour blackish brown. Occurs massive. Faintly glimmering, inclining to dull. Fracture earthy or uneven. Streak shining and resinous. Soft. Sectile. Feels greasy.

Geognostic and Geographic Situations.—It occurs in the Iberg in the Hartz, along with slaggy mineral pitch, in veins that traverse grey wacke; also in other places.

Second Kind.—Slaggy Mineral Pitch, or Asphaltum, *Jameson.*—Schlackiges Erdpech, *Werner.*

External Characters.—Colour pitch black. Occurs massive, disseminated, sometimes globular, reniform, and stalactitic. Externally and internally splendent and shining, and lustre resinous. Fracture conchoidal. Soft. Opaque. Sectile.

Geognostic and Geographic Situations.—It occurs in veins in reniform and imbedded masses in secondary limestone in Fifeshire; in clay ironstone in East Lothian; in veins at Haughmond Hill in Shropshire, and in mineral veins in Cornwall.

Uses.—The Egyptians employed it in the process of embalming bodies. The Turks quarry it in Albania, and use it, when mixed with common rosin, for paying the bottoms of ships, and for smearing the rigging.

Third Kind.—Elastic Mineral Pitch, *Jameson.*—Elastiches Erdpech, *Werner.*

External Characters.—Colour brown. Occurs massive, reniform, and sometimes with impressions. Internally shining and glistening, and lustre resinous. Fracture curved slaty, or conchoidal. Translucent on the edges. Shining in the streak. Perfectly sectile. Elastic flexible.

Geognostic and Geographic Situations.—It is found in the cavities of a lead glance vein in the lead mine called Odin, which is situated near the base of Mamtor, to the north of Castletown in Derbyshire.

Order II.—COAL.

Solid. Streak brown and black. Hardness = 0.1—2.5. Sp. gr. = 1.2—1.5.

Genus I.—COAL.

Amorphous. Hardness = 1.—2.5. Sp. gr. = 1.2—1.5.

This genus contains two species, viz. Bituminous Coal, and Glance Coal.

1. Bituminous Coal, *Jameson.*—Harzige Kohle, *Mohs.*

Colours black and brown. Resinous lustre. Bituminous smell. Hardness = 1.—2.5. Sp. gr. = 1.2—1.5.

This species contains two subspecies, viz. Brown Bituminous Coal, and Black Bituminous Coal.

First Subspecies.

Brown Bituminous Coal, or Brown Coal, *Jameson.* Braun Kohle, *Werner.*

This subspecies is divided into five kinds, viz. 1. Bituminous Wood, or Fibrous Brown Coal. 2. Earthy Coal, or Earthy Brown Coal. 3. Alum Earth. 4. Common Brown Coal, or Conchoidal Brown Coal; and, 5. Moor Coal, or Trapezoidal Coal.

First Kind.—Bituminous Wood, or Fibrous Brown Coal, *Jameson.*—Bituminoses Holz, *Werner.*

External Characters.—Colour brown. External shape resembles exactly that of stems and branches of trees, but usually compressed. Principal fracture glimmering or glistening; cross fracture shining. Fracture fibrous in the small, slaty in the great. Opaque. Streak shining.

Geognostic and Geographic Situations.—Occurs in alluvial land, or in secondary rocks; and is found in Scotland, England, Ireland, &c.

Second Kind.—Earth-Coal, or Earthy-Brown Coal, *Jameson.*—Erdkohle, *Werner.*

External Characters. Colours brown and grey. Occurs massive. Its consistence is between cohering and loose, but more inclined to the latter. Particles coarse, dusty, and soil a little. Internally faintly glimmering, passing into dull. Fracture in the more cohering masses fine earthy. Streak somewhat shining.

Geognostic and Geographic Situations.—Is found, along with bituminous wood, in Thuringia, and other countries.

Uses.—It is used as fuel where no great degree of heat is required, as in heating rooms, salt, nitre, and alum works, and in distillation.

Third Kind.—Alum Earth, *Jameson.*—Alaunerde, *Werner.*

External Characters.—Colour black. Massive. Dull, sometimes glimmering; but this is owing to an intermixture of mica. Fracture in the great, thick or thin slaty; in the small, earthy. Breaks into tabular pieces. Streak shining. Is sectile, and uncommonly easily frangible.

Geognostic and Geographic Situations.—It occurs in alluvial districts in France, Germany, Italy, and Hungary.

Uses.—It is first exposed to the air for several months, and then lixiviated, to obtain the alum it contains; it is rarely used for fuel.

Fourth Kind.—Common Brown Coal, or Conchoidal Brown Coal, *Jameson.*—Gemeine Braunkohle, *Werner.*

External Characters.—Colour Black. Occurs massive, and sometimes ligniform. Internally shining, sometimes glistening, and lustre resinous. Fracture conchoidal, and sometimes shows the fibrous woody texture. Colour lighter in the streak.

Constituent Parts.—200 grains of the Bovey brown coal, by distillation, yielded,

1. Water, which soon came over acid, and afterwards turbid, by the mixture of some bitumen	60 grains
2. Thick brown oily bitumen, . .	21
3. Charcoal	90
4. Mixed gas, consisting of hydrogen, carbonated hydrogen, and carbonic acid .	29—200

Hatchett, *Phil. Trans.* 1804.

Geognostic and Geographic Situations.—It occurs in alluvial land, and in secondary or floetz-trap rocks, in England, Ireland, France, &c.

Use.—It is used as fuel.

Fifth Kind.—Moor Coal, or Trapezoidal Brown Coal, *Jameson.*—Moorkohle, *Werner.*

External Characters.—Colours brown and black. Occurs massive, when first dug, but soon bursts and splits into rhomboidal pieces. Lustre of the principal fracture glimmering, of the cross fracture glistening, and lustre resinous. Principal fracture imperfect slaty; the cross fracture even approaching to conchoidal. Sectile. Streak shining. Uncommonly easily frangible. The most frangible species of coal.

Geognostic and Geographic Situations.—It occurs in great beds in alluvial lands, and in floetz trap rocks in Bohemia, Germany, &c.

Second Subspecies.

Black Bituminous Coal, *Jameson.*—Schwartzkohle, *Werner.*

This subspecies is divided into four kinds, viz. Slate Coal, Cannel Coal, Foliated Coal, and Coarse Coal.

First Kind.—Slate Coal, *Jameson.*—Schieferkohle, *Werner.*

External Characters.—Colour black. Occurs massive. Shining or glistening, and lustre resinous. Principal fracture nearly straight, and generally thick slaty; cross fracture imperfect and flat conchoidal, and sometimes even or uneven. Lustre increased in the streak.

Geognostic and Geographic Situations.—Abounds in all the coal districts in Great Britain.

Second Kind.—Cannel Coal, *Jameson.*—Kennelkohle, *Werner.*

External Characters.—Colour black. Massive. Internally glistening or glimmering, and lustre resinous. Fracture large and flat conchoidal, or even.

Geognostic and Geographic Situations.—It occurs, along with the preceding subspecies, in the coal formation in most of the coal fields of Great Britain.

Uses.—On account of its solidity, and the good polish it is capable of receiving when pure, it is cut into drinking vessels of various kinds, inkholders, snuff-boxes, &c.; but its principal use is as fuel.

Third Kind.—FOLIATED COAL, *Jameson.*—Blätterkohle, *Werner.*

External Characters.—Colour velvet black. Massive, and in lamellar concretions. Lustre splendent and resinous. Fracture uneven. Softer than cannel coal.

Geognostic and Geographic Situations.—It occurs in the coal formation, although not abundantly, and generally accompanied with slate coal, in Saxony and Silesia.

Fourth Kind.—COARSE COAL, *Jameson.*—Grobkhole, *Werner.*

External Characters.—Colour black. Massive, and in granular concretions, which are intimately aggregated together. Glistening and resinous. Principal fracture imperfect, and thick scaly; cross fracture fine-grained uneven.

Geognostic Situation.—Occurs in the coal formation in Germany.

2. GLANCE COAL, *Jameson.*—Harzlose Steinkohle, *Mohs.*

Colour black. Imperfect metallic lustre. No bituminous smell. Hardness = 2.—2.5. Sp. gr. = 1.3—1.5.

This species contains two subspecies, viz. Pitch Coal, and Glance Coal.

FIRST SUBSPECIES.

PITCH COAL, or JET, *Jameson.*—Pechkohle, *Werner.*

External Characters.—Colour velvet black. Occurs massive; and it is said also in plates, and sometimes in the shape of branches, with a regular woody internal structure. Internally splendent, and the lustre resinous, inclining to metallic. Fracture large and perfect conchoidal. Affords a brown coloured streak.

Chemical Characters.—It burns with a greenish flame. Its chemical constitution is still imperfectly understood.

Geognostic and Geographic Situations.—It occurs along with brown coal, in beds in flœtz trap and limestone rocks; also in beds and in imbedded portions in bituminous shale, in Scotland, Faroe Islands, and Germany.

SECOND SUBSPECIES.

GLANCE COAL, *Jameson.*—Glanzkohle, *Werner.*

This subspecies contains four kinds, viz. 1. Conchoidal, 2. Slaty, 3. Columnar, 4. Fibrous.

First Kind.—CONCHOIDAL GLANCE COAL, *Jameson.*—Muschliche Glanzkohle, *Werner.*—Anthracite Compacte, *Hauy.*

External Characters.—Colour iron black. Massive and vesicular. Internally splendent and shining, and lustre imperfect metallic. Fracture conchoidal.

Chemical Characters.—It burns without flame or smell, and leaves a white coloured ash.

Geognostic Situation.—It occurs in beds in transition and secondary rocks.

Geographic Situation.—It occurs in beds in the coal formation of Ayrshire, as near Cumnock and Kilmarnock; in the coal districts in the river district of the Forth; and in Staffordshire in England.

Second Kind.—SLATY GLANCE COAL, *Jameson.*—Schiefvige Glanzkohle, *Werner.*—Anthracite feuilleté, *Hauy.*

External Characters.—Colour dark iron black, seldom inclining to brown; those varieties that border on graphite incline to steel grey. Massive. Internally shining and glistening, and lustre imperfect metallic. Principal fracture slaty; cross fracture conchoidal or uneven.

		Panzenberg.	Dolomieu.
Constituent Parts.—	Carbon	90	72.05
	Silica	4 to 2	13.19
	Alumina	4 to 5	3.29
	Oxide of iron	2 to 3	3.47
	Loss .		8.00
		100	100.00

Geognostic and Geographic Situations.—It occurs in imbedded masses, beds and veins, in primitive transition, and secondary rocks. It is found in sandstone in Arran; in trap-rocks in the Calton Hill at Edinburgh; and in the coal formation in the river district of the Forth.

Observation.—In this country it is named Blind Coal.

Third Kind.—COLUMNAR GLANCE COAL, *Jameson.*—Stangenkohle, *Voigt.*—Houille bacillaire, *Hauy.*

External Characters.—Colour black. Occurs massive, disseminated; also in prismatic concretions. Lustre shining and glistening, and imperfect metallic. Fracture conchoidal or uneven.

Chemical Characters.—It burns without flame or smoke.

Geognostic and Geographic Situations.—It forms a bed several feet thick, in the coal field of Sanquhar in Dumfries-shire, and occurs in other parts of Scotland.

Fourth Kind.—FIBROUS COAL, or MINERAL CHARCOAL, *Jameson.*—Mineralische Holzkohle, *Werner.*

External Characters.—Colour black. Massive, in thin layers, and single pieces; also in fibrous distinct concretions. Is glimmering, bordering on glistening, and lustre silky or pearly. Soils strongly. Soft, passing into friable. Very easily frangible.

Chemical Characters.—When exposed to a strong heat, it burns without flame or smoke; some varieties scarcely yield to the most intense heat.

Geognostic and Geographic Situations.—It occurs imbedded, or in thin layers, in black coal, sometimes enclosed in pitchstone, and it is said also occasionally associated with some varieties of brown coal. It is met with in the different coal fields of Great Britain, and in similar situations on the continent of Europe.

APPENDIX.

Minerals whose Characters and place in the System have not been determined.

MINERALS of First and Second Classes.

1. ALLOPHANE, *Stromeyer.*

External Characters.—Principal colour blue; also occurs green and brown. Occurs massive, disseminated, small reniform, and botryoidal. Externally and internally shining or glistening, and lustre vitreous. Fracture conchoidal. Transparent, but only translucent on the edges in the brown varieties; semi hard; brittle, and uncommonly easily frangible. Specific gravity 1.852 to 1.889, *Stromeyer.*

Chemical Characters.—It readily gelatinates in acids.

Constit. Parts.—	Water,	41.301
	Silica,	21.922
	Alumina,	32.202
	Lime,	0.730
	Sulphate of Lime,	0.517
	Carbonate of Copper,	3.058
	Hydrate of Iron,	0.270—100
		Stromeyer.

Geognostic and Geographic Situations.—Occurs in a bed of ironshot limestone in grey-wacke slate in the forest of Thuringia.

2. AMBLYGONITE, *Breithaupt.*

External Characters.—Its colours are greenish-white, pale-mountain-green, and celandine-green, and marked externally with reddish and yellowish-brown spots. Occurs massive; and crystallized in oblique four-sided prisms; internally shining and vitreous. Cleavage said to be parallel with the sides of an oblique four-sided prism of 186° 10′ and 73° 50′. The fracture uneven. Ranges from translucent to translucent on the edges; as hard as felspar; brittle, and easily frangible. Specific gravity 3.00, 3.04, *Breithaupt.*

Geognostic and Geographic Situations.—It occurs in granite, along with green topaz and tourmaline, near Penig in Saxony.

3. APLOME, *Hauy.*

This mineral has a deep brown or orange-yellow colour. Occurs crystallized in rhomboidal dodecahedrons, which are so streaked as to point out a hexahedral cleavage. In lustre, fracture, and hardness, it agrees with common garnet, but its specific gravity is lower, not exceeding 3.444. It is found on the banks of the river Lena in Siberia.

4. CRICHTONITE, *Jameson.*—Craitonite, *Bournon.*

External Characters.—Colour velvet-black. Occurs crystallized in very acute rhomboids, with angles of 18° and 162°. Externally and internally splendent, and lustre vitreous, inclining to metallic. Cleavage imperfect. Fracture conchoidal. Opaque. Harder than octahedrite. Scratches fluor-spar, but does not affect glass. Sp. gr. =3.0.

Chemical Character.—It is infusible without addition before the blowpipe.

Constit Parts.—Zirconia, 46; Silica, 33; Alumina, 14; Iron, 4; Manganese, 1; Loss, 2 =100.

Geognostic Situation.—It occurs in primitive rocks, along with octahedrite, in the districts where that mineral is found.

5. FIBROLITE, *Bournon.*

External Characters.—Colours white and grey. Occurs in fibrous concretions, and in oblique prisms of =100°. Internally glistening. Harder than quartz. Sp. gr. =3.214.

Geographic Situation.—It is found in the Carnatic.

6. GEHLENITE, *Jameson.*

This mineral, named in honour of the late Gehlen, has not been accurately described. It is said to have a green or grey colour; to occur crystallized in rectangular four-sided prisms, and therefore must belong either to the pyramidal or prismatic series; it is nearly as hard as felspar, and the specific gravity=2.9—3.1.

Geognostic and Geographic Situations.—Occurs along with calcareous-spar in the valley of Fassa in the Tyrol.

7. LIEVRITE, *Jameson.*—Jenite, *Hauy.*

External Characters.—Colour black, and blackish-green. Occurs massive; also in distinct concretions, which are small and scopiform radiated, and in others which are thin and straight prismatic; and crystallized in oblique four-sided prisms, variously modified by acuminations and bevelments. Lustre of the fracture glistening and semi-metallic. Fracture uneven. Opaque. Nearly as hard as felspar. Does not change its colour in the streak. Specific gravity 3.825, 4.061, *Lelievre.*

Const. Parts.—	Silica,	30.0
	Alumina,	1.0
	Lime,	14.8
	Oxide of Iron,	49.0
	Oxide of Manganese	2.0—96.8. *Vauq.*

Geognostic and Geographic Situations.—Occurs in primitive limestone, along with epidote, quartz, garnet, magnetic ironstone, and crystallized arsenic pyrites, at Rio la Marine, and Cape Calamite, in the island of Elba. Said also to occur in Siberia.

8. SPHAERULITE, *Breithaupt.*

External Characters.—Colours brown and grey. Occurs in imbedded roundish balls and grains, which are sometimes reniformly aggregated; also in stellular fibrous concretions. Externally smooth, (when it has a milky incrustation,) sometimes rough. Internally alternates from glimmering to dull. Fracture even and splintery. Opaque, or translucent on the edges. Scratches quartz with difficulty. Specific gravity 2.52.

Chem. Char.—Nearly infusible before the blowpipe.

Geognostic and Geographic Situations.—Occurs in pearlstone and pitchstone-porphyries, where it is often associated with small scales of mica, and portions of felspar, in Arran, Saxony, Hungary, and Iceland.

9. SKORODITE, *Breithaupt.*

External Characters.—Colours green and brown. Occurs massive and disseminated, but most frequently crystallised, in very short broad rectangular four-sided prisms, acutely acuminated on both extremities, with four planes, which are set on the lateral edges. There in one distinct cleavage parallel with the broader lateral planes of the prism, consequently in the direction of the shorter diagonal of an oblique four-sided prism. Fracture intermediate between uneven and conchoidal. Translucent on the edges, or semi-transparent. As hard as calcareous-spar, but not so hard as fluor-spar. Sp. gr. =3.3.

Chemical Characters.—It easily melts before the blowpipe, with the copious emission of arsenical vapour, and is converted into a reddish-brown mass, which, when highly heated, so as to drive off all the arsenic, becomes attractable by the magnet. These phenomena shew that this mineral is an arseniate of iron, probably combined with manganese. It contains no copper.

Geognostic and Geographic Situations.—Occurs imbedded in a bed composed of quartz and hornstone, in primitive rocks in the Schneeberg mining district in Saxony; also at Loling in Carinthia.

10. Spak, *Jameson and Breithaupt.*

External Characters.—Colour white. Occurs in small veins, and in thin prismatic distinct concretions. Internally shining and resinous. Has a threefold rectangular cleavage. Fracture small-grained uneven, also small splintery. Translucent. Soft, inclining to very soft. Brittle, and easily frangible. Has a feeble sweetish saline taste.

Chem. Characters.—It is completely soluble in water.

Geognostic and Geographic Situations.—Occurs in the salt-mines of Wielickzka and Bochnia in Poland.

Observations.—1. Its taste is very different from that of common salt, and therefore cannot, like that mineral, be used with food. 2. It is said to be the fibrous rock-salt of Werner.

11. Spinellane, *Hauy.*

External Characters.—Colour plum-blue. Occurs crystallized, in rhomboids of 117° 23′, and 62° 37′; and in six-sided prisms acuminated with three planes. Scratches glass.

Geognostic and Geographic Situations.—Occurs on the shores of the Lake of Laach, in a rock composed of grains and small crystals of glassy felspar, quartz, hornblende, black mica, and magnetic iron-ore.

12. Blue Ironstone, *Klaproth.*

External Characters.—Colour indigo-blue. Occurs massive, and with impressions of crystals of brown iron-ore. Externally glimmering, internally dull. Fracture coarse-grained uneven. Opaque. Semihard. Rather brittle, and easily frangible. Specific gravity 3.20, *Klaproth.*

Chemical Characters.—Loses colour on exposure to heat, and when melted with borax, forms a clear green bead.

Constit. Parts.—	Oxide of Iron,	40.5
	Silica,	50.0
	Lime,	1.5
	Natron,	6.0
	Water,	3.0—100.0

Geographic Situation.—It occurs on the Orange River in Southern Africa.

Uses.—It is used for painting houses at the Cape of Good Hope.

* Chusite, Limbillite, Siderocleptc, Mellilite, and Succinite, minerals described by Saussure and Bonvoisin, appear to be varieties of Olivine and Augite.

MINERALS OF THIRD CLASS.

13. Argentiferous Copper Glance, *Jameson.*—Silber Kuperler-glanz, *Hausmann.*

External Characters.—Colour blackish lead-grey. Occurs massive and disseminated. Internally shining or glistening, and lustre metallic. Fracture flat conchoidal, passing into even. It becomes more shining in the streak, but the colour is not changed. As hard as calc-spar. Sectile, and rather difficultly frangible. Specific gravity 6.255, *Stromeyer.*

Constit. Parts.—	Sulphuret of Copper,	38.654
	Sulphuret of Silver,	60.646
	Sulphuret of Iron,	0.700—100
		Stromeyer.

Geognostic and Geographic Situations.—This rare mineral is found only at Schlangenberg in Siberia, where it is associated with copper-pyrites, calcareous-spar, and hornstone.

14. Bismuthic Silver, *Jameson.*

External Characters.—Colours pale lead-grey, becoming deeper on exposure to the air. Occurs disseminated; and rarely crystallized in acicular and capillary crystals. Lustre glistening and metallic. Fracture fine-grained uneven. Soft. Sectile.

Constit. Parts.—	Bismuth,	27.00
	Lead,	33.00
	Silver,	15.00
	Iron,	4.30
	Copper,	0.90
	Sulphur,	16.30—96.50.
		Klaproth, Beit. b. ii. s. 297.

Geognostic and Geographic Situations.—It has hitherto been found only in the mine named Friedrich-Christian in the Schapbach, in the Black Forest, where it occurs in veins that traverse gneiss, along with copper-pyrites, quartz, iron-pyrites, and galena or lead-glance.

15. Native Nickel, *Jameson.*—Haarkies, *Werner.* Nickel Natif, *Hauy.*

Observation.—It is the *Haarkies* of Werner.

External Characters.—Colour kind of brass-yellow, which inclines to bronze-yellow, and seldomer to steel-grey. Occurs in delicate capillary crystals. Shining or glistening, and lustre metallic. Crystals rigid. Brittle.

Const. Parts.—It consists, according to Klaproth, of Nickel, with a small quantity of cobalt and arsenic.

Geognostic and Geographic Situations.—It occurs in veins in gneiss, where it is associated with hornstone, quartz, calcareous-spar, and brown-spar, at Johangeorgenstadt in Saxony; also in the cavities of copper nickel in Huel Chance Mine, near St. Austle in Cornwall.

16. Pyrosmalite, *Jameson.*

External Characters.—Colour liver-brown, inclining to pistachio-green. Occurs in straight lamellar concretions, and crystallized in regular six-sided prisms. The most distinct cleavage is parallel with the terminal planes of the prism; another, less distinct, parallel with the lateral planes of the prism. Fracture uneven, passing into splintery. Internally lustre of cleavage shining and pearly. Fracture glimmering. Translucent on the edges. Semi-hard. Streak brownish-white. Brittle. Specific gravity, 3.081.

Constit. Parts.—	Protoxide of Iron,	21.810
	Protoxide of Manganese,	21.140
	Submuriate of Iron,	14.095
	Silica,	35.850
	Lime,	1.210
	Water, and Loss,	5.895—
		Hisinger.

Geognostic and Geographic Situations.—It occurs in a bed of magnetic ironstone, along with calcareous-spar and hornblende, in Bjelke's mine in Nordmark, near Philipstadt in Wermeland.

INDEX.

MINERVA, in the ancient mythology, was the Goddess of Wisdom and the Liberal Arts. Jupiter having married Metis, is said to have decided that her children would be more intelligent than their father. Hence he was induced to murder her during pregnancy; and having afterwards suffered violent pains in his head, he ordered Vulcan to cleave it open, when Minerva emerged from Jupiter's brain, fully armed, and was immediately admitted among the gods. She was known by the names of Athena, Pallas, Parthenos, Tritonia, Glaucopis, Agorea, Hippia, Stratea, Area, Coryphagenes, and Sais.

This goddess was very universally worshipped. Sais, Rhodes, and Athens, paid her particular reverence; but she had magnificent temples in Egypt, Phœnicia, Italy, Gaul, Sicily, and all parts of Greece. Being considered as the goddess who introduced arts and inventions into the world, she was invoked by artists of all descriptions, and had a temple built for her by the Athenians under the name of Minerva Μηχανιτις, *machinatrix.*

Minerva is generally represented with a helmet, surmounted by a large plume. She carries a spear, and sometimes a distaff, in one hand, and with the other grasps a shield adorned with the head of the dying Medusa. The breastplate sometimes bore the Medusa's head encircled with living serpents. The owl, cock, and the dragon, were sacred to her. Her functions and actions are very numerous, and are familiar to all classical readers.

MINGRELIA, a province of Asia, comprehending the most considerable proportion of the ancient kingdom of Colchis. It is bounded on the north by the Ceraunian mountains and Circassia; on the south and east by Immertia, and the river Phasis; and on the west by the Black Sea. The air of this country is damp and insalubrious. It is watered by upwards of thirty rivers, the principal of which is the Phasis. The soil along the coast of the Black Sea is so moist, that it is incapable of bearing the operation of ploughing. It is impossible on this account to raise either wheat or barley, and the inhabitants use as a substitute for bread a kind of paste made of a small grain called gom, which is not unlike coriander seed. Agriculture is entirely neglected in this province, and the proportion of arable land is very small. The pasturage, however, is excellent, and a great number of horses are reared. The country abounds with extensive forests of the finest trees, and also with grapes, (from which they make admirable wine) and all sorts of fruits grow wild in great abundance. There was formerly a great number of gold mines in this country, but they are no longer wrought. The Mingrelians cultivate a good deal of silk, but from their ignorance of the art of manufacturing it, nothing is made but a poor sort of handkerchief, and some common taffeties. The principal commerce is in slaves, of which they annually export about 12,000. The peasants are the slaves of the nobility, who have the power of life and death over their vassals. The natives of Mingrelia, it is said, were originally descended from a colony of Egyptians, founded here by Semiramis. They were formerly an enlightened and industrious people, but they have now degenerated into a state of deplorable ignorance and misery. They are in general well-shaped and handsome, but addicted to drunkenness, theft, and many other vices. The principal cities of Mingrelia are Talikara, which is the most considerable, situated on the right bank of the river Hippus, and well peopled, principally by Jews;—Rhregia, also situated on the Hippus, and the usual place of residence of the chiefs or princes of Mingrelia; and Cotais, or Cotatis, which stands on the Phasis. It is a very poor and ancient town, situated in a beautiful and fertile plain, and inhabited by a few Jewish, Armenian, and Turkish families. The religion of the country is that of the Greek church. The population is said to be about four millions. See Kinneir's *Geog. Mem. of Persia.*

MINIATURE PAINTING. This term is usually applied to portraits painted on a very small scale, and commonly executed in water colours on ivory, sometimes on vellum or on paper. Miniatures are also sometimes executed in oil colours.

Although this department of art, from the reduced scale on which its operations are conducted, and the delicacy of handling necessarily resulting from this, is incapable of conveying so completely the grander expressions of character, so striking in the portraits of Titian and Vandyke, to which the larger dimensions, and consequent breadth of manner and vigour of style, so powerfully contribute; it nevertheless possesses many advantages from its portable dimensions, and is equally susceptible of fidelity of resemblance, and beauty of execution. As in reference to composition, design, *chiar'oscuro*, and colouring, it is regulated by the same general principles as the other departments of the art, (See PAINTING,) we shall restrict ourselves at present to the various processes and practical details, by which miniature painting is executed.

Ivory is the substance on which miniatures are most commonly executed, being greatly superior to paper, vellum, or any other material, and, in the hand of a skilful artist, is capable of giving all the depth, richness, and brilliancy of colour, and power of effect, of an oil picture. The ivory is obtained in the shops, sawn into thin plates: That which is clearest and most transparent is the best, receives the colours most readily, and bears better repeated touching.

The ivory is to be prepared by first removing from its surface the marks of the saw, by means of the scraper, an instrument (the same as that used by engravers) consisting of three sharp edges, of the form of a triangular or saw file. The ivory is then laid upon a flat piece of ground-glass, and dusted over with finely pulverized pumice stone, previously sifted through fine gauze; a little distilled vinegar is poured upon it, and the whole well rubbed with a glass *muller*. When this process has been continued for a few minutes, it is washed with clean water and dried; it is then well rubbed with dry pumice dust and a piece of chamois leather, and is fit for use; having been, by this operation, deprived of the gloss and fine polish communicated by the scraper. Some artists use only the pumice dust dry, without the distilled vinegar; but the latter seems to be of considerable importance in removing the grease, or other animal matters, which all ivory contains. In addition to the pumice dust, which is indispensable to give a proper surface to the ivory, some, in order to whiten it more completely, boil it along with fuller's earth, and others bleach it by exposure to the action of the sun's rays; but the process which we have first mentioned will in most cases answer every purpose that can be desired, both as to colour and surface, if the ivory be of a good quality.

When the ivory is fully prepared, it is fixed upon a piece of fine white card paper, by means of a spot or two of *gum Arabic*, and thus is obviated any disadvantage arising from the transparency of the ivory.

The outline is sketched out with a warm neutral tint, applied with a fine hair pencil. Some artists make use of a black lead pencil for this purpose; but, as it is much more easy to make corrections with the water colours, the former method is preferable. The whole face is washed over with a very delicate tint, according to the complexion required; as, for instance, in a dark complexion, a wash of light red; for a fair one, a wash of yellow ochre or vermillion. The half tints, and darker shadows, are to be made out, the former with a neutral tint, composed of lake, a small portion of Indian red, and a little blue, which form a reddish pearly hue, the latter with lake and Vandyke brown. The delicate shadows are to be made out in a broad and flat manner, and the deeper markings are to be added, rounding them delicately into the *neutral tint*, according to the effect on the model. This *neutral*, or *half-tint*, makes a good warm preparation for the more decided colours. Others compose a good neutral tint of *Indian red*, *indigo*, and *burnt terra di Sienna*. The general effect of the face being thus made out, the more positive colours, such as the reds of the cheek, and other fleshy tones, are to be introduced, and may be formed by a mixture of *light red* and a little *lake*. The yellows are to be strengthened where it may be judged necessary, and the face will now have received all its warm tints, which are to be harmonized by the judicious intermixture of the cold colours.

The hair, drapery, back-ground, and, in short, every part of the picture, ought to be brought forward at the same time as the face, in order to show the proper depth and strength of colour and *keeping* in every part. The local colour of the hair is laid in with broad flat tints, marking out only the larger masses and divisions with their shadows. The colours for the hair may be composed of *burnt umber*, *lake*, and *indigo*, in such proportions as may best imitate the tints of the model; for light hair Roman ochre may be used instead of burnt umber.

Some artists, in laying on the back grounds, *float* them, as it is called, with a full mass of the proper colour, perfectly transparent, leaving it in a horizontal position to dry before it be touched upon, and after retouching it with repeated hatching and stippling till it be brought up to the effect required; in this way it is extremely difficult to produce a smooth even tint. It is therefore much more convenient to add to the colours a little *constant white*, in order to give them a degree of opacity, by which the ivory will be more easily covered, the tint will be much smoother, and it will require much less labour in hatching it afterwards.

In all draperies, except thin white ones, it is necessary to add a considerable portion of opaque colour, in order to give the requisite solidity of effect. In lighter coloured draperies, *constant white* may be mixed with the colours, but in stuffs where great strength of colour is required, those pigments which are in themselves opaque, may be used, such as the ochres, vermillion, Indian red, umber, which all give body and consistency to any other colours. In dark grey, purple, and black, a little constant white will be most suitable. In representing thin white draperies, such as muslins, and the like, the opaque white must only be used in heightening the lights; the shadows may be done with transparent colours as delicately as possible, in order to assimilate the style of handling as much as possible to the quality of surface of the object.

The draperies and back-grounds should be laid on in full masses, with a large hair pencil, crossing and working the colour in every direction; and if it be sufficiently opaque, it will cover the surface of the ivory without much retouching. The lights are to be composed of the proper colour, thickened with *constant white*.

The general effect of the whole work being made out according to the rules now given, it will be necessary to carry on the several details through all their stages in the same manner.

In bringing the face to its proper strength of shadow and colour, the warm tints ought in general to predominate; it will require however various cool tints to be introduced, in order to give brilliancy to the lights, and clearness to the shadows; these tints must be regulated by the taste of the artist, but in general it may be recommended to use purple and olive tints, the former composed of carmine and indigo, or ultramarine, the latter of indigo and burnt terra di Sienna. The colouring of the flesh will acquire additional clearness, by the introduction of reflected lights of a warm or orange colour, finely blended into the cool tints, and the full strength of tone and harmony required, will be given by touches of carmine, ochre, and raw terra di Sienna, in proper places.

When any part of the carnations have too much of any particular tint, so as to injure the harmony of the effect, it will be most easily corrected by the introduction of tints of a directly opposite colour; thus, if too blue, orange, its opposite or contrasting colour, must be introduced; if too red, it must be corrected by means of green, and *vice versa*, and so on of the rest. In the article Accidental Colours, in the first volume of this work, some account of these contrasts of colour will be found, which, though chiefly intended to elucidate a very singular optical phenomenon, affords very important illustration of the laws of the harmony of colour in painting.

The doctrine of the contrast of colour is of the utmost practical utility to the painter, by affording him the means of increasing or subduing the brilliancy of his tints in the most easy and agreeable manner; for the appearance of any given colour in a picture will not be in the ratio of its actual intensity, but will be modified by the colours with which it may be contrasted. Thus white will derive much clearness and brilliancy by being contrasted with black, blue, or grey; yellow with orange, and so on of the other colours and their contrasts.

It is indispensable to the clearness and delicacy of flesh, that transparent colours only should be admitted. The constant white on the eye, and sometimes the brightest light on the point of the nose, are the only parts where opaque colours can with propriety be used.

In finishing the hair, the shadows are composed of a deeper tint of the colour which forms the ground work, its strength being increased by the addition of a greater proportion of the mucilage of gum arabic; the lights may be taken off with the scraper, or a sharp lancet, and filled in with a little transparent colour of a proper tint.

The deepest shadows of the draperies are composed chiefly of transparent colours, worked with an increased proportion of gum arabic, by which the depth and clearness of the colours will be greatly increased. Where great richness in the tints of drapery is required, it will often be found of great advantage to lay one colour over another, instead of mixing them together in one tint, as, for instance, a wash of lake or carmine, laid over a tint of vermillion, will produce a crimson tint, almost equal in depth and richness to oil colours, a process analogous to what is called in oil painting *glazing*. The glazing colour must necessarily be perfectly transparent; and if the tint glazed in this manner be opaque, the richness of the effect will be greater.

In like manner, if any part of the picture has too much of any particular colour, it will be best corrected by a transparent wash of its opposite or contrasting colour; thus, if the red predominate, a transparent wash of green will subdue it, and bring it into harmony; if green be too prevalent, it may be harmonized with red, and so on; and the finishing touches may be added in a delicate manner, so as to bring up the effect to a proper degree of smoothness.

The scientific arrangement of the colours of the drapery in a miniature, is of the greatest importance to its effect. In subjects where delicacy of sentiment ought to predominate, the colours must be modest and sober, without much variety; in gayer subjects, a greater diversity of colour is admissible, without, however, violent contrasts or abrupt transitions, which miniature painting hardly admits of in any case.

In miniature painting, it is of great importance to have a thorough knowledge of the qualities of the various pigments made use of, both as to the tints they form when mixed with one another, and their transparency or opacity, as fitting them for the different parts of the work; for although the same tint may be composed from different pigments, its fitness for any particular part of the picture must be determined by the quality of its grain, its smoothness, transparency, or opacity. Thus, in the carnations, the most delicate and transparent pigments only can be admitted; in woollen stuffs, and other substances of the less flimsy sort, the opaque pigments, (with even an addition of white to increase their consistency,) are most suitable; while in thin light draperies, transparent colours will be most convenient for the shadows, and the lights may be delicately heightened with opaque colours.

The following are a list of the pigments most generally used in miniature painting; and in reference to the above observations, we have arranged them into three classes, viz. Transparent, Semitransparent, and Opaque.

Opaque Colours.

Constant White,	Vermillion,
Flake White,	Indian Red,

Yellow Ochre,	Burnt Umber,
Roman Ochre,	Lamp Black.
Prussian Green,	

Transparent Colours.

Gall Stone,	Carmine,
Gamboge,	Vandyke Brown,
Sap Green,	Sepia,
Brown Pink,	Ivory Black,
Lake,	Indigo.

Semitransparent Colours.

Burnt Terra di Sienna,	Antwerp Blue,
Indian Yellow,	Burnt Ochre.
Ultramarine,	

These colours are usually made up into cakes, and rubbed with water upon a stone plate or tile. The best water colour cakes are those manufactured by Newman & Co. and Smith, Warner & Co. of London.

The colours are diluted to a proper consistency with clean water, and worked with hair pencils.

In water colour painting of every kind, the addition of a very minute quantity of ox-gall to the water, will make the colours work with great ease, particularly where any greasiness occurs. The ox-gall, as procured from the shambles, may be boiled to dryness in a cup, and in this state it may be preserved for any length of time. A small quantity of this substance in the dry state, not larger than a pin-head, will be sufficient for a wine-glassful of water, and with this the colours are to be wrought. The ox-gall may also be preserved for a long time in the fluid state, by mixing it with a little spirit of wine, or other ardent spirit.

It is also necessary to have a small phial of the solution of gum Arabic, which is to be added to the colours, as may be required, particularly where it is desirable to give great depth of tone to the picture.

The chief quality in a hair pencil is, to have great elasticity, and a fine point, without being itself too small. The *sable hair* pencils are the best sort.

When a miniature picture, by repeated working and touching, has acquired any asperities on its surface, it will be necessary to remove them by the dextrous application of the scraper, and any damage that it may have sustained by this process, is easily repaired with the hair pencil, and a little colour. The scraper is also of great use in obliterating small touches, which it would be inconvenient to wash off with water, but if the alteration required is extensive, it is preferable to wash the part with water and hair pencil.

In the execution of a miniature, there are three different modes of laying on the colours, namely, by flat washes, by hatching, and by stippling. The first term sufficiently explains itself, and by this process the greater part of the miniature ought to be executed. *Hatching* is that method by which lines are made to cross each other in every direction, in the manner of a stroke engraving; and *stippling* consists of dots of greater or less size and closeness, according to the effect intended. The hatching and stippling are chiefly to be employed in the more delicate parts of the picture, where much variety and richness of colour are to be given; but they are to be introduced with much caution, so as not to detract from the smoothness or other qualities of surface which propriety may suggest.

With regard to the degree of finishing, which it may be proper to bestow on works of this kind, no rule can be given; and the example of many eminent artists of the British school, sufficiently shews, that with judicious management, guided by sound taste, all the purposes of art may be attained, either with a light and delicate, or a more elaborate style of execution. Upon the whole, we are rather inclined to give the preference to the light, airy, and tasteful style, as exemplified in the works of Mr. Cosway, and Mr. Antony Stewart, of London, which we conceive more suitable to the gay character of miniature painting. The works of Mr. G. Sanders, Mr. A. Robertson, of London, Mr. W. J. Thomson, and Mr. Nicholson, of Edinburgh, afford a striking illustration of the power and brilliancy of colour, and strength of chiar'oscuro, of which this department of art is susceptible.

As water colours are liable to fade by exposure to light, they ought to be covered with a silk curtain, if they are not secured in a cabinet, which is the most proper place for works of this description, particularly miniatures, where they may be preserved for any length of time. A remarkable proof of this is given by the works of Cooper, an eminent English miniature painter, in the time of King Charles the First; those specimens which have been preserved in cabinets have retained all the freshness of colouring for which he was so much celebrated, while those that have been exposed to light have lost all their force.

When a miniature is finished, it is covered with a convex glass, to which it is fixed all round the edge with goldbeater's skin, and thus it may be preserved from injury for any length of time.

In choosing the attitude, the good sense of the artist will naturally direct him to adopt that which will be most agreeable, and most characteristic of his model; and the same principle will regulate the effect of colour, and light and shadow, according as the subject is gay, animated, or grave; and this will be much influenced by the proportion which the light bears to the shadow, and the manner in which they are introduced, as well as by the quantity of warm or cold colour which may be allowed to predominate. Thus the effect will be gay, when the white, delicate yellows, orange, and the other light tints prevail; it will be grave or solemn, when black, blue, and neutral greys form the basis of this effect.

Miniatures on vellum or paper, are executed in the same way as all other water-colour drawings, and as these substances admit of repeated washes over each other, and of blending them together without any risk of washing off the first layers of colour, the processes of hatching and stippling are not so indispensable, although, when judiciously managed, they contribute greatly to the richness of the effect. The only preparation which the paper or vellum requires, is a simple wash of the weak solution of ox-gall already mentioned, which is of great importance in making the colours work sweetly. Whether vellum or paper be used, in subjects of so much delicacy as portraits of the size in which miniatures are executed, it is obvious that that which has the smoothest surface will be the most proper. What is called *Bristol card*, affords the best surface, and most agreeable ground; it is usually of considerable thickness, and is rendered extremely smooth, by means of *hot-pressing*.

Miniature *whole lengths*, are frequently executed in water colours on *Bristol card;* and although this material does not equal ivory in the clearness and depth of tone which it gives, it is, under the hands of a skilful and scientific artist, susceptible of much beauty of effect, and delicacy of finishing. We may mention as a proof of this, Mr. Nicholson's beautiful portraits of Mrs. Scott Moncrieff, and of the Earl of Buchan.

Miniature *whole lengths*, are sometimes executed on Bristol card, the face only being executed in colours, and the rest being finished up to greater or less effect with the black lead pencil. Sometimes the sky and black ground are also delicately tinted with water colours. Formerly, the French and Italian artists painted miniatures entirely in *body* or opaque colours, but as these colours are easily injured, and have none of the depth and brilliancy which are so great a charm in the miniatures of our best British artists, painted in the usual manner, it is now little practised. This mode of art is executed by simply adding *constant white* to the transparent colours, and thus giving them a body. Miniatures have sometimes been painted in oil colours, and this forms by far the most permanent species of art; it was much practised by our countryman Jameson, called the Scotch Vandyke, and he gave to it all the freedom of execution, and beauty of colouring, for which his larger works are distinguished. When miniatures are to be painted in oil, they may be painted on Bristol board, previously saturated with drying oil, on pannel, or plates of copper, which last is certainly the best for this purpose.

Some artists, in painting miniatures on ivory, execute the face only in water colours, in the usual way, and having covered it with a coat of varnish, finish the rest in oil colours; this combination, however, of the two materials, oil and water-colours, is seldom very harmonious; but it is very durable, as the water-colours are not liable to fade, after having received the varnish; but the water-colour miniatures executed according to the process which we have first noticed in this article, must always obtain the preference for beauty of effect, and if properly secured from external injury, and excluded from the light, will be sufficiently durable. (P. G)

MINING. See MINES OF COAL, and VEINS.

MINORCA, MENORICA, or the Smaller, compared with Majorca, is the second of the Balearic isles in point of importance, and is situated in 40° N. latitude, and 30° 45′ E. longitude, about ten leagues to the north-east of Majorca. It is of a long and narrow shape, circular towards the north, and concave on the south coast; about 13 leagues in length, and 38 in circumference. It has been successively possessed by the Carthaginians, Romans, Vandals, Moors, Arragonese, and Castilians; and, for more than a century past, has fallen by turns into the hands of the Austrians, British, French, and Spaniards. Various antiquities are still discernible, and others are occasionally discovered in the island, which indicate the history of its former possessors. In the district of Alayor, is a large round mass of unhewn stones heaped together without any cement, called by the islanders an altar of the Gentiles. There is a cavity at its base, with a low entrance; and on its conical summit, a flat place, capable of containing eight or ten persons. Its origin is ascribed to the Celtic druids. On the summit of Mount St. Agatha, also, are the vestiges of an old fortification, which is considered as a Roman work. Sepulchres, sepulchral lamps, urns, and lacrymatories, small coarse bronze figures, medals, and coins of various nations, are found in the greatest abundance.

The island is generally flat in its surface, particularly on the south coast; and the soil, though rocky or thin, is in most respects tolerably productive. It is much exposed to the north winds, which greatly injure the growth of the trees on that quarter; but snow is seldom seen in the winter season, and the climate during the spring is mild and salubrious. In autumn, the rains are extremely heavy; and in summer, the heat and drought are most oppressive.

The principal mountain is Mount Toro, nearly in the centre of the island, steep and conical, with a flat summit, on which is built an Augustine monastery, to which penitents and pilgrims ascend barefooted at all times of the year. The most remarkable natural curiosities are an extensive grotto near Ciudadella, full of beautiful stalactites; and in its vicinity, a subterranean lake of salt water. Iron ore and lead ore are common, and marble of various qualities and colours. Limestone, full of petrified shell-fish and other admixtures, is very abundant; besides fine blue slate, and excellent white soft stone, which hardens by exposure to the air. Red coral is found in great quantities on the shores; and sometimes the fishers bring up large pieces of white coral in their nets. Fossils and shells are numerous.

The wild animals of the island are chiefly hares, rabbits, and hedge-hogs; but birds of different species are very numerous. The fish around the coast is abundant in all seasons, and of excellent quality. Oysters, and other kinds of shell-fish, are also plentiful and good. Horses are sufficiently common; but mules and asses are chiefly used in riding. The mules are very handsome; and some of them are not less than sixteen hands high. The ass also is of a large breed, and by good management is rendered a very tractable animal. The other domestic animals are horned cattle, sheep, goats, and pigs, of which last considerable numbers are reared in the island. The principal crops are wheat, barley, and a little maize; but fruit of every kind is very plentiful. The olive trees grow spontaneously; but the fruit is used more for pickles, than making oil. Both red and white wines are made from the grapes.

The inhabitants of Minorca have no manufactures or articles of commerce; but might easily produce for exportation, as well as for their own use, cotton, flax, oil, saffron, and quantities of excellent fruit. Their exports consist chiefly of a little wool and cheese, to the value of 2,500*l.* sterling per annum; wax, wine, honey, and salt, to the annual value of above 17,000*l.* The imports are, corn, rice, sugar, coffee, brandy, tobacco, spices, linen, fine cloths, pitch, cordage, and some articles of furniture. The island is provided with the finest harbours in the world, particularly those of Fornella, and Port Mahon, which are capable of containing the largest fleets.

The island is divided into four districts or terminos; and the principal towns are, Ciudadella, Mahon, Alayor, Ferarias, and Mercadel. Ciudadella, the capital, situated to the north-west, with a small harbour, is a very ancient place, tolerably fortified, and containing about 700 houses. Mahon, which is now the principal town, is situated on a rocky promontory, very difficult of access from the land-side, and defended by Fort St. Philip, formerly of great strength, but of late completely demolished by the Spanish government. Alayor, about half-way between Mahon and Ciudadella, is tolerably well built, and is chiefly remarkable for the sculpture and paintings which decorate the interior of its church, and which are the works of a self-taught artist, a native of Majorca. The other two towns are mean villages in the central district of the island. The whole population of the island is estimated at 30,000. The inhabitants are a quiet race. They still preserve among them the skilful use of the sling, for which their ancestors were renowned. They are remarkably attached to their religious ceremonies, and delight in pilgrimages and processions. The dress of the men resembles that of Majorca; but that of the women is rather peculiar. They have very long waists, and short full petticoats. They wear a piece of muslin or crape under the chin, rising on each side of the face till it join a handkerchief drawn tight across the forehead. Over the head is a large piece of muslin hanging down like a cloak; and sometimes they have red mantles tied behind with yellow ribband, under which their hair, tied close at the neck, hangs down like a horse's tail. One of their strangest practices is their mode of churning, which is done by a woman holding by two pegs in the wall to keep herself steady, while with one foot naked she stamps in a tub of cream, till it becomes butter. The possession of Minorca is considered as highly important to the British navy in the Mediterranean.—See Laborde's *Travels in Spain*, vol. iii.; Williams' *Voyage up the Mediterranean*; and Armstrong's *Natural History of Minorca*. (*q*.)

MINOS. See CRETE.

MINSTREL. See BARD, DRAMA, and POETRY.

MINT, is a word used to denote the place where the king's money is coined. In our article COINING MACHINERY, we have already given some account of the English mint, and of the old as well as the new machinery used for the purposes of coinage. We shall, therefore, confine our attention at present to a short notice respecting the mints of England and Scotland, and conclude the article with an account of Mr. Barton's new machine for equalizing the thickness of slips of metals, which has been introduced into the mint since our article on COINING MACHINERY was published.

English Mint.

The early history of the English mint is involved in much obscurity. At a very early period, mints and exchanges were established in various parts of England. In A. D. 928, Athelstane established rules for the regulation of the mints. He enacted, that only one kind of coin should be current, and he granted to different towns a number of moneyers, in proportion to their size, and one moneyer to all burghs of inferior note. When any alteration took place upon the coins, the dies were issued to these mints, for which a regular fee was paid by the moneyers, besides their annual rent.

In the 18th year of Edward II. a considerable change took place. He appointed a master, warden, comptroller, king's and master's assay master, and king's clerk, with several inferior officers, and this constitution continued with but few changes till the year 1815.

In 1798 a committee was appointed to consider the establishment and constitution of his Majesty's mint, and the result of this appointment was the erection of a new mint, with highly improved machinery, between 1805 and 1810.

In 1814 Mr. Wellesley Pole was appointed master of the mint, and drew up a report relative to its constitution, which was introduced in March 1815. The following is a list of the principal officers.

1. Deputy master and warden.	9. Chief engineer.
2. King's assayer.	10 Weigher and teller.
3. Comptroller.	11. Surveyor of meltings.
4. Superintendant of machinery and clerk of the irons.	12. Do. of the money presses.
	13. Probationer assayer.
5. King's clerk and clerk of the papers.	14. Master's second clerk.
	15. Assistant engraver.
6. Master's assayer	16. Mint or bullion porter.
7. Master's first clerk & melter.	17. Warden of the mint.
8. Provost and company of moneyers.	18. Stamper of money weights.
	19. Solicitor of the mint, &c

Our limits will not permit us to enter into any detail respecting the duties of these various officers and the regulations to which they are subject;—details, indeed, which cannot be supposed to possess a higher interest than those which relate to any other great manufactory. Our readers, however, will find the fullest information on this, and all other subjects connected with the mint, in the Rev. Roger Rudding's *Annals of the Coinage of Great Britain and its Dependencies*, in 5 vols. 4to.

Scottish Mint.

The early history of the Scottish mint is very obscure. It consisted probably of very simple apparatus, and few materials, which were kept in the immediate vicinity of the king. The royal prerogative of coinage does not seem to have been ever delegated to subjects in Scotland, and it is explicitly declared to be vested in the king, who, according to a *statute* 1424, *cap*. 24 is to cause new money to be struck when he considers it suitable and profitable for the realm. Various places of coinage appear on the earlier coins, but the principal mint was certainly at Edinburgh, at least from the time that this city became usually the royal residence, and it continued there until the union of the kingdoms. The other mints, if such they can be called, were at St. Andrew's, Perth, Dundee, Aberdeen, Stirling, Dunbarton, Linlithgow, Berwick, Roxburgh, and Annan. The mint of Perth or Dundee was worked before the accession of James VI. It is not explained whether gold was struck elsewhere than in Edinburgh; and the name of the place of the mintage billon, or copper washed with silver, first introduced in the reign of James II between 1436 and 1460, is rarely seen upon it: *Cardonnel Numismata Scotiæ*, p 147. Anciently the mint is denominated the *cunyie house* or coining house, and its apparatus, the *irons*. Therefore, when the reformers in 1559 took possession of the mint, they considered themselves as effectually interrupting its operations, by carrying off the coining irons; and, in a royal proclamation, it is declared, "they have taken, and yet withhold the irons of our cunyie house, which is one of the chief points that concerneth our crown." *Keith's History*, p. 94. *Knox's History of the Church*, p. 301, 302 They defended their proceedings, because the government were impoverishing the country, by issuing a quantity of base money, called hardheads. The same simplicity of apparatus was continued with little deviation until the reign of Charles II. when the coining press was introduced into the Scottish mint; but if the nature of the products be considered, it seems not unlikely that some better mechanical method than merely hammering coins or medals must have been adopted. On the event of the union, Queen Anne issued a warrant in 1707, directing that the officers of the mint should be instructed in the plan pursued by the English mint, and soon after the whole currency was recalled by proclamation, to be recoined.

Some antiquaries conjecture that the earliest Scottish mintage belongs to Alexander I. But it is doubtful whether the silver penny ascribed to him is not of his successors of the same name. Many are seen of William, who reigned 1189—1214, yet nothing is said of the mint until the time of David II. in 1329—1371. Then a statute ordains a new coinage, with a distinguishing mark, *signum notabile*, that the chamberlain shall agree, on part of the king, with the coiner, (*monetarius*) and the workmen; and the warden, (*custos monetæ*) and master of the money or master coiner, (*magister monetarius*,) are also named: *Statute, Dav. II. cap.* 38. 46. In this reign, the mint perhaps subsisted on a regular establishment, for certain privileges, such as exemption from taxes, sitting on juries, and other burdens, are conferred on Adam Tore, warden, James Milliken, mint-master, and their servants, by a charter dated in 1358. These privileges were renewed by James V. in 1542 and his successors, and so lately as the year 1781, the officers of the mint proposed to take advantage of them. The number of officers, and the nature of their duties, were different at different times. At length the establishment is described, in an act of Privy Council in 1567, as consisting of a general of the coining house, master coiner, warden assayer, and sinker, together with melters, forgers, and printers; and it is described nearly in the same terms in *statute* 1597, *cap.* 249. with the addition of another officer, the counter warden. By the *articles of the Union*, § 16. it is provided that the establishment shall be subsequently preserved on the same basis as before it, and now the officers consist of general, master, counter-warden, assayer, and smith. It is not evident, when the denominations of the diffierent officers was bestowed, from which alone a correct history of the establishment could be deduced. In the records we find appointments to the office of general in 1559, and afterwards of master of the coining-house in 1538, warden in 1539, counter-warden 1542, master-coiner 1565, sinker or hacker of the irons 1546, keeper of the king's coining irons 1525, assayer 1329—1370. This last office was then granted to John Goldsmith, burgess of Edinburgh. Mr. Rudding observes, that he has obtained the name of only two wardens of the Scottish mint, but we have remarked so many, that there seems to have been a regular succession from a very early period. Indeed, the duties of this officer, and those of the counter-warden, have been always very important. By *Stat.* 1483, § 93, it is enacted, that the king shall appoint a wise man, that has knowledge in money, to be warden, who by *Stat.* 1551. § 33, 58. is rendered responsible for the quality of the coinage. He is to furnish the master-coiner, who is made responsible for the quantity of the coinage, with bullion, and keep an account of the number of ounces struck yearly, *Stat.* 1488. It has been affirmed, that foreigners were employed as engravers to the Scottish mint of old, but we have been able to find very few, if any, such. Briot, a French artist, was employed to engrave the dies for the coronation medal of Charles I. in 1633, and the successors of this sovereign commanded the celebrated Thomas Simon, in 1662, to make puncheons for gold and silver coinage in the Scottish mint: *Vertue, Works of Simon, Appendix*, p. 71. The abilities of the artists were exceedingly various, and the erroneous legends prove their ignorance of the language, regarding which they were employed; thus, on the coins of James IV. 1488—1513, for Rex Scotorum, we see, Rex *Cot, Cotto*, or *Cotru*. The quality of the products of the Scottish mints, however, was not inferior to what came from some of the cotemporary mints in Europe, and in the sixteenth century, probably surpassed those of England. Many of the dies are said to have been recently in preservation. A great quantity of base coin was continually in circulation; and, notwithstanding successive ordinances that the national coinage should be of the same weight and fineness as the English, there were many complaints in England of its inferiority. Its circulation there was prohibited, but it was allowed to be brought to the mint as bullion. *Rudding—Annals of the Coinage*, vol. i. p. 443, 484. The numerous forgeries in Scotland led to a penal statute against "forging the king's irons;" and magistrates were enjoined to establish "sufficient clipping houses" where the "clipper" was to have a certain remuneration for destroying false money. *Stat.* 1540, *cap.* 124.—1567, *cap.* 19.

From the strict prohibitions against exporting the precious metals, and the anxious enactments for their import under inspection of the warden, the mint evidently laboured, in general, under a deficiency of bullion. However a very fine coinage from the native gold of Scotland was issued by it in the year 1539, in what are called bonnet pieces. Nearly two centuries antecedent to that period, a gold coin or medal was struck of David, which has been supposed English workmanship; and in 1478 a gold medal of James IV. weighing two ounces, was struck at Berwick, and sent by him to the shrine of a saint in France.—*Pinkerton on Medals*, vol. ii. p. 113. At this latter period the native gold was separated from the sand by washing; and it is affirmed that, in the subsequent reign, Germans repairing hither in quest of that metal, had engaged 300 persons in their service, and recovered as much as to afford large sums to the king. In the earlier years of James VI. Cornelius Devosse, a German lapidary in London, obtained a grant of the gold mines in Scotland, from the recommendations of Queen Elizabeth, on condition that the whole gold procured by him should be carried to the mint. The subject continued to attract much attention after the union of the crowns, more, perhaps, than it merited. A master of all mines and minerals was appointed in 1607, and the gold and silver mines of Lesmahago were bestowed on the Marquis of Hamilton in 1620.—*Records of the Privy Seal.* In 30 days, eight pounds of native gold were brought to the mint, by the German lapidary, where it was coined into L.3 pieces, each an ounce in weight. All of these, which could not exceed 100 in number, have utterly disappeared. The workmen also obtained gold, which they sold for 20 shillings Sterling an ounce. Besides what was brought to the mint, it is said in the Manuscripts of Atkinson on this subject, who was personally concerned, that a partner in the mining concern got as much native gold as enabled an artist in Edinburgh to make "a fair deep bason," capable of holding an English gallon to the brim, which the Earl of Morton presented full of gold unicorns to the king of France, assuring him that both were from the native gold of Scotland. It is not recorded by any other author, that the mint produced that coin, the unicorn, of Scottish gold. Another contract seems to have been made with a different foreigner, wherein provision was made in like manner for supplying the mint. Atkinson affirms that Mr. Bulmer, afterwards Sir Bevis Bulmer, presented a porringer, made of Scottish gold, to Queen Elizabeth, and alludes to a coinage different from the former. Somewhat later, namely in 1633, a fine medal of Scottish gold, issued from the Edinburgh mint, on the coronation of Charles I. inscribed around the edge, EX AURO UT IN SCOTIA REPERITUR. There was no gold coinage in the two reigns succeeding; and the last in Scotland was that of William III. in 1701, struck from some gold sent home by the Scots Darien Company. Native gold is still found in small quantities in Scotland. But though silver has been frequently extracted from lead-ore, and though Atkinson gives an account of the finding and losing of a rich silver-mine at Hilderstone, in the county of Linlithgow, we have not heard of any coinage from it.

Perhaps no documents are extant which shew the total coinage in any of the metals issuing from the mint during the reign of any of the Scottish sovereigns; nor is it probable that either bullion or money ever could be abundant in a country alike destitute of domestic products and foreign commerce. William the Lyon having been taken prisoner, was ransomed for 40,000 merks, and David II. nearly two centuries after, was ransomed for 100,000, which must have drained the nation of a large portion of the currency, and led to the employment of the mint for the special purpose of producing it. Attempts have been made to prove that great advantage was derived from a monopoly of trade with France. "Nay," says one author, "who would believe it, were it not demonstrable from unquestionable vouchers, the records of the mint, so immense were our profits this way, that, in the reign of James VI. we coined 119 stone-weight of gold, and 986 of silver, within the space of one year." *Preface of the Translation of Beague's Campaigns*, p. 28. From a few authentic details of the operations of the mint, which have occurred to us, we incline to conclude that the quantity of gold within the period specified, is somewhat overrated, but that the computation of silver is not so.

Between November 1583 and April 1585, inclusive, the mint coined 6 stone, 13 lb. 10 oz. of gold into lyon nobles, the metal being computed at 16 pounds per stone; and the coinage of the fineness of 21½ carats. From the 4th of November 1592 to the 18th of January 1594, the mint consumed 12 stone, 2 lb. ½ oz. in a coinage of 4*l.* pieces, which were struck at 35 different times. Within the same period, there were likewise struck in "Thistle nobles," of which we have never seen either a specimen or a figure, five pounds six ounces on the 10th of November, 1593. The quantity of gold daily used on these occasions varied from 19 ounces, to 11 pounds 4 ounces. *Manuscript Accounts of the Mint*. From 16th December 1602, to 19th July 1606, and from 20th September 1611, to 14th April 1613, the mint struck 51 stone 11lb. 9 oz. of gold. *Ruddiman's Preface to Anderson's Diplomata*, p. 85. If the quantity of 119 stones be actually overrated, it is not inconsistent to believe that the author may have made up his calculations from several portions of successive years, and by combining them, he may have conceived that 119 stone were coined in the space of one year. Gold was rated at a very high price.

On certain occasions, the consumption of silver was very considerable, and it is also probable that the preceding computation of the whole during a year of the reign of James VI. at 15,776 pounds of bullion is within the truth. Regarding this also, we find only a few detached notices preserved. Being rated at too high a value, the *statute* 1581, *cap.* 107, recals a late coinage which had been struck from 211 stone, 10 lb. of silver, and the mint proceeded to strike 548 stone, in ten, twenty, thirty, and forty shilling pieces, between 7th April, 1582, and 1st February, 1583. From the 1st of May of that year until the 1st of October of the year following, 264 st. 12 lb. of silver was consumed in pieces of the same denomination. No less than 1138 st. 10 lb. seem to have been converted into eight and four-penny groats of three deniers fine, during the first nine months of 1584, and 217 st. 7 lb. into penny and two penny pieces, in the first three months of 1590, though, during the two preceding years, the mint was in great activity. Ruddiman observes, that, notwithstanding 596 st. 7 lb. 13 oz. of silver was used in the periods above mentioned, between 1602 and 1612; the value of the gold coinage within the same period, surpassed it by 1554*l.* sterling. The quantity of silver consumed by the mint was therefore very considerable; and we find it employed in a coinage during 1694 and 1695, when both the weight of silver, and the number of pieces struck, were all distinctly enumerated in the books of the counter warden.

For the purpose of supplying the mint, in the 17th century, a duty was imposed, first on exports, and then on imports also, of a certain quantity of bullion, which the trader had it in his option to pay in money, at the rate of a shilling an ounce. Thus the exporter of 20 sheep was taxed with two ounces of bullion, and the importer of French wines, twelve ounces per ton. They did not supply the bullion, however; but the mint, during most of the reign of Charles II. seems to have coined about 200 stone of silver yearly.

During the same reign, it was authorised to employ 6000 tons of copper in coinage. Many abuses prevailed, and the officers whose province it was to supply both that metal and bullion, converted not less than 40,000 stone to money, obtaining from every pound the value of three shillings Sterling.

At the date of the Union, the old silver currency being recalled for the purpose of a new coinage, there came in 142,180*l.* Sterling of hammered money, and 96,856*l.* of milled money, which latter must have been executed subsequent to the succession of Charles II. The operations of the mint were suspended on the death of his predecessor, which the commissioners from Scotland represented to Parliament, occasioned an extreme scarcity of money, and it ceased to work a short time subsequent to the union of the kingdoms. (*c.*)

Description of Mr. Barton's New Machine for equalising the thickness of Slips of Metal for making Coin.

Fig. 1. of Plate CCCXCVII. represents a side elevation of the machine, as it would appear when in action, and Fig. 2. a horizontal plan of it. This machine operates in the same manner as wire drawing-machines, viz. by drawing the slips of metal forcibly through an oblong opening formed between two surfaces of hardened steel. The box or case which contains the steel dies, and also the pinchers employed to hold the metal and draw it through, are represented on a larger scale in fig. 3, 4, and 5, on the plate. Fig. 3. shews a section of the die-box, and elevation of the pinchers. The dies are composed of two cylinders, *a*, *b*, made of steel; they are rendered extremely hard and very straight upon

their surfaces, being highly polished; these cylinders are fitted into convex cavities formed in the pieces of metal A, B, and are retained in their places by clamping pieces *c*, *c* pressing against them, by which means the steel cylinders are firmly supported, and prevented from bending during the violent action of the metal while passing between them. The pieces of metal A, B, are fitted into a box C of cast iron, so as to bear flat against the bottom of the same, and are secured by bars, *e*, *e*, screwed across the front, as seen in Fig. 5. which represents a front view of the box containing the dies, the lower piece B rests upon the ends of three screws, *d*, *d*, *d*, which pass through the metal of the box C, whilst the upper piece A is forced down by the action of a large screw D, which has a toothed wheel N upon its uppermost end, with a pinion and lever to turn it round by and adjust the distance between the dies; the screw D is furnished with a clamping nut *f*, to remove any shake which might remain in the threads of the screw; the pieces A and B are confined sideways by small screws *g*, *g*, pressing against them very forcibly; *h*, *h* represent two extending screws, which are introduced between A and B, to force them asunder, and bring them into firm contact with the ends of the screws D and *d*, *d*. *d*. The box containing the dies is fixed at one end of a long horizontal frame, as seen at C, Fig. 1. and strengthened by cast-iron brackets, *i*, *i*, Figs. 1. and 2. The frame is furnished with adjusting bearings, *k*, *k*, at each end, to support two axes E and F, which have wheels fixed upon them adapted to receive endless chains of metal of the form seen at *l*, *l*; which lie in channels formed along the surface of the frame. A large cog-wheel G is fixed upon the axis F, to give motion to the endless chains; this cog-wheel is turned by a pinion H, fixed upon an axis *m*, extending across the top of the frame, and working in bearings at each end; a cog-wheel I is fixed upon the axis *m*, and works into the teeth of a pinion K, upon a second axis across the frame, which also carries a drum-wheel L, for giving motion to the whole machine by an endless strap. Fig. 3. and 4. represent the pinchers which take hold of the slips of metal and draw them through the dies. The two jaws of the pinchers are united by a joint pin *n*, which projects on each side of the pinchers, and is furnished with small wheels or rollers, *o*, *o*, Fig. 4. to run along the edges of the channel formed upon the frame. In order to receive the endless chains, *p*, *p* are two wheels similar to *o*, *o*, but are fixed upon an axle which passes through between the tails of the pinchers; the axle of the wheels *p*, *p* is attached to strong links of iron *q*, *q*, the ends *t* of which are formed like a hook to take hold of the rounds of the endless chains so as to draw the pinchers along with it; the pinchers are situated over the endless chains, and will run backwards or forwards upon their wheels. They are caused to gripe the slips of metal firmly between their jaws by the axle of the wheels *p*, *p*, acting between two inclined planes formed upon the insides of their tails. The links *q*, *q* are furnished with a weight *r*, which operates to raise the hooked part *t* above the links of the endless chains, whenever the strain upon the pinchers ceases by the slip of metal having passed through and out of the dies. The slips of metal to be operated upon by the drawing machine are first rendered thinner at one end, in order to introduce them between the dies and between the jaws of the pinchers. This thinning of the ends is effected by the machine represented at Fig. 6. in the plate; it consists of a small pair of rollers mounted in an iron frame, similar to a rolling-mill. The upper roller A is cylindrical, whilst B is formed with three flat sides, leaving only portions of the cylinder entire, between the flat sides, the distance between the centres of the rollers is regulated by screws having wheels on their upper ends in the manner described for the drawing dies C in Fig. 1, 2, &c. The rollers have pinions upon their axes which cause them to turn round together; they are put in motion by an endless strap passing round a drum, upon the axis of which is a pinion working into the teeth of a wheel fixed upon the axis of the lower roller B.

The end of a slip of metal is presented between the rollers whilst they are in motion, not on that side of the roller which would operate to draw the slip in between them, as in rolling mills, but on the contrary side, so that when one of the flat sides of the roller B comes opposite the circumference of the roller A, an opening is formed, through which the end of the slip of metal is to be introduced, until it bears against the fixed stop *b*. at the back of the rollers; now as the rollers turn round, the cylindrical portions come opposite, and press the metal between them, forcing it outwards, rendering the part which has been introduced between the rollers as thin as the space between their cylindrical surfaces, which allows the end of the slip of metal to be passed between the dies of the drawing machine to be seized by the pinchers.

In using the drawing machine, a boy takes hold of the handle *s*, (when the hook *t* is disengaged from the endless chain) and moves them upon their wheels towards the die-box C. This causes the jaws of the pinchers to open by the two pins, *v*, *v*, which are fixed across between the links *q*, acting upon inclined parts outside of the pincher tales, as seen in Fig. 3. The pinchers are pushed up so close to the die box, that their jaws enter the cavity *w*, which brings them near the dies, in order to seize the end of the slip of metal introduced between them. The boy now holds the handle *s* upon the top of the pinchers fast, and with the other hand draws the handle *x*, at the end of the link *q*, backwards. This closes the jaws and gripes the metal. He then presses down the handle *x* till the hook *t* seizes the endless chain whilst in motion, and carries the pinchers and slip of metal along with it; when the whole length of the slip of metal has passed through between the dies, the strain upon the pinchers is suddenly relieved, which causes the weight *r* to raise the hook *t* above the chain, and stop their motion. The machine in the mint has two sets of dies, and endless chains, as will appear from Fig. 2.

The following information relative to the Mint of the United States, has been furnished by Robert Patterson, Esq. the present Director of that institution.

Mint of the United States, at Philadelphia.

This institution was established by an act of Congress passed the 2d day of April, 1792.

The officers of the mint are, at present, a director, a treasurer, a coiner, an assayer, a melter and refiner, and an engraver, with one clerk. for the whole institution.

The coins to be struck at the mint, as established by law, are, in gold—eagles, (10 dollar pieces.) half eagles, and quarter eagles; in silver—dollars, half dollars, quarter dollars, dimes, and half dimes; and, in copper—

cents, and half cents. Gold and silver are coined for individual depositors only; copper, on account of the government, but to be transported in exchange for an equal amount in specie, or paper receivable at the bank of the United States, to all parts of the United States, at the expense and risk of the government.

The amount of coinage, in different years, depends on that of the deposits. In the year 1820, the number of pieces coined was 6,492,509, amounting to $1,864,786.

The machinery is moved by a steam-engine.

The drawing-machine, for equalising the thickness of the slips of metal, is precisely the same as that described in page 614 of this Encyclopedia, called "Berton's New Machine," and has been in use since the year 1793.

MISSIONS. In this article we propose to give a general view of the attempts made by the Protestant churches for the propagation of Christianity among heathen nations: Of the principal missions established by the Church of Rome, some account may be found in our history of those countries which were the scene of them. See ABYSSINIA, ANGOLA, CALIFORNIA, CANADA, CHINA, JAPAN, &c.

In 1559, the celebrated Gustavus Vasa, king of Sweden, sent a missionary of the name of Michael into Lapland, with a view of extending Christianity in that country; for though it had been introduced some ages before the reformation, yet most of the inhabitants were still little better than Pagans. But though it is now nearly three centuries since the Swedes began to extend the gospel in Lapland, it has hitherto made small progress. The inhabitants, indeed, are professed Christians; but the Christianity of most of them is merely nominal, and among some of them the form of it may be sought in vain.

In 1716, Frederick IV. king of Denmark, sent two missionaries into Norwegian Lapland; and, according to the accounts which are given of that part of the country, the inhabitants are better provided with the means of Christian instruction than those of Swedish Lapland; but we suspect religion has made no great progress among them.

In 1802, the Edinburgh Missionary Society* sent the Rev. Henry Brunton and Alexander Paterson on an exploratory mission to the countries lying between the Black and the Caspian Seas. The Russian government favoured the undertaking, and afforded them every assistance and encouragement. This mission now consists of three branches, Karass, Astrachan, and Orenburg; and it is in contemplation to establish a fourth in the Crimea. Besides writing a number of small works in the Tartar language, Mr. Brunton translated into it the New Testament; and a version of the Old Testament is now carrying on by the other missionaries. Of these, large editions were printed, and extensively circulated through the regions of Tartary. Several of the natives have embraced Christianity; and, among others, one of the sultans of the country, a young man of highly respectable talents, and who is connected with some of the principal families in the East.

In 1705, Frederick IV. king of Denmark, sent Bartholomew Ziegenbalg and Henry Plutscho to Tranquebar, with the view of converting the Hindoos to the Christian faith. Though the undertaking met with much opposition and obloquy, particularly from the Europeans and Roman Catholics in India, yet it was fostered with parental care by his majesty, and finally triumphed over every obstacle. This mission now consists of four branches, Tranquebar, Vepery near Madras, Tritchinapoly, and Tanjore. Since its commencement, about 54,000 of the natives, as nearly as we can estimate them, have been baptised or received by the missionaries. It is a common idea that the converts consist almost entirely of the race of Pariars; but though this was the case in the first years of the mission, the state of things is now materially altered. At Tranquebar, Vepery, and Tanjore, more than two-thirds of them are of the higher casts; and even those of the lower order are so much improved, that were a stranger to visit their places of worship on the Sabbath, he would be surprised at the cleanliness of their appearance, and might even mistake them for the higher class of Hindoos. It has often been alleged, that any attempt to convert the inhabitants of Hindostan to Christianity would alarm their prejudices, and even endanger our dominion in the East; but the missionaries on the Coast of Coromandel have pursued their peaceful labours for upwards of a century, without ever exciting the slightest commotion among the Hindoos or Mahomedans, and have even acquired, in a remarkable degree, their respect, and confidence, and love. On the monument erected by the East India Company to the memory of Mr. Swartz, who died about twenty years ago, it is stated that the late Hyder Ally, in the midst of a bloody and vindictive war with the Carnatic, sent orders to his officers "to permit the venerable Father Swartz to pass unmolested, and shew him respect and kindness, for he is a holy man, and means no harm to my government." Such, indeed, was the high estimation in which he was held by all classes of the natives, that Colonel Fullarton assures us, that "the knowledge and integrity of this irreproachable missionary had retrieved the character of Europeans from the

* The following is a list of the principal institutions among the Protestant churches, which have supported missions among the heathen:

The Corporation for the Propagation of the Gospel in New England, and the adjacent parts of America, erected 1649. Of this Society the Hon. Mr Boyle was about 30 years the governor.
The Society (in London) for promoting Christian Knowledge, instituted 1698.
The Society for the Propagation of the Gospel in Foreign Parts, incorporoted 1701.
The Society in Scotland for propagating Christian Knowledge, incorporated 1709.
The Royal Danish Mission College.
The Moravians or United Brethren, 1732.
The Methodist Missionary Society, 1786.
The Baptist Missionary Society, instituted 1792.
The London Missionary Society, instituted 1795.
The Edinburgh (now the Scottish) Missionary Society, instituted 1796.
The Church (of England) Missionary Society, instituted 1799.
The American Board of Commissioners for Foreign Missions, instituted 1810.
The Baptist American Board of Commissioners for Foreign Missions, instituted 1814.

imputation of general depravity." (Fullarton's *View of English Interests in India*, p. 183.) Besides compiling various works of a philological and religious nature, the missionaries translated the whole Bible into the Tamul and Telinga languages; the Old Testament into that dialect of Portuguese which is spoken in India; and the New Testament, together with some parts of the Old, into Hindostanee.

In 1793, the Baptist Missionary Society sent the Rev. William Carey and Mr. John Thomas to Bengal, with the view of attempting the conversion of the Hindoos in that part of India. For several years they laboured without any apparent success; but since the commencement of the present century they have baptised a considerable number of the natives; and though some of these afterwards relapsed into Paganism, yet the great body of them remained stedfast to their Christian profession: their character was on the whole materially improved by Christianity, and was in many respects ornamental to it. Serampore, a Danish settlement about fifteen miles from Calcutta, was the grand seat of this mission; but within these few years, numerous branches have been established in different parts of the country, which promise to contribute essentially to the extension of Christianity among the Hindoos. The grand work, however, for which the Baptist Missionaries are distinguished, is the translation of the Scriptures into the languages of the East. Here they are without a parallel, either in ancient or modern times. Under the superintendence chiefly of one individual, Dr. Carey, the Scriptures are translating into upwards of FORTY different languages. The *whole Bible* has already been published in the Sungskrit, the Bengalee, the Orissa, the Hindee, and the Mahratta; and the *New Testament* in the Chinese, the Shikh, the Telinga, the Kunkuna, the Affghan, the Asamese, the Mooltanee, the Kurnata, and the Guzerattee. Besides translating the Scriptures into so many languages, Drs. Carey and Marshman have published many works of a literary nature, which form a stupendous monument of their talents, and diligence, and zeal, and which will be of essential service to their successors, in learning the languages, the principles, and the manners of the natives, and thus may be of important use in advancing Christianity in the East. Dr. Carey is professor of the Sungskrit, Bengalee, and Mahratta languages, in the College of Fort William, and with singular disinterestedness, devotes his salary, amounting to about 1500*l.* a-year, to the funds of the mission. Two others of the missionaries, Marshman and Ward, contribute nearly an equal sum annually to missionary purposes. Within less than twenty years, the missionaries themselves have devoted upwards of FIFTY THOUSAND POUNDS to the objects of the mission.

Within these few years the London missionary Society, the Church Missionary Society, the Methodist Missionary Society, and the American Board for Foreign Missions, have all directed their attention to Hindostan, and have established numerous stations in that extensive and interesting country. Hitherto no particular success has crowned their labours; but the measures they are pursuing promise silently to sap the foundations of Hindooism, and to pave the way for the establishment of Christianity. Among these we may particularly notice the extensive scale on which the education of the young is conducted. This is an object to which the missionaries direct much of their attention, and their exertions promise to be attended with the most favourable results. In some of the schools the Scriptures are employed as a school-book, without the natives making any objection to them, or if prejudices against them existed at first, they soon subsided. In others they are not used, lest this should excite opposition among the natives, and defeat the whole plan. The teachers are generally Hindoos, some of them Brahmins, but it is necessary to maintain a strict superintendence over them, as without this they are sure to neglect their duty. The number of schools connected with the different missionary stations in India amount to about 300, in which are educated upwards of EIGHTEEN THOUSAND children.

About the middle of the 17th century the Dutch introduced the Protestant faith into the island of Ceylon; but unfortunately the measures they employed for its propagation were in some respects extremely reprehensible. Besides settling ministers, and establishing an extensive system of schools on the island, they issued a proclamation, ordaining that no native should be raised to the rank of a modeliar, or admitted to any employment under government, unless he subscribed the Helvetic Confession of Faith, and professed himself a member of the reformed church. In consequence of this absurd and impolitic order, vast numbers of the Cingalese abandoned the religion of their ancestors, and embraced the faith of their conquerors. Even in 1801 the native Protestant Christians in Ceylon still amounted to upwards of 342,000, according to the general return in the ecclesiastical department; but in 1813 there were only, according to a similar return, about 146,000. The fact is, that a large proportion of those who are called Christians are in reality heathens; for though they have been baptised in their infancy, they are totally ignorant of the principles of the gospel, and are worshippers of the idle Buddhu. Not a few avow themselves both Christians and Buddhists, and are willing to be sworn as either the one or the other in a court of justice.

Within these few years a considerable number of missionaries of various denominations have settled in Ceylon, and have been patronised in the most liberal manner by the British government. Among these the Methodists have been singularly distinguished by their activity and zeal. In 1819 they had formed no fewer than thirteen or fourteen missionary stations in different parts of the island; and in the schools which they had established there were 4484 children, of whom several hundreds were girls; a circumstance which is the more interesting, as in Ceylon, females, notwithstanding their great importance in society, were in general excluded from the blessings of education.

To Java, Amboyna, Sumatra, Timor, Celebes, Formosa, and others of the eastern islands, on which they established themselves, the Dutch in the 17th century sent ministers to convert the inhabitants to the Christian faith. Vast multitudes of the natives, as in Ceylon, submitted to baptism; but most of them, we suspect, might nearly as well have retained the religion of their ancestors. In Java alone the number of Christians was upwards of 100,000; and in the Molucco Islands there are still probably not fewer than 40,000; but for many years past they have been much neglected, and are now in a great measure destitute of the means of religious instruction. Several missionaries, however, have of late been sent from Holland to these islands, and editions of the Scriptures in Malay are preparing for the use of the inhabitants.

In 1807, the Rev. Robert Morrison was sent by the London Missionary Society to Macao, with a particular view to the translation of the Holy Scriptures into the Chinese language. In learning the language he had to make it as much a matter of secrecy as if he had been plotting the overthrow of the government; the persons who assisted him trembled for their own safety, should they be discovered. In January, 1814, he published the New Testament, part of it translated by himself, and part of it taken from a valuable MS. in the British Museum, a transcript of which he carried with him from England. He now proceeded with a translation of the Old Testament, and it is expected that it will soon be completed. Besides these works, Dr. Morrison published several others, chiefly of a philological nature, with the view of assisting the future student in acquiring the Chinese language. In April 1815, the Rev. William Mylne, who had been sent out to assist him in his labours, proceeded to Malacca with the view of establishing a branch of the Chinese mission in that country, as they found themselves greatly restricted in their labours at Macao. Here he was joined by other missionaries, and an extensive establishment was formed by their united exertions. They instituted schools for Chinese, Malay, and Malabar children; they printed various works in the Chinese and Malay languages; they forwarded them in great numbers to the different settlements in the archipelago where the Chinese resided, to Siam, Cochin-China, and even to China itself: and they are now erecting a college for the cultivation of Chinese and European literature.

In 1792, the Moravians, or United Brethren, sent missionaries among the Hottentots in the neighbourhood of the Cape of Good Hope. Here they at first met with violent opposition from many of the colonists: the grossest calumnies were circulated with respect to their designs, and a conspiracy was even formed against their life. The success, however, with which their exertions were crowned, amply recompensed them for all the difficulties and trials which they encountered during the first years of their residence in that country. They have now two flourishing settlements, the one about 120, the other 40 miles from Cape Town; and they lately began a third near the borders of Caffraria. Since the commencement of the mission, they have baptized about two thousand of the Hottentots, a large proportion of whom, we have reason to suppose, are an ornament to their Christian profession. Besides christianizing so large a number of these wretched outcasts of society, they have been singularly successful in improving their external condition, and in promoting civilization among them. Bavians Kloof, the first settlement which they established in this country, lies in a valley surrounded by high mountains, watered by the river Sonderend and several smaller streams. When the missionaries first settled at this place it was a perfect wilderness, yet such are the improvements they have made upon it, that it now looks like a kind of paradise. Some of the Hottentots' houses consist of four apartments, which are white-washed, and look remarkably neat and clean; others are still mean and dirty. To every house is attached a garden, surrounded with bright green quince hedges, and full of peach and other fruit trees, the bloom of which perfumes the air with its delicious fragrance. Their growth is so rapid and promising, that, in the cultivation of his garden, many a Hottentot has lost his national character of idleness and sloth, and acquired a relish for an active industrious life. The whole settlement is about a mile in length, and a quarter of a mile in breadth. The gardens are so numerous and so beautiful, that the whole looks like a city in the midst of a wood. "But in order," says Dr. Lichtenstein, in his Travels through Southern Africa, "to form a just estimate of these excellent men, their manner of conducting themselves to the Hottentots must be seen: the mildness, yet dignity with which they instruct them, and the effect which has already been produced in improving the condition of their uncivilized brethren, is truly admirable. It is the more astonishing, since all has been accomplished by persuasion and exhortation: no violence or even harshness has ever been employed." It has been often stated as a circumstance highly honourable to the Moravian missionaries, that in their missions among barbarous tribes, they endeavour to civilize them before they attempt to christianize them; but nothing could possibly be more contrary to fact. With them Christian instruction is from the very first the primary object, and is considered as the grand engine of civilization. Both, in fact, are carried on at the same time, and have mutually a powerful influence in promoting each other,—a plan unquestionably much more rational than that which is commonly attributed to them, and for which they have obtained so much credit. In 1819, the new settlement which the Brethren had formed near the borders of Caffraria, was entirely destroyed by the Caffres in the course of their late eruptions into the colony: several of the Hottentots were murdered, and upwards of 600 head of cattle belonging to them and the missionaries carried away; but since the restoration of peace, the Brethren have again returned to that part of the country.

In 1798, Dr. Vanderkemp, a Dutch physician of considerable eminence, and three other young men, were sent by the London Missionary Society to South Africa. In that country this Society has now no fewer than twelve settlements, some of them within the colony of the Cape of Good Hope, others beyond its boundaries. At these different places, many thousands of heathen of various nations have enjoyed the benefit of Christian instruction; and upwards of fifteen hundred have been admitted by baptism into the bosom of the church. Dr. Vanderkemp, and others of the missionaries, have been censured for neglecting to promote civilization among the people under their care; but though there appears to have been some foundation for the charge, they were by no means so negligent in this respect as their enemies alleged. As the Hottentots were extremely indolent, it was early a maxim with them to teach them the necessity of industry, by allowing them to feel the sorrows of want, and to give them nothing but what they earned by their own labour, except such as, through age or sickness, were unable to work. The beneficial effects of this system was evident in the improved habits of the people, and in the vast increase of their wealth. They not only possess large herds of cattle, sheep and goats; but, where it is practicable, have cultivated considerable tracts of land, and planted excellent gardens. Of late years, the missionaries, in consequence of the accusations which were brought against them, have paid more particular attention to the civilization of the people under their care; and, though they have many obstacles to encounter, yet in some of the stations the progress of improvement has been uncommonly rapid.

In 1804, the Church Missionary Society sent missionaries to Sierra Leone, with the view of introducing Christianity among the neighbouring Susoos. From several of the chiefs they met with the kindest reception, and the greatest encouragement; but to others, their proposal of teaching them "good things" seemed very unaccountable, and even almost ridiculous. What they had hitherto known of white men, prepared them to view with surprise and suspicion any desire of Christians to settle among them with a benevolent design. The object to which the missionaries principally directed their attention, was the education of the young,—a measure which they pursued on an extensive scale, and with considerable success. But while they prosecuted their labours with disinterestedness and zeal, they had to struggle with difficulties of no ordinary kind, most of them arising out of the iniquitous traffic in slaves. It may appear to us a very extraordinary circumstance, that the inhabitants of Africa should cling to that as a blessing, which we had abolished as her greatest curse; but the fact is, the slave trade had, from time immemorial, been the main support of the country, and the removal of the slave factories stopped the whole trade of the natives, which could not fail to be felt as a serious evil, until some other profitable traffic was established. Hence they hailed the appearance of a smuggling vessel on their shores, and, on a short notice, supplied her with a cargo of slaves in exchange for tobacco and powder and rum, which quickly spread idleness, disorder, and misery, through the whole country. The governor of Sierra Leone having sent armed vessels to destroy the slave factories, and to capture the smuggling ships, the Susoos became extremely exasperated against the missionaries, imagining it was they who communicated information to him of the arrival of smugglers on the river, though they in fact scrupulously avoided interfering in matters of this description. The two settlements which the missionaries had established in the country were burnt to the ground; and the enmity to them became at length so general and so violent, that in 1818 they retired with a considerable number of the children to Sierra Leone. A similar establishment, which was formed on the Bullom shore, was also abandoned, chiefly in consequence of the pernicious influence of the slave trade.
